Outside Brazil, only 60 cases of smallpox were reported in the Americas after 1966. All were in areas adjacent to Brazil. Except for 30 cases in northern Argentina in 1967, when sources of infection were not identified, all could be traced to importations. Because surveillance was poor throughout the areas neighbouring Brazil, other importations probably occurred but did not result in sustained transmission.

- *Argentina* (1967): Thirty reported cases of which 27 were in Misiones Province, which borders on Brazil, 2 in Formosa Province and 1 in Santa Fé Province, both of which provinces are in the north of Argentina although some 400 kilometres from the nearest endemic Brazilian areas. None of the cases was investigated nor were efforts made to trace the source.
- *French Guiana* (1968): One case, in a Brazilian traveller, in the Amazonian area of the country (*Wkly epidem. rec.*, 1968a).
- *Uruguay* (1968, 1969): Two cases in 1968 and 3 in 1969 resulting from 4 importations from the adjacent, heavily endemic state of Rio Grande do Sul, Brazil. Only 1 secondary case occurred.
- *Argentina* (1970): Twenty-four reported cases between April and June in the border town of Colonia Alicia, Misiones Province. The outbreak was detected by epidemiologists from Rio Grande do Sul State, Brazil. The first case, in a 19-year-old man, was diagnosed in a Brazilian hospital situated 100 kilometres from Colonia Alicia. The patient reported having been exposed to cases in Argentina. Investigations, carried out first by a Brazilian team and subsequently by Argentine authorities, revealed an outbreak of 24 cases which had occurred after importation from a nearby Brazilian border town (*Wkly epidem. rec.*, 1970c). Following containment of the outbreak, Argentina undertook a mass vaccination campaign in Misiones and the neighbouring provinces, during which 443 000 people (84% of the population) were vaccinated (Rodrigues, 1975).

Table 12.5. Brazil: comparison of vaccination campaigns using the multiple pressure technique (Belém) and the jet injector (Macapá)

	Belém[a]	Macapá[b]
Estimated population	450 000	35 700
Number of persons vaccinated	411 000	32 700
Coverage (%)	91.3	91.6
Number of workers	1 200	50
Number of person-days	6 010	126
Number of vaccinations per person-day	68.4	259.5
Percentage of successful vaccinations	80.0	90.0
Number of vehicles used	50	2
Total cost of campaign	US$27 520	US$708
Average cost per dose	US$0.067	US$0.022

[b] Vaccination at established sites and by mobile units, as well as door-to-door.

ated the cost and efficacy of vaccination with jet injectors in relation to vaccination utilizing the conventional multiple pressure technique (Millar et al., 1971) (Table 12.5). With the use of the jet injector an average of 259.5 persons were vaccinated per worker-day, compared with a corresponding figure of 68.4 when the multiple pressure technique was employed. The cost per vaccination was US$0.022 with the jet injectors and US$0.067 using multiple pressure vaccination. Moreover, the jet injectors produced a higher proportion of successful vaccinations. The members of the group responsible for the trial were enthusiastic and recommended a renewed effort to eradicate smallpox. They proposed that a federal director and staff should be appointed to help to organize and

BY COURTESY OF D A HENDERSON

Plate 12.4. The demonstration in 1965 of the efficacy of the jet injectors provided an important stimulus to Brazil to undertake an effective national smallpox programme. This device could vaccinate as many as 1000 persons each hour.

execute state vaccination campaigns throughout Brazil, and that jet injectors should be provided in order to complete the campaigns, as they stated, "in months instead of years". It was also recommended that state personnel should immediately be selected and trained in the organization of surveillance programmes, a recommendation that was sound in principle but destined to be ignored.

DEVELOPMENT OF THE BRAZILIAN NATIONAL PROGRAMME, 1966

The demonstration by the Amapá team of the efficacy of the jet injector and the decision in May 1966 by the Nineteenth World Health Assembly to undertake an intensified global eradication programme persuaded the Brazilian authorities to begin a new national programme.

On 31 August 1966, a federal decree was promulgated which required an intensification and coordination of public and private activities throughout the country to combat smallpox in all its clinical forms with a view to achieving the eventual eradication of the disease. The aim was to conduct a mass vaccination campaign among the population at large, state by state. It was expected that a surveillance system would be developed to detect and contain outbreaks but surveillance was not intended to begin until each state had completed its vaccination campaign.

Federal financial assistance was given to augment vaccine production at the Oswaldo Cruz Institute (Rio de Janeiro) and plans were formulated for the development of freeze-dried vaccine production at the Institute for Biological Research (Pôrto Alegre) and the Butantan Institute (São Paulo). To aid these laboratories, as well as others in the Americas, PAHO arranged for the Connaught Laboratories of Toronto, Canada, to serve as a reference laboratory to certify vaccine potency and purity and to provide the staff of the assisted laboratories with technical support and training (see Chapter 11).

Provision was made for additional staff for the Brazilian programme. Twelve full-time professional workers—8 medical officers and 4 administrative staff were assigned to the national eradication programme by the federal Foundation of Special Public Health Services. Foundation personnel, in contrast to most employees of the national health ser-

vice, were paid sufficiently large salaries to permit them to work full time in the campaign. PAHO was asked to recruit 3 medical epidemiologists and a statistician, and to provide 26 vehicles and 72 jet injectors, as well as equipment for the vaccine production centres. Vaccination was to be undertaken state by state, with the great majority of field workers to be locally recruited and trained, and discharged when the programme was completed. Workers were expected to have had 6 years of education and supervisors 12 years. Those performing especially well as supervisors and on the assessment teams were to be retained for service in other states.

The programme was launched in November 1966, and by the end of the year 452 000 persons had been vaccinated. Although it was a hopeful beginning, the subsequent development of the programme was hampered by erratic federal commitment, frequent changes in leadership and serious problems with the quantity and the quality of vaccine produced. The outcome, only a few months before the last case occurred, was anything but certain.

THE BEGINNING OF THE VACCINATION CAMPAIGN, 1966–1967

The initial plan called for a campaign (Table 12.6) which in 3 years would reach more than 90% of Brazil's population (95.8 million in 1970). The projected targets were highly ambitious and not until the last quarter of 1969—fully 3 years after its commencement—did the programme achieve the expected momentum (Fig. 12.3). In an endeavour to meet these desired targets, virtually all the time and energy of the staff were directed to the vaccination campaign.

The initial smallpox campaigns were conducted in the north-eastern states, in which socio-economic conditions were the least favourable, operational problems were the most difficult and smallpox incidence was deemed to be the highest (Fig. 12.4). Three states (Sergipe, Rio Grande do Norte and Pernambuco), with a total population of more than 7 million, were thought to have been sufficiently well vaccinated (80% reported coverage) during the 1962–1966 campaign not to need a repeat programme. Only a portion of Piaui State was considered to require vaccination. Alagoas (population 1.6 million), crucially situated between Pernambuco and Sergipe, was selected as the state in which to initiate

Table 12.6. Brazil: numbers of vaccinations planned and performed in the mass campaign, 1966–1971 (millions)[a]

operations. An experienced staff, consisting of 60 vaccinators, 16 drivers, 12 team leaders, 1 jet injector technician, and 3 supervisors, launched the campaign at the beginning of the rainy season, in November 1966, and concluded it 5 months later. Meanwhile, campaigns had begun in the rest of Piaui (January), Paraíba (February), Ceará (May) and, at the end of the year, in Rio de Janeiro State. In June, smallpox cases were hospitalized in the federal capital, Brasília, and 34 cases occurred in outbreaks in neighbouring areas. Because of this, a campaign was initiated in Brasília (June) and in the neighbouring state of Goiás (September). Although the outbreak was small and the attention it received was perhaps not warranted, the

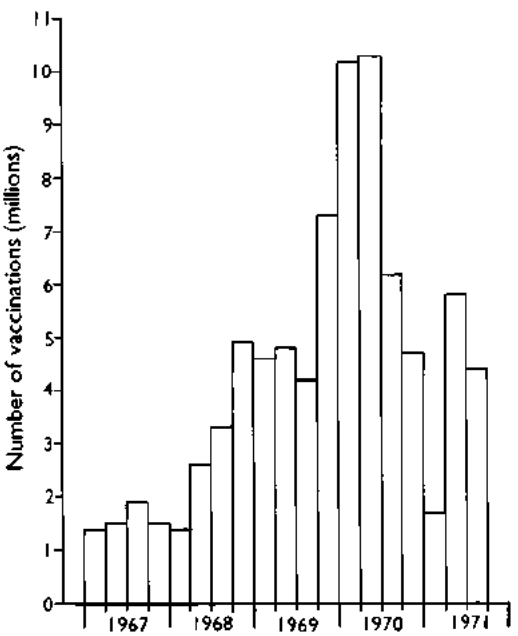

Fig. 12.3. Brazil: number of vaccinations performed by trimester, 1967–1971.

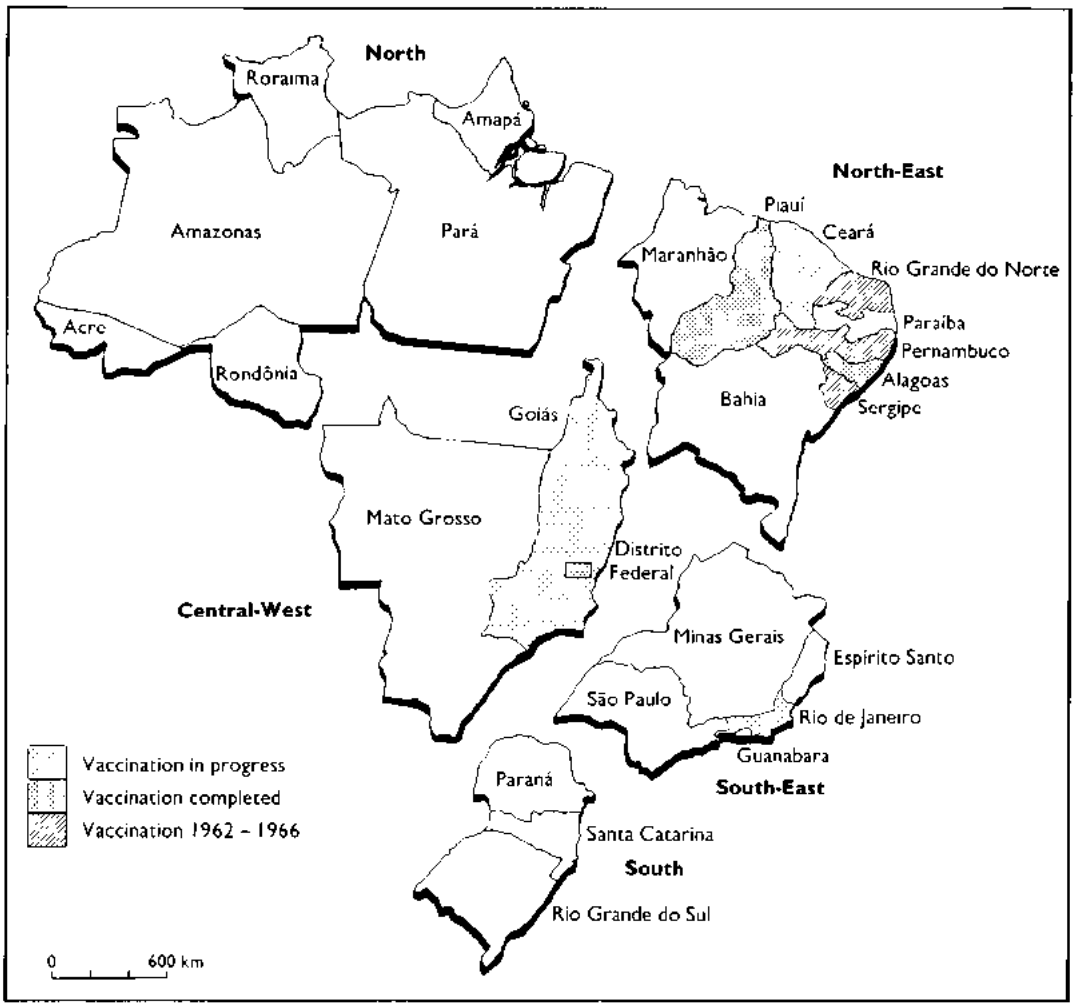

Fig. 12.4. Brazil: status of the smallpox vaccination programme, by region, December 1967.

publicity associated with a campaign in the federal capital was helpful in promoting the programme nationally.

The vaccination campaign within states was undertaken on a *município*-by-*município* basis (as an administrative unit a *município* corresponds roughly to a county in the USA). There were then some 4000 *municípios* in Brazil. An intensive vaccination campaign of several days' duration was conducted in each *município* before the team or teams moved to the next. The inhabitants of the state capitals were usually the first to be vaccinated, after which the teams moved to more sparsely populated areas. Each team consisted of 4 or 5 vaccinators, a leader and a driver. Groups of 4 teams were directed by an area supervisor. Jet injectors were used for vaccination at collecting points in both urban and rural areas. When bifurcated needles became available in 1968, they were used primarily in rural areas. All individuals aged 3 months and over were vaccinated.

The Outbreak in Branquinhas

Although progress in terms of numbers vaccinated was far less in 1967 than had been expected, a more serious problem came to light in July of that year. Twenty-one cases of smallpox were reported from the town of Branquinhas, Alagoas State, which had completed its systematic vaccination campaign only 3 months before. The *município* of Branquinhas had a population of 6317, of whom 1435 lived in the town. A vaccination team had spent 6 days in the *município* and reported that it had performed 6558 vaccinations, a

CENTERS FOR DISEASE CONTROL, 1965

Plate 12.5. Leo Morris (b. 1935), a statistician, worked with Henderson at the Communicable Disease Center during 1966 for the programme in western and central Africa. He joined the programme in Brazil in 1967 as a WHO staff member and was instrumental in developing the national weekly surveillance report and in promoting the investigation of outbreaks, including the one at Branquinhas, which demonstrated the need for continuing assessment of the vaccination campaign.

number larger than the estimated population. There seemed to be only two likely explanations: either many vaccinations had been unsuccessful because of substandard vaccine or poor technique, or the number of reported vaccinations was exaggerated.

Staff attached to the national campaign investigated immediately and found not 21 but 51 cases of smallpox. Only 2 cases had previously been vaccinated (Morris et al., 1970b). A survey of randomly selected households in the city revealed that vaccination take rates were satisfactory but that only 49% of the inhabitants had actually been vaccinated by the teams. Surveys in two rural areas showed that 75% of the residents had been vaccinated in one of them and nobody in the other. It was apparent that records had been falsified and that supervision and planning were poor.

The Repercussions of the Branquinhas Outbreak

Until the Branquinhas outbreak, the national programme director had refused to assign even a few personnel and vehicles to "do nothing but evaluate", as he expressed it. As in many other programmes, it was believed that all possible resources should be deployed in administering vaccine. Branquinhas was a turning-point. It was agreed that assessment teams must be created, and these began work early in 1968 (*Wkly epidem. rec.*, 1968c). Each comprised 4 persons, who visited vaccinated areas about 7–9 days after the completion of a programme. A household probability survey was conducted, in which, in a sample of households, the vaccination coverage of all household members was determined, as were the take rates for primary vaccination among children between 3 months and 5 years of age (Lavigne de Lemos & Morris, 1969). With improved supervision and a knowledge that their work was being continually assessed, the teams consistently achieved much better vaccination coverage. The data from 26 *municipios* in 2 states—Minas Gerais and São Paulo—compiled in 1969 illustrate this (Table 12.7).

In most *municipios*, independent assessment showed that more than 90% of individuals aged between 3 months and 14 years—the age group in which three-quarters of all cases occurred— had been vaccinated. The proportion of older persons vaccinated during the campaign tended to be lower, but a great many of them had already had smallpox or had been vaccinated at some time in their lives. In areas in which less than 80% of those under 5 years of age were found to have been vaccinated, a repeat vaccination campaign was

BY COURTESY OF D.A. HENDERSON, 1966

Plate 12.6. Oswaldo José da Silva (b. 1907), in the centre, was director of the national programme in Brazil, 1967–1968. A former malariologist and PAHO staff member, he was a skilful administrator and was responsible for the establishment of Brazil's national vaccination campaign structure. With him are K.S. Ramakrishnan from the WHO Regional Office in New Delhi and John Copland, administrative officer of the Smallpox Eradication unit in Geneva from 1967 to 1977.

conducted. Primary take rates were usually above 90%, although when revaccination responses were checked, the take rates were usually only 50–60%. Considering the low potency and lack of stability of the vaccine used (see below), the results were surprisingly good.

Because the programme was making less progress than had been planned, and because of the Branquinhas incident, a new director, Dr Oswaldo da Silva, was appointed in September 1967. Dr da Silva had worked in both Brazil and PAHO in the malaria eradication programme and was widely respected for his skills in management and his grasp of logistics. Following his appointment, a more effective organizational structure began to take shape.

Critical to the ultimate success of the programme was the establishment in May 1967 of a national smallpox reporting system and the publication each week of a surveillance report (*Boletim semanal da Campanha de Erradicação da Variola*), which documented the numbers of cases reported each week, described developments in the programme and recorded the results of investigations by field staff (WHO/SE/73.52, Lavigne de Lemos & Souza). Fostered by an imaginative young WHO epidemiologist-statistician, Mr Leo Morris, it was modelled on reports of surveillance programmes at the United States Communicable Disease Center, in which he had previously worked. This simple mimeographed report was sent to more than 2000 senior health and programme staff. It served to instruct, to motivate and to give the widely scattered staff a sense of common purpose.

With repeated reminders to states to report cases each week on standardized reporting forms, the notification system gradually improved, but it was apparent from the several field investigations conducted that few of the many cases were being detected. Some of these investigations revealed significant problems. One was an outbreak in a 250-bed children's hospital in Vitória, Espírito Santo State, which was reported in October 1967. Investigation revealed that 51 cases had occurred over a 10-month period. During this time, there had been at least 11 and perhaps 14 separate introductions of smallpox into the hospital; between 36 and 40 children were infected there subsequent to admission for other causes. None of the children had ever been vaccinated; 5 died (Morris et al., 1970a). That hospitals served as important foci for disease transmission was subsequently to be documented repeatedly in Brazil and elsewhere. The proper isolation of patients and the vaccination of staff and of patients on admission to hospital were seldom effectively practised.

By the end of 1967, work had been completed in the Federal District, Piauí and Alagoas. More support was obviously required, and the Ministry of Health requested WHO to provide 178 vehicles (in addition to the 26 which had been supplied in 1965) and 97 jet injectors (in addition to the 122 then in use). Of great help in Brazil was the minimum time-lag between the decision to provide vehicles and their availability. Locally manufactured vehicles could be delivered within weeks of placing an order, whereas in other parts of the world 12–24 months might elapse between order and delivery. The requested supplies arrived early in 1968.

THE VACCINATION CAMPAIGN GAINS MOMENTUM, 1968

Under Dr da Silva's leadership, the monthly numbers of vaccinations steadily increased

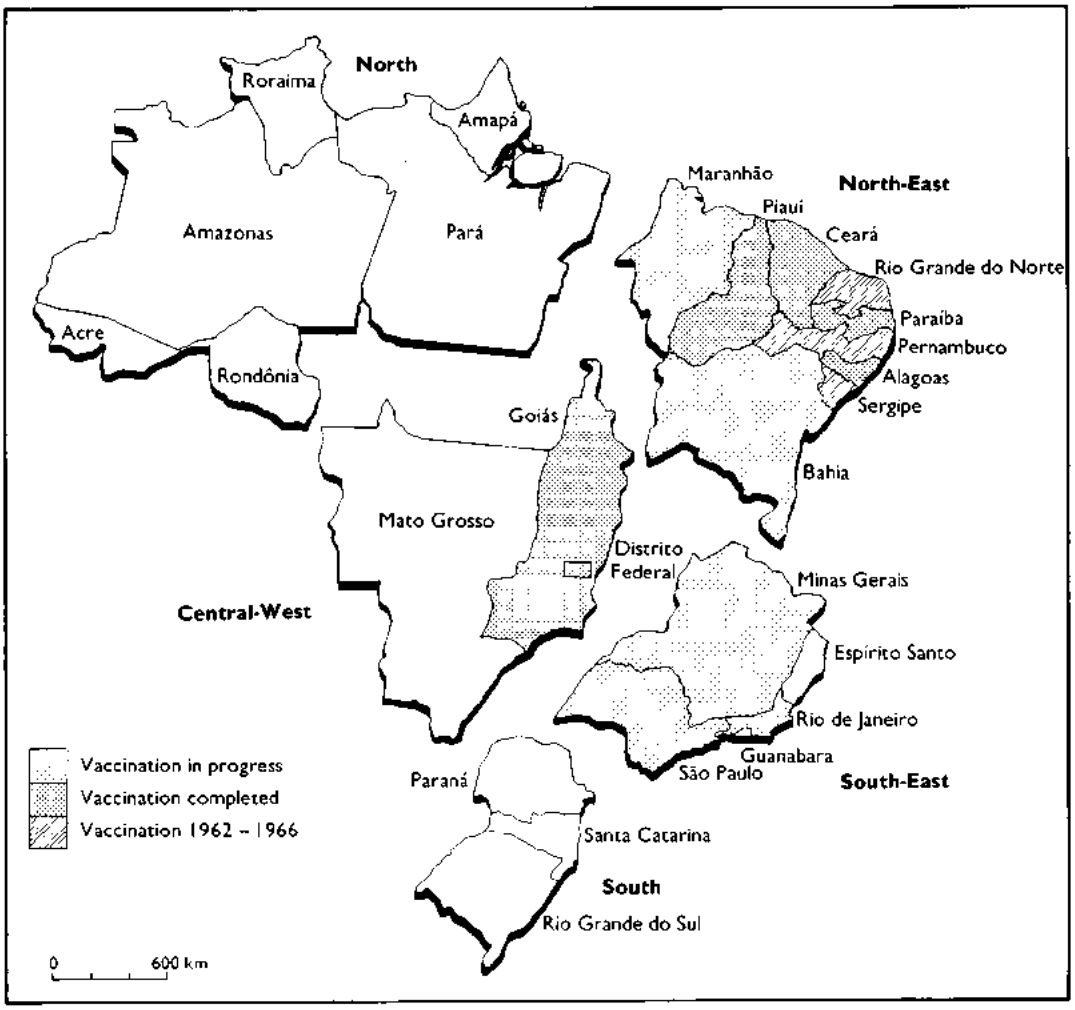

Fig. 12.5. Brazil: status of the smallpox vaccination programme, by region, December 1968.

during 1968; and with a programme of assessment in operation, there was a greater degree of confidence that the numbers reported were accurate. In addition, in states in which the systematic vaccination campaign had been completed, the staff began to investigate some of the cases reported. Virtually nothing was done, however, to strengthen surveillance in the states in which vaccination campaigns had not been conducted.

More than 12 million vaccinations were given in 1968—almost twice as many as in 1967 (Table 12.8). Fully 1000 staff were active in the field. Work was completed in 3 of the 4 states in which vaccination campaigns had been initiated in 1967, and programmes were begun in 3 additional states (Fig. 12.5) (*Wkly epidem. rec.*, 1968b).

The number of reported cases of smallpox showed little change (4372 in 1968 compared with 4514 in 1967), but because reporting was thought to be more complete the staff were encouraged (Table 12.9).

However, at the end of 1968, the government, as a general economy measure, made substantial cuts in the budget for the programme: per diem payments for Brazilian national staff were eliminated, thus curtailing travel; supplementary payments which had permitted senior staff to work full time in the programme were stopped; and the complement of programme staff was reduced to 759. Nearly 9 months elapsed before full support for the programme was resumed. Dr da Silva's target of 5 million vaccinations per quarter or 500 000 vaccinations per week was not to be achieved for another year.

[a] The last case occurred in April.

THE BEGINNING OF AN EFFECTIVE SURVEILLANCE PROGRAMME, 1969

The concept of assigning at least one epidemiologist to every state, to be responsible for the development of a system which would ensure the prompt transmission of weekly reports of cases from reporting centres and to investigate and contain outbreaks, had been increasingly stressed by the WHO Smallpox Eradication unit. However, neither the Brazilian nor the PAHO staff showed interest. Meanwhile, the efficacy of surveillance-containment activities had become increasingly apparent in eradication programmes, particularly in western Africa. With the aim of stimulating interest in the development of a surveillance programme, a special meeting of all of WHO's smallpox advisers in the Region had been convened in Rio de Janeiro in April 1968, in which Brazilian national staff also participated. It proved to have little impact.

Finally, in October 1968, Dr Nelson Morais, newly appointed as General Secretary of the Ministry of Health and himself an epidemiologist, was contacted by WHO and persuaded that a special effort should be made to develop a surveillance programme for smallpox which might eventually extend to other infectious diseases. At his urging, a special training programme in the surveillance and epidemiology of smallpox was conducted in São Paulo during January 1969 (*Wkly epidem. rec.*, 1969d). Instruction was provided by staff from the smallpox eradication programme, the Adolfo Lutz Institute and Mr Morris. Those who attended included 15 of the medical officers attached to the smallpox eradication programme who had

I. VEHNES, 1970

Plate 12.7. Clovis H. Tigre (b. 1938), director of the programme in Rio Grande do Sul State, developed one of the 4 special state surveillance programmes in Brazil which demonstrated the need for national surveillance. The Rio Grande do Sul programme was exceptionally effective and eventually incorporated the administration of many other vaccines, a forerunner of WHO's later initiative, the Expanded Programme on Immunization.

responsibility for the vaccination campaign, plus 3 epidemiologists, Dr Ciro de Quadros, Dr Nilton Arnt and Dr Eduardo Costa, who had recently graduated from the School of Public Health in Rio de Janeiro. The medical officers were to conduct surveillance after mass vaccination had been completed but the 3 epidemiologists were each to be assigned to the populous states of Paraná, Bahia and Minas Gerais, in which vaccination campaigns had not yet been conducted. There they were to undertake surveillance programmes which might serve as prototypes for other initiatives in infectious disease surveillance. The special surveillance programmes in the 3 states began in March and were extended to a fourth state, Rio Grande do Sul, later in 1969 (Suzart de Carvalho Filho et al., 1970). Approximately 35% of Brazil's population lived in these 4 states.

Although Dr Morais was convinced that surveillance was important, the highest priority for Dr da Silva and the senior smallpox eradication programme staff remained the vaccination campaign, then foundering because of the government's curtailment of funds. There was a reluctance to divert resources to surveillance activities. Only one of the epidemiologists was eventually given a programme vehicle, and then after weeks of discussion. The others were obliged to rely on state health department vehicles, which were rarely available. The only other resources available to them were a driver and a vaccinator, plus whatever help they could recruit from health centres or hospitals. The 3 epidemiologists worked for less than a year before being obliged to resign because of yet another change in the administration of the programme. Subsequently, Dr Arnt and Dr de Quadros were recruited for service with WHO in Africa and Asia, in which they played vital roles in the development of surveillance programmes.

Although the surveillance containment programme that had been set in motion was modest and short-lived, the results proved to be decisive. Through the activities of reporting centres, which would report cases weekly, and through field investigations the epidemiologists soon began to discover large numbers of unreported cases (Azeredo Costa et al.,

1971; Arnt & Morris, 1972, Quadros et al., 1972). In an early report, Dr de Quadros and his colleagues documented their findings in the investigation of 27 officially notified cases. By tracing the sources of the outbreaks and through extensive search to identify all cases in each outbreak, they discovered 33 outbreaks in which 1492 cases had occurred. By extrapolation, the studies suggested that the actual number of cases was 50 times greater than the number being reported. In the studies, residents in all the affected households were interviewed to determine if any had previously contracted smallpox and all were examined for vaccination scars (Table 12.10). A uniform reporting form was designed. Although the population under study consisted only of persons residing in houses in which a case had occurred and so were not representative of the community at large, the proportion of residents in affected households who had *ever* been vaccinated was 20% or less. This level of vaccinial immunity was far lower than in any other country of South America.

Epidemiological observations documented the fact that smallpox spread widely among household contacts. Of 674 persons who had neither a history of smallpox nor a vaccination scar, 466 (69%) contracted smallpox (Table 12.11). As expected, a previous attack of smallpox provided total protection, but previous vaccination, even if it had been performed many years earlier, was far more efficacious than had been thought. Only 7 of 204 persons with a vaccination scar developed the disease, and among them it was much milder than among the unvaccinated. The vaccine–efficacy ratio showed levels of protection of 90% irrespective of the interval since previous vaccination (Suzart de Carvalho Filho et al., 1970). These findings served to emphasize the need to give priority to primary vaccination over revaccination.

The outcome of the surveillance programme in Paraná State, conducted by Dr de Quadros, was most dramatic. He began the programme in March, 3 months before the mass vaccination campaign commenced in the state capital. Operating alone in a state

with a population of 7 million, he visited health units throughout Paraná to explain the programme and to persuade them to report cases weekly. He investigated every report—which entailed working 7 days a week—and, when outbreaks were discovered, borrowed health staff from clinics and hospitals to perform containment vaccination. By later standards of the Intensified Smallpox Eradication Programme, the containment measures were comparatively simple, but in Paraná they were effective. By August, at a time when the vaccination teams were just completing work in the capital, he had

discovered and contained the last known outbreak. In all, 30 000 persons were vaccinated during containment operations. The mass campaign gradually moved across the state but the staff found no other outbreaks.

Dr da Silva was increasingly impressed by and supportive of the surveillance programme, but at the same time frustrated by a lack of funds and support for the vaccination campaign. Significant progress was being made only in São Paulo State, which financed the programme with state funds. Exasperated, he resigned in July, and for political reasons Dr Morais was replaced in September. Three months later the appointment of the 3 epidemiologists was terminated. Dr da Silva was but the second of 5 persons who were to direct the programme between 1967 and 1972, during which period there were 3 different ministers of health.

Such stability as the programme enjoyed was largely provided by the WHO epidemiologist-statistician, Mr Morris, who, with his Brazilian counterpart, continued to produce the weekly *Boletim* and faithfully recorded the substantial increase in the number of reported cases during 1969. Because of the field investigations, the number of cases in the 4 states tripled between 1968 and 1969, from 1681 to 5370 (Table 12.12). Although this was partially offset by a decline in the number of reported cases elsewhere in Brazil, the net outcome was the highest total number of cases to be recorded in the country since 1962. Because of the *Boletim's* extensive circulation, this dramatic increase in the number of cases (Fig. 12.6) attracted wide attention, including that of the press, the Minister of Health and even the President. Although programme staff repeatedly pointed out that better reporting was the probable cause, there was alarm, and support and resources became much easier to obtain.

With additional resources from the government and additional vehicles and jet injectors from WHO, the tempo of the

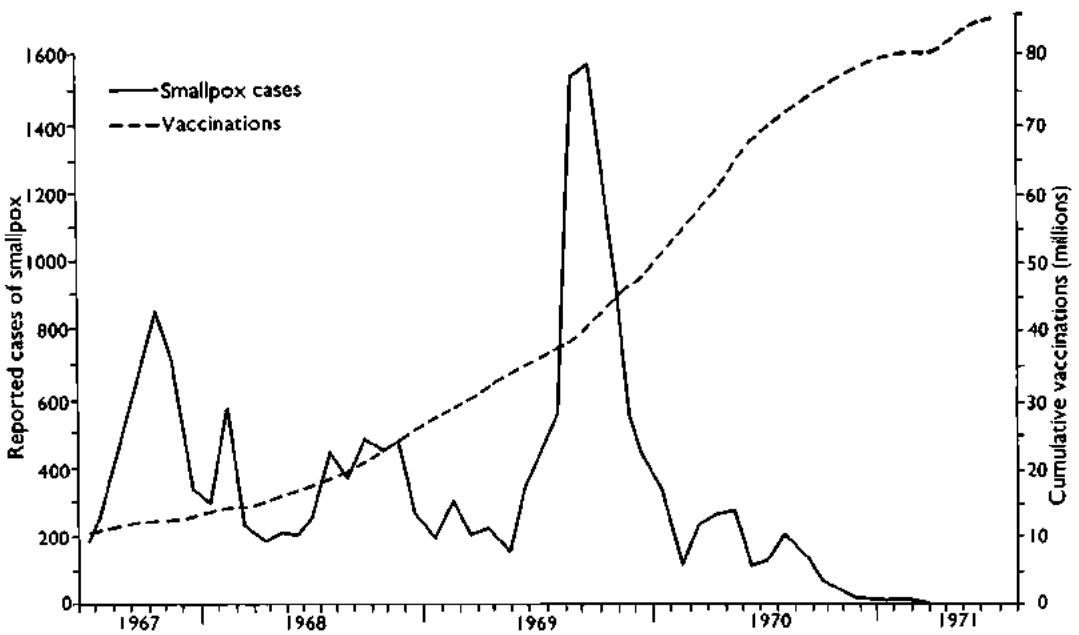

Fig. 12.6. Brazil: reported cases of smallpox and cumulative numbers of vaccinations, by 4-week intervals, 1967–1971.

vaccination campaign rapidly increased (Fig. 12.7). During the last quarter of 1969, 7.3 million persons were vaccinated compared with only 4.2 million during the third quarter. However, with the departure of Dr Morais, Dr da Silva and the 3 epidemiologists, surveillance deteriorated. As was revealed in a survey by a WHO consultant, Dr Paul Wehrle, by February 1970, only 16 of the 27 states and territories had surveillance officers responsible for the investigation and containment of cases. At that time, reports on the situation with regard to smallpox during the month of January were available for only 14 of the 27 states and territories. Even in the states to which officers had been assigned, few notification units were submitting weekly reports. Bahia State, for example, had 200 reporting units, most of which reported monthly rather than weekly. In that state, the consultant found one outbreak that had been reported in November but was not investigated until January. In Pernambuco, only 13 of the 54 reporting posts were found to be currently sending reports. In the other states the situation was not notably better.

CONCLUSION OF THE VACCINATION CAMPAIGN, 1970

The momentum achieved in the vaccination campaign during the last 3 months of 1969 continued into 1970. Programmes were begun in all of the remaining states, the government allocated additional funds, the USA agreed to provide bilateral assistance, and by the end of the year more than 30 million vaccinations had been performed.

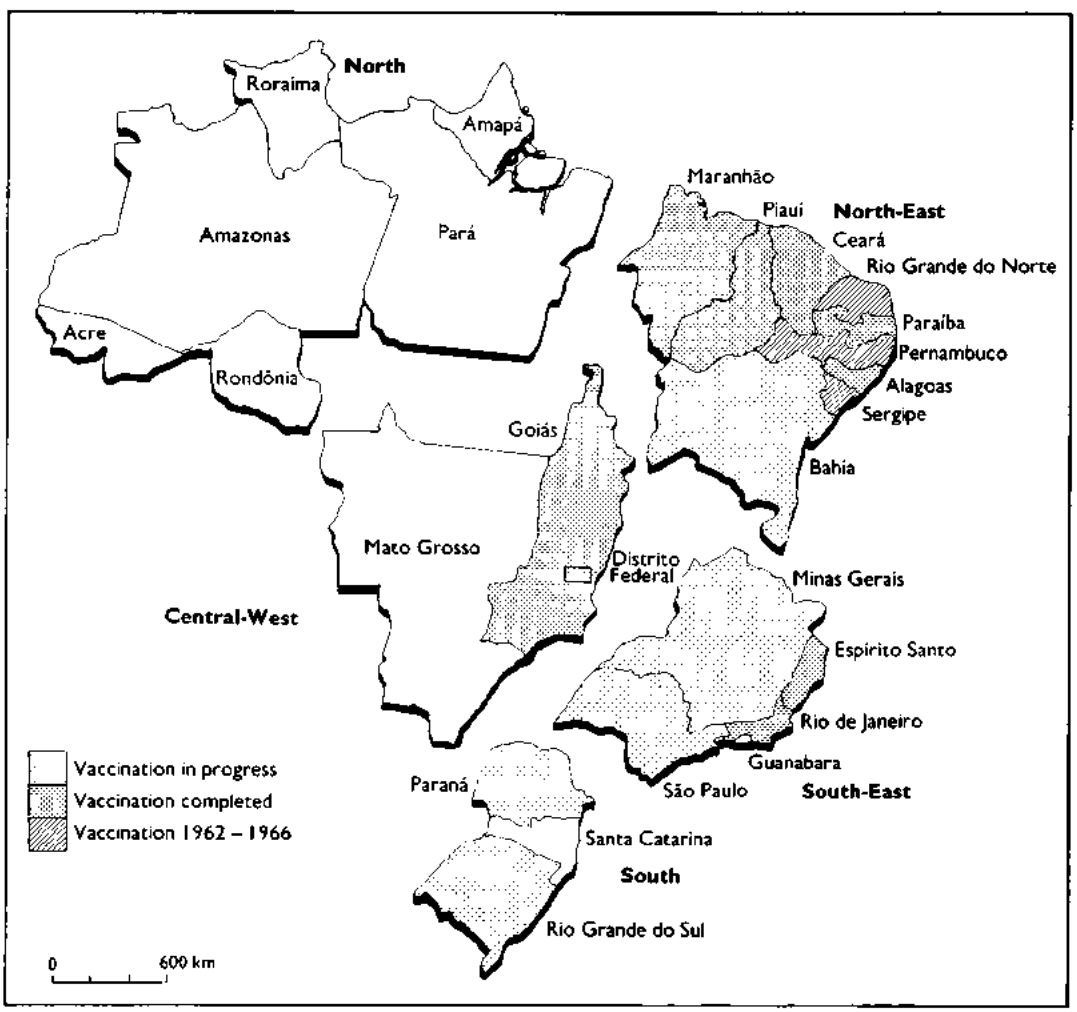

Fig. 12.7. Brazil: status of the smallpox vaccination programme, by region, December 1969.

The Largest Recorded Outbreak during the Brazilian Programme

The largest recorded outbreak in Brazil occurred in the *município* of Utinga, Bahia State, in 1969. A total of 507 cases occurred in a population of 9277 (Azeredo Costa et al., 1971; Azeredo Costa & Morris, 1975). The outbreak was discovered in August, when a newly created surveillance unit in Bahia investigated a single reported case in the *município* of Bom Jesus da Lapa, 300 kilometres south-west of Utinga. The patient, a resident of Utinga, was already ill when she arrived in Bom Jesus da Lapa. The team immediately went to Utinga and discovered an epidemic which had been in progress since February. No cases had been notified by the local authorities. A house-to-house search in the city revealed 246 cases in a population of 2200. Cases occurred also in the surrounding rural areas, in one of which 154 of the 505 residents (30.5%) had contracted smallpox.

Results of a Survey in 104 Households with Smallpox in Utinga City
(Azeredo Costa & Morris, 1975)

Age group (years)	*Number of residents*	*Number with history of smallpox*	*Number with vaccination scar*	*Number fully susceptible to smallpox*	*Number of cases*
⩽4	103	0	9	94	57
5–14	214	21	32	161	124
15–29	148	55	26	67	50
⩾30	153	75	46	32	15
Total	618	151 (24.4%)	113 (18.3%)	354 (57.3%)	246

A survey of residents of the 104 infected households revealed that about 25% had a history of smallpox; another 18% had a vaccination scar. Of the susceptible individuals, 69% contracted smallpox. No cases occurred among those who had already had smallpox; 4 cases occurred among those with vaccination scars, the years of vaccination being 1938, 1947, 1965 and 1967 respectively. The last 2 were very mild cases with few lesions. The age-adjusted vaccine–efficacy ratio was calculated to be 94%.

Ironically, the last of the states to begin a campaign was the state of Guanabara (Fig. 12.8) which, in effect, consisted of the metropolitan area of the city of Rio de Janeiro, the headquarters of the national smallpox eradication programme. The health officer in that state had been one of the least cooperative in reporting cases and had vigorously resisted joining in the vaccination campaign, in part because he considered that the attendant publicity would adversely affect the important tourist industry. Not until October 1970 did he finally agree to permit a selective programme of vaccination at schools, factories and construction sites and among the inhabitants of the slums (*favelas*) and rural areas around the city. A hectic campaign commenced in an effort to reach all of the 1500 schools before the end of the school year in December.

The last cases of smallpox to be discovered in Brazil did not occur in the remote areas of the Amazon basin or in the economically depressed regions of the north-east but in the city of Rio de Janeiro itself, less than 10 kilometres from the national headquarters of the smallpox eradication programme.

The Last Known Cases of Smallpox in Brazil

In November 1970, it was thought that the last cases of smallpox had been detected in Brazil. For more than 12 weeks, no cases were discovered. However, on 1 March 1971, during the last week of the special house-to-house search and vaccination campaign in high-risk areas of the city of Rio de Janeiro, a vaccination team discovered 2 patients with rash and sent them to the isolation hospital. Investigation quickly revealed that 14 cases in all had occurred in 2 groups of adjoining households. The first patient, who had be-

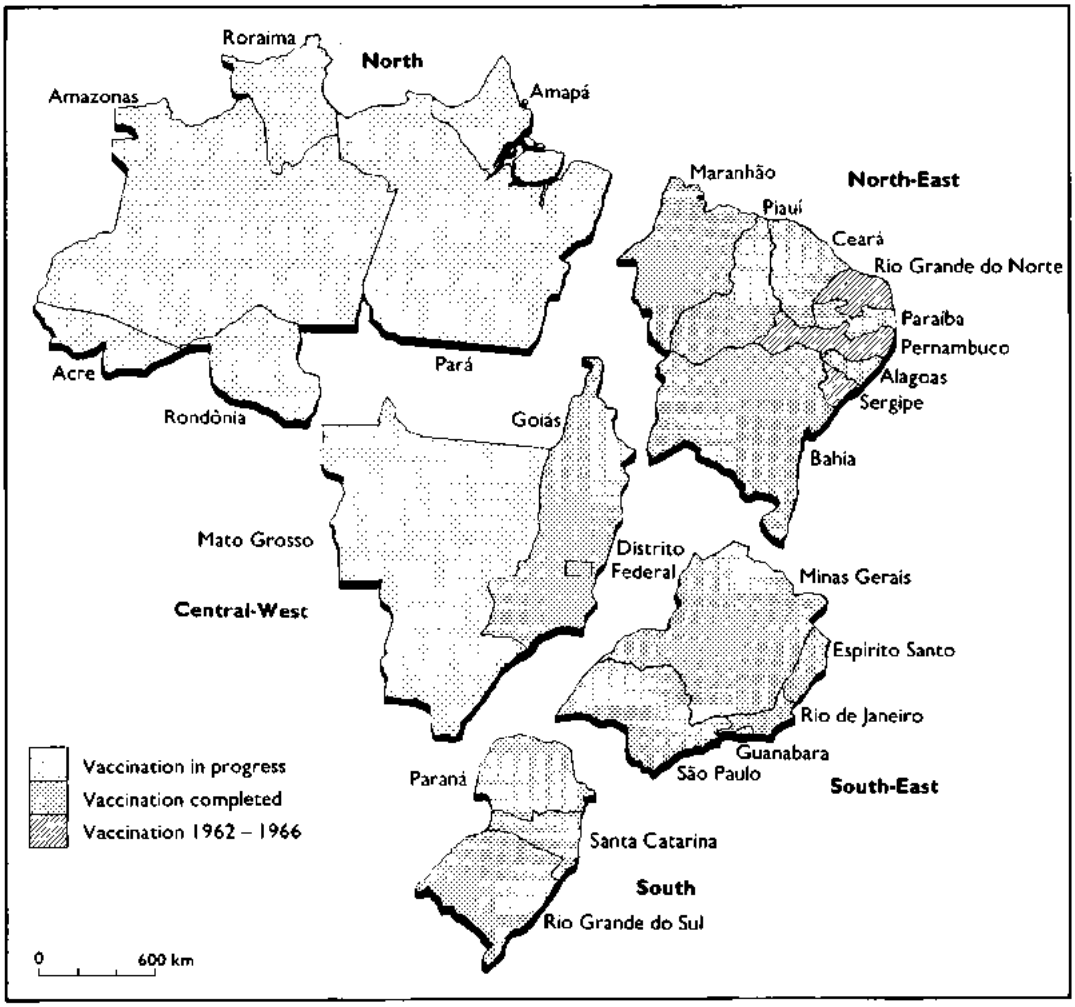

Fig. 12.8. Brazil: status of the smallpox vaccination programme, by region, December 1970

come ill on 22 December 1970, had been displaced from a previously infected area of the city in which many houses had been demolished. Between December 1970 and March 1971, the summer period of seasonally low incidence, smallpox spread slowly.

Intensive search and containment measures were conducted throughout the community. Two additional cases occurred in this area, both of whom were in the incubation period when vaccinated. They were not the last cases, however. The Rio de Janeiro isolation hospital served no better as an isolation facility than did such institutions in most other parts of the world. Three more cases occurred among already hospitalized patients. The third, detected on 19 April, was the last case in the Americas.

Expansion of the Reporting Network, 1970–1971

Although the rudimentary surveillance system had been temporarily strengthened by the addition of the 4 epidemiological units in 1969, few suspected cases were investigated or outbreaks contained until late in 1970. The inadequacy of the system until 1971 is apparent from the data presented in Table 12.13.

During 1970, epidemiological surveillance units began to be established throughout Brazil. Each was under the direction of a physician-epidemiologist who had been specially trained by national programme staff. The units were charged with the following responsibilities:

(1) To establish a network of reporting

Table 12.13. Brazil: number of reported and suspected cases of smallpox and proportion investigated by programme staff, 1967–1973

Year	Number of reported cases	Number of suspected cases	Total	Number investigated by programme staff	% of reports investigated

1972	0	718	718	718	100
1973	0	131	131	131	100

[a] Excludes the states of Paraná, Minas Gerais, Bahia and Rio Grande do Sul, in which special programmes of investigation were conducted (see text).

centres which would report weekly, on a standard form, the presence or absence of suspected cases of smallpox. Each health post would serve as a reporting centre, and in the absence of such a post in a *município*, a responsible official would be asked to provide the requisite information.

(2) To establish and maintain contact with hospitals, physicians, schools, community leaders and any other persons who might be aware of the existence of possible smallpox cases.

(3) To investigate immediately all suspected cases and to undertake the necessary epidemiological and laboratory investigations.

By the end of 1970, surveillance units had been established in 18 states and territories; 2665 reporting centres were in operation.

Meanwhile, smallpox staff joined malaria teams to conduct a systematic programme of search and vaccination throughout the extensive Amazon basin. Five months of work were required, from September 1970 to January 1971; however, no cases of smallpox were detected. Independently, a team of physicians from the International Committee of the Red Cross contacted 20 of 36 Indian tribes in the Amazon basin and reported that they, too, had found no cases among the 4500 individuals whom they examined (*Wkly epidem. rec.*, 1971a).

From 1971 to 1973, Brazil's first national system for disease reporting gradually matured (Table 12.14) under the direction of the last and one of the most able of Brazil's programme directors, Dr Claudio do Amaral, who was later to serve with the WHO smallpox eradication programme in Ethiopia. The number of reporting centres grew from 3243 in 1971 to 6381 in 1973; 444 suspected cases were investigated during 1971 and 718 cases during 1972. Laboratory specimens to confirm diagnosis were obtained from nearly three-quarters of all cases and examined in laboratories in Brazil and the USA (Noble et al., 1970; Schatzmayr & Mesquita, 1970). The systematic vaccination campaign concluded in 1971 with the programme in the Amazon basin and with the revaccination of the population of several states (Pernambuco, Rio Grande do Norte, Alagoas and Piauí) which had been vaccinated during the period 1962–1966 but not subsequently.

In 1972, a national assessment was undertaken during which 778 719 persons in 451 different localities were examined to determine what proportion of their populations bore vaccination scars (WHO/SE/73.51, Amaral et al.). The results are shown in Table 12.15.

The total of 80% with vaccination scars was impressive considering that programmes in some states had concluded as long as 4 years earlier. When the results were examined by state, at least 70% of the population were found to have vaccination scars in all states except Bahia and Ceará, in which the proportions were 59% and 56% respectively.

NUMBERS OF REPORTED CASES AND DEATHS, 1968–1969

Because of the work of the surveillance officers, data are available for 1968–1969 regarding the age and sex distribution of cases, and the case-fatality rates at different ages (Suzart de Carvalho Filho et al., 1970) (Table 12.16).

Nearly three-quarters of all cases (72.6%) occurred among persons under 15 years of age. Among the 9854 cases, only 75 died—a case-fatality rate of just 0.8%, characteristic of

L. MORRIS

Plate 12.10. In 1970, state surveillance units were established throughout Brazil to improve the reporting and investigation of suspected cases. The provision of uniforms, an important fringe benefit, also served to enhance morale.

variola minor. However, among infants under 3 months of age, the case-fatality rate was 16.7% and among those aged between 3 months and 1 year it was 2.0%—more than twice that observed in most other age groups.

RESOURCES EMPLOYED

Data on national expenditures for the campaign are available only for the period 1966–1971. In all, the government of Brazil spent the equivalent of US$4 506 369 from its own budget. The World Health Organization and the Pan American Health Organization expended US$1 763 780 during the same period, primarily for advisers, vehicles, jet injectors, and vaccine and vaccine production equipment, and the sum of US$892 195 was made available by the United States government. Expenditures by state governments are not included in these figures; in São Paulo they were considerable. Additional costs—far lower than these—were incurred during the subsequent 2 years during which the pro-

gramme conducted a variety of search activities to ensure that eradication had been achieved. The national and international expenditures from 1966 to the end of 1971, when transmission was interrupted, thus amounted to US$7 162 344 overall or about US$0.077 per head of population (Table 12.17).

Information regarding the number and category of national personnel employed in the programme as well as the numbers of vehicles and jet injectors was compiled at the end of December each year from 1968 to 1971 (Table 12.18).

SMALLPOX VACCINE PRODUCTION

The development and expansion of facilities for the production of smallpox vaccine in Brazil proved to be a most difficult and frustrating problem. Indeed, the Brazilian programme was unique in that it was possible to interrupt transmission despite the use of vaccines which rarely met accepted standards of potency and stability, and which often contained pathogenic bacteria. The success of the programme testified to a generally well-managed systematic vaccination campaign and vaccine standards that tolerated a substantial margin of error.

In 1967, it had been apparent that large supplies of freeze-dried vaccine would be required for the systematic vaccination campaign in Brazil, as well as additional quantities for Argentina, Bolivia, Colombia, Ecuador, Paraguay, Peru and Venezuela, in each of which an extensive vaccination campaign was planned. When the programme began, freeze-dried vaccine was being produced in a number of South American countries (Table 12.19).

In 1966, little of the vaccine produced by most laboratories met accepted standards of potency and stability, and most of the laboratories were drying the vaccine in containers of 100 or more doses. Since freeze-dried vaccine, after reconstitution, was as thermolabile as liquid vaccine, it should have been used only on the day it was reconstituted. The result was that either significant quantities were wasted or, if the vaccine was kept for several days after being reconstituted, it suffered a considerable loss of potency.

The Connaught Laboratories agreed to test batches of vaccine regularly and to assist laboratories through consultant visits and training, locally and in Canada. Equipment and assistance were eventually provided by PAHO to laboratories in Argentina, Brazil, Chile, Colombia, Cuba, Ecuador, Mexico, Peru, Uruguay and Venezuela. Support was given to countries that requested it, thus accounting for the allocation of resources

even to countries at little risk such as Chile, Cuba and Mexico. It would have been more logical to concentrate efforts in Brazil, whose laboratories were experiencing the greatest problems. The Connaught consultants, however, were directed to travel throughout the continent assisting laboratories in numerous countries. Less than one-third of their time was spent at the principal vaccine production centre in Brazil, the Oswaldo Cruz Institute, which experienced constant difficulties and never did succeed in producing a consistently satisfactory product.

Data regarding the quality of vaccines produced by the different laboratories in the Americas are regrettably scanty. Each laboratory was supposed to test its own vaccine and to send samples of each batch to the Connaught Laboratories until it was certain that a satisfactory vaccine was being produced consistently; thereafter, 2 batches were to be sent for testing every 3 months. Comparatively few samples, however, were submitted for independent testing. From an assessment of the limited data available from the Connaught Laboratories and from reports of visits by consultants, it would appear that the vaccine produced in Argentina, Chile and Colombia consistently met WHO standards, while that produced in Ecuador and Peru sometimes failed to meet standards of stability—i.e., when the vaccine was incubated at 37 °C for 1 month, its titre fell below an accepted minimum standard. The Brazilian laboratories seldom produced batches of vaccine which met international standards (see Chapter 11). Many batches were low in initial potency and most failed to meet stability standards. Vaccine for use in Brazil's systematic vaccination programme was produced exclusively at the Oswaldo Cruz Institute. Vaccine from the other laboratories was distributed to health centres and hospitals for what was termed "maintenance vaccination."

At the Oswaldo Cruz Institute, much of the vaccinia virus was grown in embryonated hens' eggs. Experience elsewhere had shown that, for technical reasons which are still unexplained, virus harvested from this source rarely met accepted standards of stability. In the endemic countries, none of the laboratories except the Oswaldo Cruz Institute and Brazil's vaccine production centre in Pôrto Alegre used this method of production. In addition to being unstable, many of the batches from the Oswaldo Cruz Institute failed to meet minimum standards of potency. However, the vaccine which the Institute produced on calves (about half of its production) was little better, in terms either of potency or of stability, and most batches were found to be contaminated with numbers of pathogenic bacteria (coagulase-positive staphylococci and non-haemolytic streptococci). Of 43 batches of Oswaldo Cruz vaccine tested by the Connaught Laboratories as late as 1970, 35 failed to meet accepted stability standards, and 13 of the 43 batches were below minimum standards of potency. In January 1970, 15 vials of Brazilian vaccine were collected from the field and tested; only 2 met the accepted standards of potency. Moreover, as a WHO consultant noted at that time, the vaccine was not labelled as to origin or lot number and no expiry date was stamped on the containers.

Vaccine production units at Recife and Pôrto Alegre had equally poor records, and although WHO consultants recommended that they should be closed, they continued to produce vaccine. Not until late in 1970, near the end of the programme, did fully satisfactory vaccine become available. At that time, the Butantan Institute in São Paulo began producing a consistently satisfactory vaccine from virus harvested from calves.

Despite the poor vaccine, assessment teams usually found that take rates for primary

Table 12.20. Brazil: number of doses of vaccine produced and number of vaccinations performed, 1967–1972 (millions)

	1967	1968	1969	1970	1971	1972
Doses of vaccine produced	31.3	49.4	61.0	72.3	44.7	29.3
Vaccinations performed:						
"Attack phase"	6.6	12.2	20.9	31.6	12.0	0
"Routine maintenance"	11.4	9.2	5.0	5.7	6.0	13.9
Total	18.0	21.4	25.9	37.3	18.0	13.9

vaccinations were above 90%. However, to achieve a high proportion of successful takes, it was necessary to ensure that the vaccine was kept refrigerated until the time of use. When refrigeration was available, the take rates were generally satisfactory, but in more remote areas that lacked such facilities, they were not. The results of assessment in Espírito Santo State illustrate this: take rates of 98% were obtained among those vaccinated in urban areas, but in the more remote areas in which refrigeration was a problem, the rates were 88–93%. In other parts of the world, where fully potent and stable vaccine was available, take rates of 98% or higher were the rule, even when vaccine was kept at ambient temperatures for a month or longer.

The large quantities of vaccine reported to have been produced in Brazil (Table 12.20) far exceeded the amounts required for the numbers of vaccinations performed. Yet, despite the large volume of production reported, available vaccine supplies so frequently dropped to critical levels in Brazil that reserve supplies were requested from and donated by Argentina in 1970. The explanation of this paradox lies, in part, in the vagaries of Brazilian laboratories in reporting vaccine production. Virtually all other laboratories reported the numbers of doses produced in terms of 1 dose being equivalent to 0.01 ml of reconstituted vaccine. An ampoule containing the standard amount of 0.2 ml or 0.25 ml was reported as 20 or 25 doses. When the conventional scarification technique had been used, this correspondence between the number of doses and the size of the ampoule was approximately correct, but with the introduction of the jet injector and the bifurcated needle many more persons could be vaccinated with the same amount of vaccine. Notwithstanding this development, producers elsewhere continued to report production on the basis of 0.01 ml of reconstituted vaccine being equivalent to 1 dose. The Oswaldo Cruz Institute, however, produced vaccine in ampoules which, when reconstituted, contained 0.35 ml and 1.0 ml and which were designated, respectively, as 100 and 400 doses. Similar practices were followed in other Brazilian laboratories. Not only was reported production inflated by a factor of 3–4 compared with that of other laboratories, but wastage in the field was greater because of the larger ampoules.

The extensive use of a consistently inferior vaccine in Brazil throughout most of the period of the programme was compensated for by the closely supervised vaccination campaign. Had vaccines of comparable quality been employed in most other programmes, the transmission of smallpox would not have been interrupted.

CONCLUSIONS

Eradication was finally achieved in Brazil, and in South America as a whole, in April 1971, nearly 5 years after the promulgation of the federal decree of 31 August 1966 which set the programme in motion in Brazil. However, as in many other countries, the progress achieved by the programme was erratic and the chances of success were in doubt as late as 1970.

Several factors may be seen, in retrospect, to have been essential to the achievement of eradication. In the initial stages, Dr da Silva's organizational talents, tested during years of work in malaria eradication, served to establish an effective administrative structure. Thereafter, observations made during field investigation, assessment of vaccine coverage and surveillance altered strategy and provided a necessary stimulus to government at critical moments. At an early stage, field investigation of an outbreak in a town whose inhabitants were said to have been well vaccinated dramatically pointed up the need for routine assessment of vaccination coverage and take rates. An assessment programme,

The Precarious Status of the Programme in Brazil, February 1970

Extracts from a letter from D. A. Henderson to Dr Charles Williams, Deputy Director of PAHO, dated 10 February 1970:

"It seems quite clear that the situation is not good. Both Drs Candau [Director-General of WHO] and Horwitz [Director of PAHO] were very concerned and had communicated this to me during the EB [WHO Executive Board meeting, held in January]...

"The visit of Dr Wehrle [a WHO consultant] originally had been thought of as an effort to strengthen surveillance as, from the reports, it seemed like one additional modest push in the right direction could put the programme over the top... however, surveillance, such as it is, is collapsing along with a good many other things; much had been said about the development of the network of reporting centres but, in fact, very little had been done and even in those states where it was said to be well-established, this was anything but the case.

"Candidly, I'm afraid that WHO is in no small way at fault. Despite Brazil having been recognized as the No. 1 problem, from the beginning, Connaught Laboratories' consultants have been dispatched from Cuba to Mexico to Peru with an occasional brief stop at the one laboratory which supplies 80–90% of all vaccine to the one endemic country...Parenthetically, the Brazilian laboratories are now the *only* producing laboratories in endemic countries manufacturing sub-standard vaccine. Money has been directed to smallpox projects in any number of countries (most recently Venezuela!) when, in fact, the real need is Brazil plus the need to keep a watchful eye on Paraguay and northern Argentina. Now even the man for this latter function has been terminated, so I have just learned...

"I would hope we could chart some alternative future course at the earliest possible time ...some sort of reasonably high level discussions in Brazil should be arranged at the earliest possible time."

using a sample survey technique, was quickly developed; this evolved into one of the most effective and thorough of any smallpox eradication programme.

The weekly surveillance bulletin (the *Boletim semanal*), launched in May 1967, documented the programme's progress or setbacks for staff at all levels and communicated information on new developments and procedures to everyone concerned. When a perceptive health secretary assigned 3 surveillance officers for surveillance–containment functions and these workers promptly discovered an additional 50 cases for each case investigated, the weekly bulletin broadcast the news of what seemed to be an alarming epidemic. The press, the Minister of Health and even the President took a new interest in the programme. By the middle of 1970, it achieved its full momentum.

Whether transmission could have been interrupted without the extensive vaccination programme but with effective surveillance–containment measures is an unanswerable question. Because the disease occurred only in the mild variola minor form, there was less of a stimulus for vaccination, and thus vaccinial immunity in Brazil in 1967 was probably among the lowest in the endemic countries. Transmission was successfully interrupted in Paraná State by surveillance–containment measures alone, but Paraná was one of the more prosperous states with a more extensive health infrastructure than those in the north-east and in the Amazon area.

Whatever the shortcomings of the programme, eradication was achieved in somewhat less than 5 years in a population of nearly 100 million people. In the course of the programme, a large cadre of young health staff obtained practical training and experience in epidemiology, which they were subsequently to apply to other health problems during service in Brazil and in international health organizations. The household probability survey, used in assessment, was later adapted for similar use in other programmes, ranging from family planning to poliomyelitis; and the weekly smallpox surveillance bulletin has since become Brazil's weekly communicable disease report.

INTRODUCTION

In 1967, smallpox was endemic in 5 Asian countries, whose total population amounted to 769 million. Four of these countries—Afghanistan, India, Nepal and Pakistan—were contiguous, sharing long borders, which travellers (including people infected with smallpox) crossed with relative freedom. However, the fifth country, Indonesia (population, 112 million), lay some 2000 kilometres south-east of the nearest endemic area on the continent—East Pakistan (after 1970, Bangladesh). Comparatively few people travelled between Indonesia and the other 4 countries. Thus, it seemed logical and opportune to concentrate resources and energies initially in Indonesia in the expectation that on becoming free of smallpox, the country would not be seriously threatened by importations (*Wkly epidem. rec.*, 1969a). WHO resources committed to Indonesia could then be shifted to other programmes in Asia. The fact that smallpox transmission had once been interrupted in Indonesia, immediately before the Second World War, added strength to the belief that the objective could be attained.

As had been hoped, Indonesia was the first of the 5 Asian countries to become free of smallpox. The programme began there in June 1968; the last known case occurred little more than 3½ years later, on 23 January 1972. The achievement of eradication so quickly in such a large and populous country was both a surprise and a stimulus (and to some degree an embarrassment) to health staff in Bangladesh, India and Pakistan, whose programmes had by then been in progress for a decade. That this feat had been accomplished with little more than US$1 million in international assistance made it even more notable.

Success was not easily achieved in the Indonesian programme. Smallpox was tenacious and spread readily even among populations with exceptionally high levels of vaccinial immunity—a marked contrast to the

behaviour of the disease in most endemic countries of Africa and the Americas. Full credit for the achievement is due to an imaginative group of Indonesian and WHO staff, who conceived and evolved effective strategies that were later adapted for use in other parts of the world and proved vital to the interruption of smallpox transmission in the Indian subcontinent. Among Indonesia's contributions to global eradication were the concept of a special programme involving a village-by-village search for cases, the introduction of a reward system for anyone reporting a case of smallpox and the development of the widely used WHO smallpox recognition card (see Chapter 10, Plates 10.29, 10.30).

A number of papers were prepared describing selected aspects of the Indonesian programme, although a book would have been warranted to recount the whole gamut of activities. There was little time available to attempt a detailed narration, however. When eradication was certified in 1973, experienced staff were urgently needed in other countries; key Indonesian staff and the WHO advisers who had been assigned there responded promptly and, in so doing, contributed to the record of achievement compiled in India, Bangladesh and Ethiopia.

THE DECISION TO BEGIN THE PROGRAMME

Originally it had been hoped that the campaign in Indonesia might begin during the first year of the Intensified Smallpox Eradication Programme but its start was delayed until June 1968. In part, this stemmed from doubt and inertia in the WHO Regional Office for South-East Asia in New Delhi, India. The then Regional Director believed that the health resources in the countries of the region were too inadequate to permit eradication to be realized. He frankly and publicly stated his view that the World Health Assembly's decision to undertake global eradication was ill-advised, and consequently offered little support to the programme. Likewise, the Regional Adviser for Communicable Diseases, the senior technical officer, took little interest. A memorandum of 10 October 1967 from Henderson to his superior in WHO Headquarters, Dr Karel Raška, the Director of the Division of Communicable Diseases, summarized the situation prevailing during much of that year:

"In December [1966] and April [1967], the considerable importance of an early visit to Indonesia to assess Government interest and capability to undertake [smallpox eradication] had been agreed by [the Regional Adviser for Communicable Diseases] and myself. No visit has yet been undertaken and none is contemplated until possibly November. In fact, I gather there was no correspondence with Indonesia on the question of [eradication] until July ... No solutions are proposed; no possible courses of action are outlined."

Subordinate to the regional adviser and ostensibly responsible for providing assistance to countries in developing smallpox eradication programmes was a 2-man intercountry advisory team for epidemiology whose duties then encompassed a range of different activities. During his visit to New Delhi, Henderson had met the team, which had exhibited both an interest and a desire to proceed rapidly in the development of WHO smallpox eradication programmes. Subsequent communication with them by mail proved difficult. All correspondence relating to smallpox eradication between WHO Headquarters and the regional office, as well as between the countries and the regional office, was routed first to the regional adviser. Seldom was it passed to the intercountry team. By the end of November 1967, the intercountry team had been permitted to make only two brief visits, to Afghanistan and Nepal, the only countries in the region in which WHO-supported smallpox eradication programmes were then in progress. In the autumn of 1967, one of the team's members, Dr Jacobus Keja, prepared a draft plan of operations for Indonesia but was denied permission to visit the country to discuss the plan.

The lack of activity in the South-East Asia Region and its failure to obligate smallpox eradication funds allotted for the calendar year led to important financial ramifications in the global programme as a whole. When the budget for smallpox eradication for 1967 had been approved by the Nineteenth World Health Assembly, several countries had expressed the view that an allotment of US$2.4 million for the first year was too large and proposed instead that a sum of US$1 million should be provided (see Chapter 9). The larger allocation was eventually agreed on, but only after assurances had been given by the Director-General that the full amount was needed and could be spent. In the American and Eastern Mediterranean Re-

gions, activities were progressing sufficiently well to ensure that the funds allotted to them would be obligated. However, US$806 000 had been assigned to the South-East Asia Region and little of it had been spent. If these funds were not obligated by the end of the year, not only would they be lost to the programme, but the possibility of questions arising at the next World Health Assembly could be foreseen, conceivably resulting in reductions in subsequent budgets for smallpox eradication. Because of this problem, the Regional Director finally agreed, in November 1967, that the intercountry team should discontinue its other activities and assume primary responsibility for smallpox eradication under a higher-level regional office official, the Assistant Director for Health Services. With this administrative change, the development of a programme in the region became feasible.

Three other events occurred during the autumn of 1967 which were to alter significantly the possibilities for eradication in the South-East Asia Region and in Indonesia in particular. A new WHO Regional Director, Dr Herat Gunaratne, was nominated in September 1967 and took office in February 1968. As President of the Twentieth World Health Assembly, in May 1967, Dr Gunaratne (a former Director-General of Health Services in the smallpox-free country of Sri Lanka) had stated categorically that the eradication of smallpox was wholly achievable, that it was simply a matter of will and determination. As testimony to this belief, he offered his own considerable enthusiasm and support for the programme.

The second event was the appointment in November 1967 of Dr Julie Sulianti Saroso to the post of Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health. This decisive and energetic woman was determined to revivify a discouraged and listless health staff who had received little pay for more than 4 years because of a decision by the previous government that health care costs should be borne primarily by private individuals. Although the health staff were expected to supplement meagre salaries through charges for their services, few were successful in obtaining even subsistence wages. Dr Sulianti promptly asked for help from WHO. The regional office decided that Dr Keja should visit Indonesia en route to an intercountry seminar on smallpox, due to begin in Bangkok on 11 December. He arrived in Jakarta on 7 December 1967.

The third event was the development of epidemic smallpox, beginning in August 1967 with an outbreak in the capital city, Jakarta. By November, more than 50 cases a week were being reported (Fig. 13.1).

With Dr Sulianti, Dr Keja at once decided to carry out a sample survey of the city to

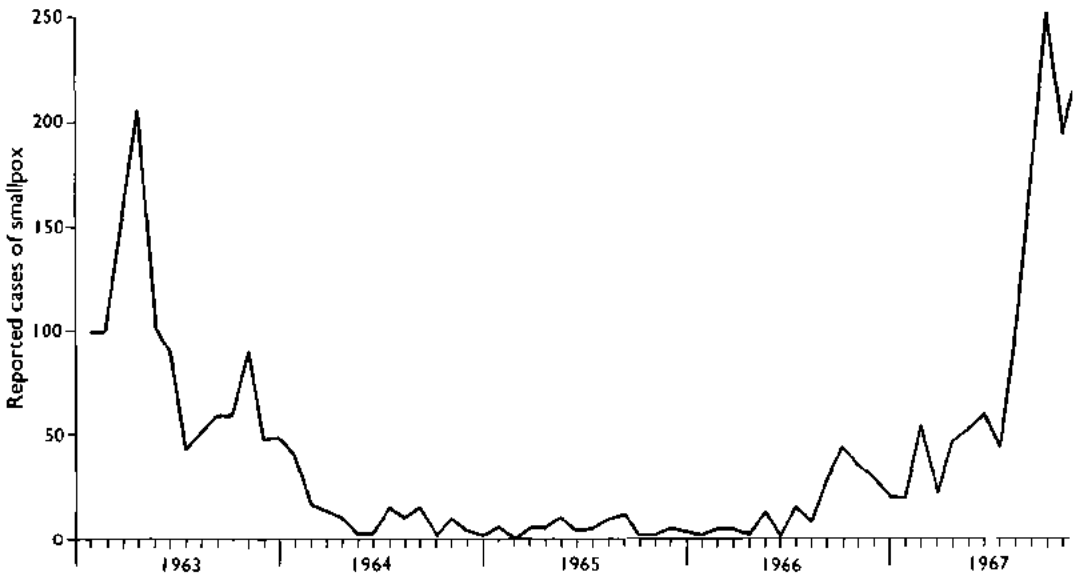

Fig. 13.1. Jakarta Municipality: number of reported cases of smallpox, by 4-week intervals, 1963–1967.

BY COURTESY OF N. KUMARA RAI

Plate 13.1. Several national and intercountry seminars on smallpox eradication were held in Indonesia. At the concluding seminar, in September 1972, Julie Sulianti Saroso, Director-General for the Control and Prevention of Communicable Diseases, presented an award to Nyoman Kumara Rai, who had directed the Indonesian Programme since April. Standing behind the Director-General are 2 WHO advisers, G.G.O. Cuboni (*far left*) and W. L. R. Emmet.

assess vaccinial immunity—the first of many such surveys to be conducted during the global programme. For this survey, 20 field staff from the smallpox and malaria programmes were selected and trained. Each examined 200 children for vaccination scars and the facial pockmarks of smallpox in a house-to-house survey beginning from randomly selected points in the city. In only 4 days, the survey had been completed and the results analysed. From the survey and a review of other available data, it was apparent that there were major problems:

(1) Reporting was incomplete. In all, 1265 cases and 413 deaths had been recorded during 1967, but because so many cases were found during the survey the actual number of cases was thought to be at least twice this figure.

(2) The number of vaccinations given was insufficient to sustain immunity. Jakarta Municipality's 49 vaccinators had performed 384 000 vaccinations in 1967, but only 35 295 (9.2%) had been primary vaccinations. In a population of 1.4 million, with a birth rate of 40 per 1000, it was calculated that 56 000 primary vaccinations would be required annually simply to protect newborn infants.

(3) The proportion of successful primary vaccinations was unsatisfactory. Take rates of only 60–80% were observed, a phenomenon attributed to the use of vaccine of lower than acceptable titre as well as unsatisfactory vaccination technique.

However, vaccinial immunity, though still not adequate, was found to be far higher than expected. Vaccination scars were seen in 90% of children aged 5–14 years, in 75% of those aged 1–4 years, and in 45% of infants aged less than 1 year. Nevertheless, the situation was clearly disturbing. Smallpox was spreading rapidly throughout a reasonably well vaccinated urban population; the vaccination campaign was lagging and was further compromised by the use of substandard vaccine; extension of the epidemic into less well vaccinated rural areas was only a matter of time. A programme for smallpox eradication

[a] Population estimates as recorded in 1968. United Nations (1985) data show a total population of 114 798 000 for Indonesia in 1968.

was urgently needed and indeed its development proceeded rapidly.

The above-mentioned WHO intercountry smallpox seminar in Bangkok, which, by lucky timing, took place immediately after the Jakarta survey, provided the opportunity for a draft plan of operations to be finalized. Indonesia's representative, Dr Ignatio Setiady, Director of Communicable Disease Control, met Henderson and Dr Keja, and using the latter's earlier prepared draft, worked out a plan for the programme and estimated the cost involved and the assistance required.

A critical problem, and one that was never really solved, was that of providing Indonesian staff with high enough salaries to permit them to work virtually full time. Vaccinators, for example, were then receiving the equivalent of US$2 a month, which was insufficient to buy food for themselves, let alone for their families. WHO's resources could not deal with the situation in its entirety. Despite this problem, it was apparent from the survey that somehow a large proportion of the population was being vaccinated. With hope rather than confidence that the vaccinators would continue to function, it was agreed that supplementary WHO funds would be provided to a small number of senior Indonesian staff to permit them to carry out full-time supervisory functions; other personnel would necessarily work only part time, and field operations would have to take this into account. WHO also agreed to provide a medical officer and to purchase various items, including 15 vehicles, 135 motor cycles, 1550 bicycles, 23 refrigerators and vaccine production equipment. By the end of December, funds for equipment and supplies had been obligated. Less than a month later, on 24 January 1968, Indonesia's Minister of Health signed a formal agreement with WHO authorizing the programme. Field operations were scheduled to begin in June 1968.

WHO

DEMOGRAPHY AND GEOGRAPHY OF INDONESIA AND ITS HISTORY OF SMALLPOX CONTROL

The country's demographic and geographical features, as well as its remarkable history of smallpox control, were determining factors in the development and progress of the programme.

The Indonesian archipelago, extending over more than 4800 kilometres, consists of

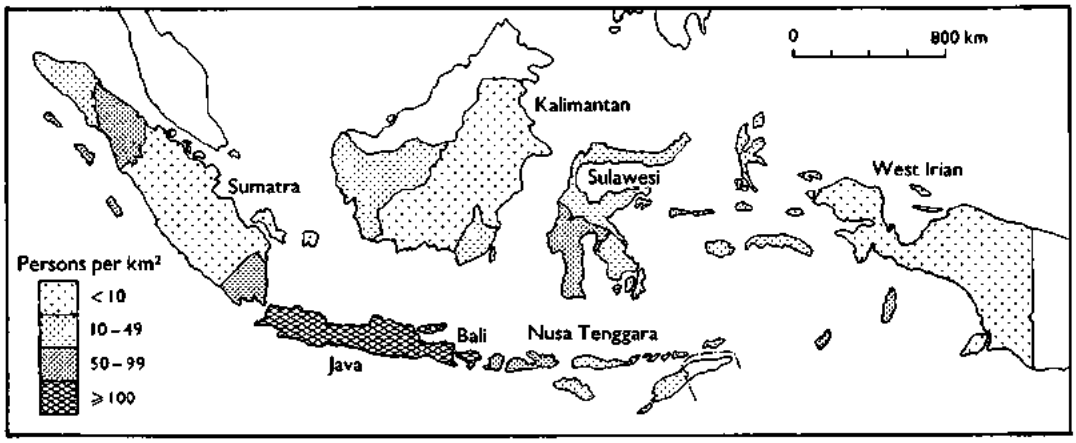

Fig. 13.2. Indonesia: population density, 1968.

some 13 000 islands, of which 3000 are inhabited. In 1968, 66% of the country's 115 million people lived on the densely populated islands of Java and adjacent Bali (Fig. 13.2; Table 13.1). Most of them (83%) lived in localities with 5000 or fewer inhabitants or in rural areas. However, it was estimated that fully 60% of the population could be reached by motorized vehicle, 20% by boat and 20% on foot or by bicycle.

For administrative purposes, Indonesia in 1968 was divided into 26 provinces, which were subdivided into 288 regencies and municipalities (Table 13.2), consisting of 3203 subdistricts. The smallest administrative unit was the village. The size of the population in these administrative divisions varied considerably from one area to another.

Although organized vaccination campaigns in Java dated back to 1856, an extraordinarily effective campaign was begun in the 1920s which was successful in interrupting smallpox transmission as early as 1936 (Table 13.3).

Of the 21 cases recorded between 1937 and 1940, 7 were found to be importations and the others were suspected to be either importations or mistaken diagnoses (Polak, 1968). The Second World War intervened and morbidity reporting ceased. After the war, no cases are known to have occurred in Indonesia until May 1947. The first cases were reported from the Riau Islands, adjacent to Malaysia, in which smallpox was then endemic. Over the next few years, the disease swept eastwards across the western and central islands of the archipelago, 99 016 cases being reported in 1950. However, smallpox did not spread beyond Sulawesi and West Nusa Tenggara to the numerous but more sparsely populated islands to the east—East Nusa Tenggara, Maluku and West Irian (Fig. 13.3).

The methodology employed in the vaccination campaign of the 1920s and 1930s is of interest, since the structure and many of the operational components of the campaign still existed in 1968 (Polak, 1968), although the number of staff had diminished and the

quality of performance was poorer. A trained vaccinator was assigned a vaccination district of about 100 000 persons. Under the supervision of a medical officer who was responsible for several regencies, he travelled by bicycle and on foot through his assigned district on a strictly prescribed schedule. During each 3-month period, he devoted 8 weeks to primary vaccination and 5 weeks to revaccination. Infants were brought to designated collecting points not more than 6 kilometres from their homes and up to 150 were vaccinated daily. In the case of revaccination, up to 500 persons were dealt with each day. When outbreaks occurred, intensive programmes of vaccination were conducted in the areas infected. Most vaccinators used liquid vaccine, produced by the government-owned quasi-independent Lymph Institute in Bandung (Biofarma), which had opened in 1891. In the more remote districts, a remarkably stable, room-dried and vacuum-sealed vaccine was used which had been first produced in 1926 (Otten, 1932).

In the systematic vaccination campaign, resumed after the Second World War, both liquid and room-dried vaccines and eventually some freeze-dried vaccine were used. High inflation rates and the drastic reduction of salaries of government health staff forced vaccinators and other personnel to take additional jobs. Periodic *ad hoc* mass vaccination campaigns were also conducted, financed by local merchants and village organizations. The numbers of vaccinations reported by vaccinators in Java from 1963 to 1967 indicate the extent of activity (Table 13.4).

In all, 15–25% of the population in the different provinces were reported to have been vaccinated annually by the special vaccinators. Of the total number of vaccinations, 10–15% were recorded as primary vaccinations. In addition, vaccinations were performed in local clinics and maternal and child health units; these were not included in the totals but their number was thought to be large. On the basis of this information, it was difficult to guess the probable extent of vaccinial immunity. Not only were the reports of vaccinations performed considered to be suspect, but primary take rates were reported to range from 33% to 88%. Both high and low rates were recorded during the use of each of the 3 forms of vaccine then being produced: liquid, room-dried, and a small quantity of freeze-dried vaccine. Be-

cause refrigeration facilities were limited, low primary take rates with the thermolabile liquid vaccine were understandable. The low take rates with the more stable freeze-dried and room-dried vaccines reflected, in part, the low potency of some batches; moreover, none of the dried vaccine was kept under refrigeration, since the manufacturer claimed that it retained its potency at room temperature for 18 months. Although a few batches attained this degree of stability, most did not.

Special mass vaccination campaigns had been conducted in Jakarta in 1962–1963, in East Java in 1964, in West Java in 1965 and in Central Java beginning in the autumn of 1966. The campaigns were not well supervised or well coordinated and were chronically short of funds to pay vaccinators and to purchase vaccines from the Biofarma laboratory.

Despite the apparently questionable efficacy of the campaign, vaccinial immunity in Java proved to be surprisingly high, although the level of immunity varied widely from one locality to another. Sample cluster surveys, similar to the one conducted by Dr Keja in Jakarta in December 1967, were carried out in January and February 1968 throughout Java. In all, 56 619 children under 15 years of age were surveyed. All the children were examined to determine whether facial pockmarks were present and whether or not they had a vaccination scar. From these studies, an estimate of the level of vaccinial immunity was obtained (Table 13.5), as well as an approximation of the completeness of smallpox notifications.

Less than one-quarter of all the children were considered to be fully susceptible to the disease. Only 807 (1%) had facial pockmarks characteristic of smallpox. Since persons less than 15 years of age constituted approximately half the population and since only a small proportion of those older than 15 were fully susceptible, it was assumed that not more than perhaps 10–15% of the total population were then susceptible to smallpox. Not surprisingly, at that time more than 75% of smallpox cases were reported to be occurring among children under 15 years of age (Table 13.6) and upwards of 80% of cases occurred among those without a vaccination scar.

SMALLPOX INCIDENCE, 1963–1967

National data for smallpox prior to 1963 provide little indication as to the incidence or

[a] No cases were reported from Maluku, East Nusa Tenggara or West Irian during this period.

geographical distribution of the disease. Not only did villages and regencies fail to report to provincial authorities, but many provincial administrations submitted no reports to the national authorities. The number of cases officially recorded at the national level varied from 1000 to 10 000 during the period 1952–1962. Better data are available for the years 1963–1967, because smallpox control staff visited each of the provinces during 1968 to compile provincial data from previous years in order to obtain baseline information. In 1963, 17 431 cases were recorded, of which all but 3658 were from West Java (Table 13.7). The most complete data available pertain to the years 1965–1967, and these show a wider dispersion of smallpox throughout the central and western islands of Indonesia.

Major epidemics were reported in 2 areas during the period 1965–1967 (Fig. 13.4). In 1965, East Java reported 36 120 of the 56 359 cases recorded in Indonesia and this epidemic was followed in 1966 by one in neighbouring West Nusa Tenggara. Central and South Kalimantan experienced epidemics in 1965, which gradually subsided over the next 2 years without a planned vaccination campaign. Other provinces of Indonesia also reported significant numbers of cases, but because of inadequate reporting few conclusions can be drawn about the comparative magnitude of the smallpox problem in these areas. That reporting was seriously deficient was shown in the January 1968 survey in Java. In this survey, estimates of recent smallpox incidence were derived from the prevalence of facial pockmarks. The survey revealed that, at most, 10% of all cases were actually being reported. Thus, it was calculated that more than 100 000 cases had occurred in 1967 in Java alone. Reporting from the other islands, in which the health resources were fewer, was much less complete than in Java.

ORGANIZATION OF THE PROGRAMME, JANUARY–JUNE 1968

Dr Sulianti lost no time in setting the eradication programme in motion. As a first step she changed a meeting on tuberculosis vaccination scheduled for February 1968 into a planning seminar for smallpox eradication. It was to be the first of a series of annual national meetings which reviewed the programme's progress and established specific plans and targets for the succeeding year. Those attending included Dr Sulianti's staff; senior health officials from the provinces, regencies and municipalities; directors of

Estimates of the Completeness of Case Notification

It was common knowledge that many cases of smallpox were not reported to the health authorities but the general belief was that the true figure was not more than perhaps 2–3 times the number of recorded cases. The fact that 10 067 cases were known in 1967 to have occurred that year was of concern to health officials but it was not cause for real alarm. Dr Keja suspected that underreporting was a much more serious problem and performed a number of simple calculations to estimate its magnitude. The 1968 survey teams had found that 39 out of 8636 children under 1 year of age had the characteristic facial pockmarks and thus had contracted smallpox during the preceding year, 1967. Extrapolating from this rate of 4.5 cases per 1000 to the entire population of children under 1 year (2 457 000), Dr Keja arrived at a figure of 11 056 cases. However, since Indonesian data showed that 40% in this age group died of smallpox, he reasoned that the actual number who had had smallpox was 1.67 times larger. Making further corrections to allow for the fact that at least 10% survived without recognizable pockmarks, and calculating that those under 1 year of age accounted for not more than one-fifth of all smallpox cases, he estimated that at least 100 000 cases of smallpox had occurred during 1967 in Java alone, or 10 times more than the number recorded. The numbers in the survey were small and the method of estimation, although unsophisticated in statistical terms, was understandable to non-technical people. The Minister of Health was incredulous and asked other statisticians to examine the data. All of Dr Keja's assumptions served to understate the magnitude of the problem. Case-fatality rates among infants under 1 year were nearer 50% than 40%; the proportion of those surviving without recognizable pockmarks was closer to 35% than 10%; and the proportion of cases in Indonesia among those under 1 year was actually 14% rather than 20%. Finally, Dr Keja had made no effort to correct the estimate to reflect the fact that the children who were examined were all less than 1 year of age and thus, on average, had actually been exposed to smallpox only over a 6-month period. His decision to develop a conservative but understandable estimate had been deliberate. The figure of 100 000 cases was impressive in itself. When Indonesian statisticians independently made their own estimates, they calculated that the number of cases had more likely been in the range of 200 000–500 000. The Minister was persuaded that smallpox was indeed a problem of high priority in Indonesia.

maternal and child health, school health and malaria control programmes; and representatives from the armed forces, the Ministry of Home Affairs and the Central Bureau of Statistics. The seminar represented a laudable effort to involve a wide range of civil and military authorities in the programme although, in fact, few of those present were to make significant contributions until late in its course.

It was decided to launch the programme in June 1968 in Java and Bali, in which 66% of the population lived, and to extend it to the outer islands a year later. Additional vaccinators would be appointed for each subdistrict (40 000–50 000 population), which would more than double the number then in the field. However, they would work only part time, as did the others, because their pay remained low. A supervisor would be appointed for each regency (500 000–1 000 000 inhabitants) and additional supervisory staff would be provided at provincial and national levels. In each of the 90 regencies and the 6 provinces, a "fire-fighting" team of 3 or 4 persons would be formed from existing staff specifically to contain outbreaks.

Because the vast majority of cases were occurring among the unvaccinated, vaccinators were instructed to concentrate on primary vaccination. The maternal and child health centres were directed to vaccinate all infants attending clinics (estimated to represent about 40% of the total number of infants) and the school health services to vaccinate all schoolchildren (corresponding to about 50% of all children of school age). The newly developed bifurcated needles and the multiple puncture technique of vaccination would be employed by all vaccinators

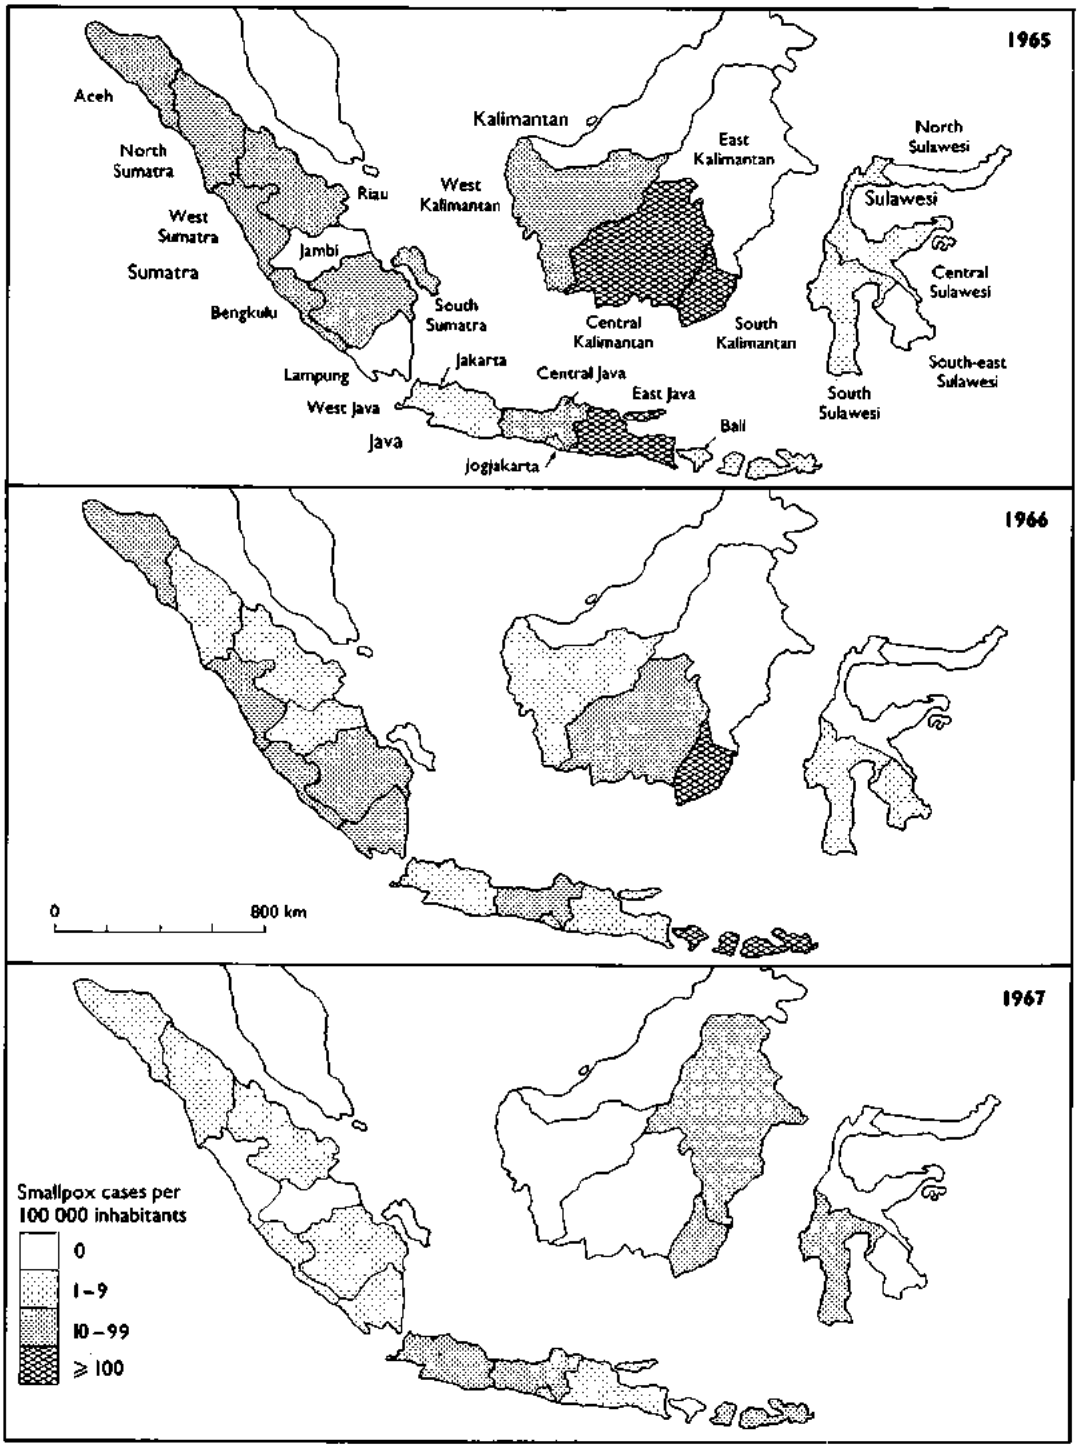

Fig. 13.4. Indonesia: number of reported cases of smallpox per 100 000 inhabitants, 1965–1967.

except the members of national surveillance–containment teams, who would use jet injectors supplied by WHO. It was agreed that only freeze-dried vaccine would be employed, that cold-storage depots would be established at national, provincial and regency levels, and that each batch of vaccine produced by the Biofarma laboratory would be tested by WHO

laboratories and released for use only after certification that it met WHO standards of potency, stability and bacterial content.

In support of the programme, WHO eventually provided a total of US$1 300 363 to cover the purchase of supplies and equipment, local costs and staff costs (Tables 13.8 and 13.9); it also provided for the acquisition of 4.1 million doses of vaccine. Indonesia's expenditure amounted to US$3 600 000. The total outlay was equivalent to just over US$0.04 per head of population.

The central staff initially consisted of 4 medical officers (later increased to 8), 7 health inspectors (later 10) and 12 administrative staff. A WHO medical officer was assigned throughout the programme (Dr M. F. Polak, July 1968–January 1969; Dr Reinhard Lindner, January 1969–July 1971; Dr G. G. O. Cuboni, May 1971–1973), and an operations officer, Mr William Emmet, was appointed in August 1970. WHO short-term consultants assisted for a period of approximately 24 man-months.

The programme was conducted by a specially created Smallpox Eradication Unit in the Directorate of Epidemic Control under the direction of a motivated and committed physician, Dr P. A. Koswara. This unit, in turn, reported to Dr Sulianti. At the provincial level, there was a smallpox eradication programme section, also headed by a full-time medical officer. At the regency/municipality level, the responsibility for the programme rested with a medical officer assisted by an experienced senior sanitarian and one or more assistant supervisory sanitarians.

THE EARLY STAGES OF THE PROGRAMME, JUNE 1968–JULY 1969

At the beginning of the programme, preoccupation with the vaccination component was perhaps inevitable. This approach had proved effective in the late 1930s, despite reliance on the use of thermolabile glycerolated vaccine in the main islands and a variably potent but stable room-dried vaccine in more distant areas. National and WHO programme staff believed that with an already high level of immunity, the increased number of vaccinators, using a freeze-dried vaccine of assured potency, should be able to find and vaccinate the comparatively small proportion of susceptible people and so interrupt transmission rapidly. As would prove true in other countries of Asia, this strategy did not work.

Throughout Indonesia, 3130 vaccinators —approximately 1 for each subdistrict—and 324 regency supervisors conducted the programme. On average, this amounted to 1 vaccinator for every 39 000 persons, the ratio ranging from 1 to 9000 in sparsely inhabited areas to 1 to 50 000 or more in densely populated regions. The pre-war procedure, according to which vaccinators visited each

Plate 13.3. Petrus Aswin Koswara (1931–1974), directed the national programme until April 1972. Standing at centre, he is speaking with Dr Hasan Anoez, Provincial Medical Officer in South Sulawesi, and D.A. Henderson in 1971.

village 4 times a year to give primary vaccinations and one-third of all villages to perform revaccinations, was modified to emphasize primary vaccination. During 8 weeks of each quarter, vaccinators were instructed to visit all villages to give primary vaccination to all preschool children (up to 4 years of age), including newborn infants. During the remaining 5 weeks, they were instructed to visit one-quarter of all villages to vaccinate or revaccinate all children aged 5–14 years. The programme was modified in Bali, in which vaccination was entrusted to malaria surveillance workers. If well executed, this intensified campaign would have ensured, within 1 year, vaccinial immunity in nearly all children from birth to 14 years of age, the age group in which most cases were occurring.

The problems of vaccine supply and quality were gradually resolved over a period of 18 months. Biofatma ceased production of the liquid and room-dried vaccines and began to produce freeze-dried vaccine only. UNICEF provided additional vaccine production equipment and WHO recruited consultant assistance for the laboratory. Better methods of quality control, as well as improved production methods, were instituted. By the end of 1968, the quality of the freeze-dried vaccine began to meet accepted WHO standards and, during 1969, the laboratory began to produce sufficient vaccine to meet Indonesia's needs. In the meantime, vaccine donated to WHO by New Zealand, Thailand, the USSR and the USA augmented the supply. National and provincial cold-storage depots were already available; WHO provided additional refrigerators for use at the regency level. To simplify procurement and distribution, the national health authorities decided to purchase all vaccine from Biofarma with national funds and to distribute it without charge to provincial health departments, which, in turn, were to distribute the vaccine to regencies.

Not surprisingly, a host of problems arose in a programme which was to be so greatly strengthened and executed in such a large population with only 6 months of preliminary planning and organization. One by one, these difficulties were resolved. To cite a few of the more important: deliveries of vehicles, bicycles and other items transported by sea were delayed by months because of customs

Plate 13.4. Biofarma laboratory, Bandung, (**A**) which produced smallpox vaccine for the programme. As late as 1968, room-dried vaccine was still being prepared by the procedure introduced by Otten in 1926. The vaccine pulp was dried in desiccators (**B**), after which it was put in vials which were sealed under vacuum (**C**). The vaccine was remarkably heat-stable but difficult to produce and was often contaminated with bacteria.

clearance formalities; government fiscal procedures were cumbersome and payments for vaccine to Biofarma were held up, resulting in the periodic cessation of production in late 1968 and 1969; payments to staff were similarly interrupted from time to time, with a consequent suspension of work; the recording of cases and transmission of data were seriously deficient; and effective supervision at the beginning of the programme was minimal. All these problems had to be dealt with more or less simultaneously and all persisted to some degree or recurred throughout most of the programme.

For the vaccination campaign, it was decided to establish an annual target for primary vaccinations equivalent to 6% of the population and one for revaccinations equivalent to 30% of the population. It was an unrealistic expectation, given that the vaccinators worked only part time and that the supervision and planning of vaccinator tour schedules were marred by lack of experience. Vaccinators on average performed only 20–80 vaccinations per day, of which between 2 and 20 were primary vaccinations. The programme never met its targets, although it began to approach them in 1970 (Table 13.10). A repeat stratified cluster sample survey in June 1969, similar to that performed in January 1968, showed no significant change in the proportion of susceptible persons (*Wkly epidem. rec.*, 1969c).

The plan had called for "fire-fighting teams" at regency level to contain outbreaks, but few of the regency teams functioned well—and most of them not at all—because of lack of interest and motivation. Vaccination to control outbreaks was neither thorough nor systematic; the sources of cases were not traced, and few of the locales of outbreaks were revisited to ensure that transmission had been stopped.

Indonesia, so densely populated, had seemed to be an ideal place to use jet injectors in outbreak containment. The injectors were provided by WHO and, in August 1968, a consultant was recruited to train special vaccination teams in their use and maintenance. As was true in many other areas, the concept was attractive in theory but disappointing in practice. Except in urban areas, the population was not accustomed to gathering in large numbers at collecting points, and unless they did so the considerable capacity of the injectors could not be realized. Maintenance and repair of the injectors and the logistics of providing a flow of spare parts proved to be formidable obstacles. Within a year, the jet injectors had been abandoned in favour of bifurcated needles. Not only did the latter yield far better results in comparison with the old vaccinostyle (as was revealed in a short trial in Ciloto, West Java) but they also proved to be considerably more economical in the use of vaccine. Beginning in March 1969, the bifurcated needle was accepted as the standard equipment for vaccination in the programme.

Improvement in the supervision and execution of the programme was needed at all levels and, to effect this, 13 "advance teams" (1 each in Jakarta, Jogjakarta and Bali, 2 in East Java and 4 each in West and Central Java) were established in January 1969. These teams provided a critical link in supervision between the national programme directorate and the regencies and were ultimately instrumental in instituting an effective surveillance–containment programme. They were given a month of special training and sent to the field. Each team was provided with a WHO vehicle and was headed by a physician who was able to work full time in the programme, thanks to a salary subsidy paid by WHO. The initial plan called for the teams to spend two-thirds of their time in surveillance and containment activities and one-third in improving the supervision of vaccinators.

[a] No cases were reported in Maluku, Bali, Nusa Tenggara or West Irian during this period.

Despite the chaotic beginning and the numerous problems, remarkable progress was recorded in some provinces (Table 13.11). East Java had experienced major epidemics in 1964 and 1965 and, in consequence, had conducted mass campaigns. However, the vaccination survey of December 1967–January 1968 (see Table 13.5) showed that vaccinial immunity was no better than in West Java and far lower than in Central Java despite the mass campaigns. In July 1968 a dynamic Provincial Director of Communicable Disease Control, Dr Bahrawi Wongsokusomo, and his assistant, Dr Witjaksono Hardjotanojo, took charge of the programme in East Java and vowed that they would interrupt transmission before January 1969. Vaccination activities were intensified, but—more important—any outbreaks found were energetically contained. During the last 6 months of 1968, only 133 cases were detected in the entire province. Between January and June 1969, only 3 outbreaks occurred, each of which could be traced to importations from Central Java; all were well contained after discovery. It was a remarkable achievement, accomplished almost wholly with provincial resources.

In Jakarta, under the leadership of Dr Guno Wiseso, special teams equipped with jet injectors demonstrated the efficacy of the outbreak-containment strategy. During a 3-month period, they investigated and contained 73 outbreaks, in which 217 cases had been reported (*Wkly epidem. rec.*, 1970a). The teams searched for additional cases, endeavoured to find the origins of the outbreaks and vaccinated the inhabitants of the affected administrative units (about 200 persons in each unit), as well as the people living in the 4 surrounding units. During these activities they discovered an additional 215 cases and vaccinated some 73 000 persons. A subsequent assessment revealed that smallpox transmission had ceased within 2 weeks of containment in two-thirds of the outbreaks (Table 13.12). Although these results would be considered poor by later standards, it was clear that outbreaks could, in fact, be quickly stopped.

No smallpox cases were reported in Bali or in the islands to the east after the programme began, and in February 1969 Jogjakarta recorded its last cases. By June 1969, smallpox in Central Java was being reported from only 4 of 35 regencies but West Java continued to report nearly 1000 cases per month. Meanwhile, the complement of vaccinators and supervisors in Java steadily increased and by June had more or less reached the numbers planned (Table 13.13). In Kalimantan, Sulawesi and Sumatra, the programmes did

not officially begin until July 1969, and thus all reports were considered to be suspect.

The number of cases reported in Indonesia between January and June 1969 amounted to 8789, a total not significantly different from the 8847 cases recorded during the same period in 1968. Although the staff believed that there was more complete reporting of cases, it was impossible to measure the extent of improvement. What was certain, however, was that reporting was still incomplete. The reporting of cases to the regency medical officer was the responsibility of village chiefs, but many chiefs completely neglected this task, even though they were aware that cases were occurring. Moreover, some regencies failed to report to the provinces, or, if they did, the reports were greatly delayed. In June, reports from almost one-quarter of all provinces in Java and Bali were overdue by a month or more. Reporting from other provinces was even more delayed and incomplete.

When the programme began, plans had been made for its assessment by a WHO–Indonesia team one year later. In June 1969, this was undertaken and recommendations were developed. The team was sharply polarized on the issue of mass vaccination. One group maintained that, with vaccinial immunity so high, the mass vaccination campaign could be said to have been completed already and that all efforts should be directed to surveillance and containment. A second group argued for a special campaign to move rapidly and systematically throughout the country to vaccinate the now very small proportion of people who had no vaccination scars.

A compromise was reached and the teams recommended that: (1) special programmes should be mounted to deal with the backlog of unvaccinated children under 15 years of age in Jakarta and West and Central Java (the number was estimated to be 3.3 million, or 16.6% of a population of 19.9 million children); and (2) surveillance should be strengthened through improved reporting by village chiefs and other health staff, and more active outbreak containment by the special "fire-fighting" and advance teams. It was recognized that the backlog vaccination campaigns would tax, and perhaps overstrain, available government resources, but the campaign was accepted as a component of the strategy.

THE STRATEGY CHANGES, JULY 1969

The resources available did not permit the implementation of backlog vaccination campaigns throughout the whole of Java, and so priorities were defined. In East Java and the islands to the east, in which transmission had been interrupted, efforts were to be directed solely to the early detection and containment of imported cases. In Central Java, lying immediately to the west, smallpox incidence was declining and prospects for the early interruption of transmission appeared good. Thus, the decision was made for vaccination teams (called "backlog-fighting teams") to begin work in the eastern regencies of Central Java and to move westward in the expectation that smallpox would progressively disappear in an east-to-west direction. Given the prob-

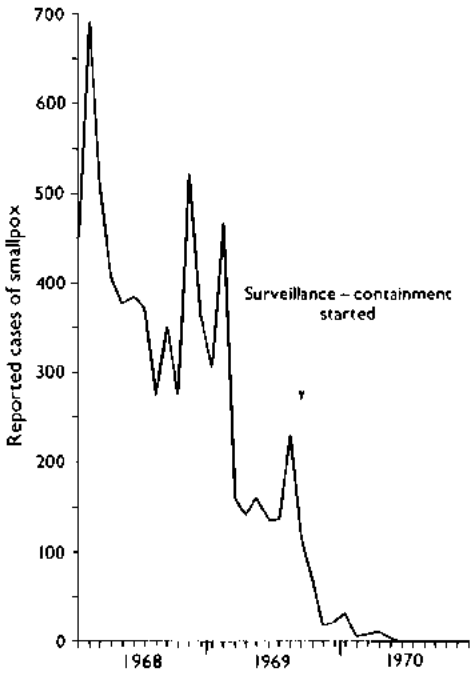

Fig. 13.5. Central Java: number of reported cases of smallpox, by month, 1968–1970.

ability that the situation in West Java would soon follow the same course, backlog-fighting teams were scheduled to commence operations in the province's 7 easternmost regencies.

As the backlog-fighting teams began vaccination in Central Java, the 4 provincial surveillance teams started work in the northwest, where smallpox incidence was the highest. Directed by a capable epidemiologist, Dr P. R. Arbani, these teams concentrated entirely on case detection and outbreak containment. Gradually they extended the scope of their operations to include the whole province. The number of cases in Central Java declined dramatically (Fig. 13.5). In December only 31 cases were detected, and by May 1970 the last case had occurred. The advance teams had performed only 54 000 containment vaccinations, a small fraction of the 5 million vaccinations which were being given annually in the province.

West Java presented a more formidable problem. Provincial supervision had been inadequate for many years and this was reflected in the low levels of vaccinial immunity throughout the province. During the first half of 1969, an average of almost 250 cases had been reported weekly—in a province whose notification system was the poorest in Java. In July, 4 special teams, each consisting of 5 vaccinators and a team leader, were recruited for each of the 7 regencies bordering on Central Java (Koswara in WHO/SE/71.30). As in Central Java, the teams proceeded house by house and village by village, performing primary vaccinations and containing any outbreaks that were found.

By October 1969, it became apparent that smallpox transmission was continuing in West Java, even in regencies in which backlog fighting had been completed. Although the teams were instructed to intensify surveillance–containment activities, few did so. In one regency, Tjirebon, in which no such activities had been conducted (*Wkly epidem. rec.*, 1970a), a WHO adviser was assigned to undertake surveillance–containment activities only. National staff supervised combined surveillance–containment and vaccination programmes in 3 other regencies, including Bandung, in which smallpox incidence remained high. Two months later, in December, a main focus of smallpox in the province was found to be yet another regency, Bogor, in which so far no work was in progress. Resources were all but exhausted and only a single team could be assigned there to conduct a surveillance–containment programme.

Three different types of programme had therefore developed in an unplanned operational experiment: (1) in Tjirebon, backlog vaccination was followed by an intensive

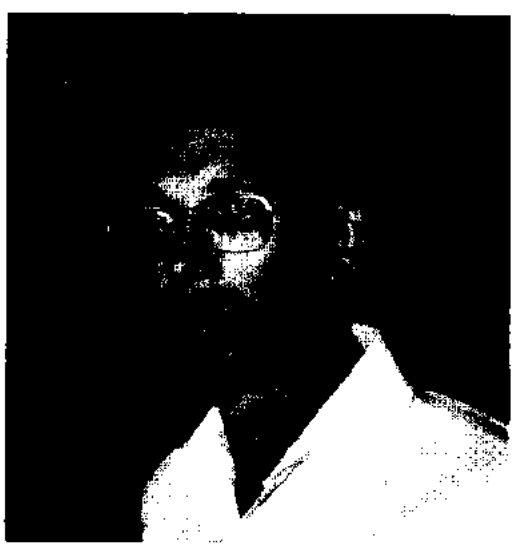

Plate 13.5. Reinhard R. Lindner (b. 1926) was the WHO smallpox adviser to the Indonesian programme from 1969 to 1971.

surveillance–containment programme; (2) in Bandung, a combined backlog vaccination and containment programme was directed by national supervisors; (3) in Bogor, a surveillance–containment programme only was conducted. The results of this experiment were to decide the subsequent strategy of the programme in Indonesia.

Tjirebon Regency

The backlog vaccination operation had begun in July 1969 and ended 18 weeks later. During 2025 man-days, the teams visited 188 287 households in 267 villages. In all, 208 smallpox cases were discovered in 24 villages. On completion of the work, a sample survey showed that the proportion of unprotected children below 1 year of age had decreased dramatically, from 83% to 26%; of those aged 1–4 years, from 36% to 11%; and of those aged 5–14 years, from 3% to 2%. The illusion of a highly successful programme was shattered when just 2 days after the programme had been completed, 12 mobile teams from other provinces undertook a 2-day training exercise in Tjirebon. They discovered that in 7 infected villages transmission was still continuing. By tracing the sources of infection, an additional 118 cases and 3 undetected outbreaks were discovered.

Greater efforts were obviously needed, and a WHO consultant, Mr Michael O'Regan, was assigned in mid-November. On arrival, he found a frustrated but hard-working staff with a disorganized record system and no day-to-day operational programme. In the yaws and leprosy programmes in which Mr O'Regan had worked, methods had been developed for the systematic search for cases throughout extensive areas. Applying similar principles in Tjirebon, he obtained reliable maps and lists of villages from the army and, with regency staff, planned a programme consisting of a systematic village-by-village search for cases and house-to-house searches when outbreaks were found. The basic work was performed by 7 search teams each composed of 2 men on bicycles, their work being supervised by 2 search teams with vehicles. In every village, the programme was explained to the village leader and assurances were given that, should he report a case, a team would come to the village within 24 hours. Outbreaks, when discovered, were contained and the locality concerned was revisited weekly until 4 weeks after the last case had occurred. Identification of the source of each outbreak permitted the discovery of other, unreported outbreaks. Each night the staff met, reported their findings and planned the following day's work. The initial search revealed that, as at 1 December 1970, there were 31 villages with active cases, but within 2 months transmission had been interrupted (Fig. 13.6).

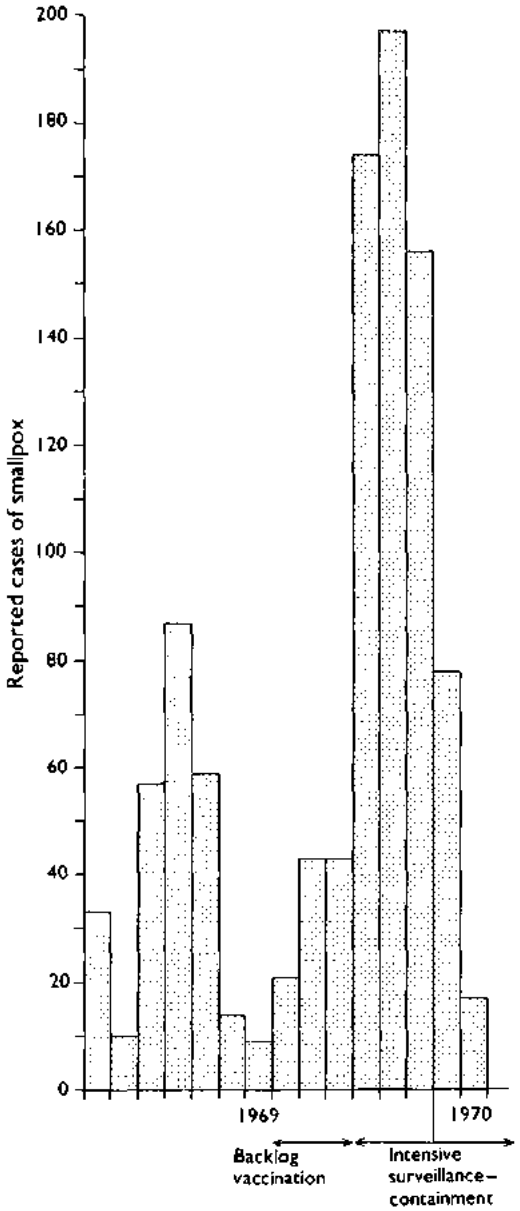

Fig. 13.6. Tjirebon Regency: number of reported cases of smallpox, by 4-week intervals, 1969–1970. The last interval in 1970 includes 6 importations and 11 delayed reports of inactive cases.

Cases continued to occur as a result of importations from other regencies but these were quickly contained. The Tjirebon programme was the first in the Intensified Programme in which teams undertook a systematic area-wide search for cases without simultaneously performing vaccinations. The technique was later to be widely applied throughout Indonesia and was to prove vital in interrupting transmission in the Indian subcontinent.

Bandung Regency

In Bandung, the combined surveillance–containment and backlog-fighting operation under the supervision of national staff had begun early in November 1968 and ended 26 weeks later. The teams visited 401 490 households in 242 villages and performed 163 194 primary vaccinations; 74 outbreaks with 565 cases were detected and contained. Altogether 4020 man-days were required. The resources needed to interrupt transmission were even greater than those expended in the Tjirebon programme.

Bogor Regency

A single surveillance team with a vehicle had been assigned to Bogor in December 1969, after a national team investigating a reported outbreak discovered that not 1 but 18 out of 24 subdistricts were infected. Because no additional resources could be spared, the team continued to work alone. During 42 weeks, active search and containment detected 2101 cases in 101 villages, but transmission was completely interrupted; only 15 175 containment vaccinations were performed. Time was required to interrupt transmission in this densely populated area, but it was achieved at a cost of only 1802 man-days.

Plate 13.6. Vaccinators in Indonesia moved from house to house, concentrating their efforts on young children and infants who had not been vaccinated previously. For this work, the bifurcated needle was especially valuable.

Factors Affecting Transmission

In October 1970, after transmission had been interrupted in the 3 regencies, surveys were conducted to determine comparative levels of vaccinial immunity (Table 13.14).

Smallpox transmission had been rapidly interrupted in Tjirebon once surveillance–containment measures had been effectively applied, but vaccinial immunity was already

[a]Based on Koswara (in WHO/SE/71.30).

high there. Success had also been achieved in Bandung with improved supervision but at a considerable cost in resources. Bogor presented a contrast. There, transmission had also been successfully interrupted with surveillance–containment only, although 2–3 times as many unprotected children remained. The proportion that was unprotected was almost as high in the infected areas—in which containment vaccination had been extensive—as it was in the less endemic areas.

Everyone involved in the programme was surprised by the tenacity of smallpox in these and other regencies of Java despite comparatively high levels of vaccinial immunity and intensive surveillance–containment measures. It was a contrast to the situation in Brazil and western Africa, in which surveillance and containment had quickly stopped transmission, even in less well vaccinated populations (see Chapters 12 and 17). Indonesia, demographically and socially, was different in several respects (*Wkly epidem. rec.*, 1970a). Population density in Java was one of the highest in the world and, traditionally, families carried children who were sick from house to house to visit relatives. The tradition of isolating cases, so often observed in other countries, was uncommon. Thus, many more susceptible persons, on average, were exposed to smallpox cases than in most other areas. Because of high levels of vaccinial immunity and the greater frequency of exposure of susceptible persons, the age distribution of cases was different in Java from the corresponding distributions in Brazil and Pakistan, for example (Table 13.15).

Table 13.15. Comparative percentage distribution of smallpox cases, by age group, 1969[a]

5–14	37	33	37	39
⩾15	5	11	28	31

[a]Based on Hartohusodo (in WHO/SE/71.30).

In Java, more than half of all cases were found in children under 5 years of age; few cases occurred in adults. In Africa, South America and Asia, cases were more evenly distributed among all age groups.

Another factor of importance in smallpox transmission in Indonesia was climatic: smallpox was readily transmitted throughout the year (Fig. 13.7). Indonesia, located between 5°N and 5°S of the equator, did not have the wide seasonal fluctuations in transmission which were characteristic of countries such as Brazil, India and Pakistan (*Wkly epidem. rec.*, 1969a) (see Chapter 4). In these countries, in which transmission rates declined sharply during the summer and early autumn months, many chains of transmission terminated spontaneously and the containment of outbreaks during these periods was comparatively simple. In Indonesia no such circumstances obtained.

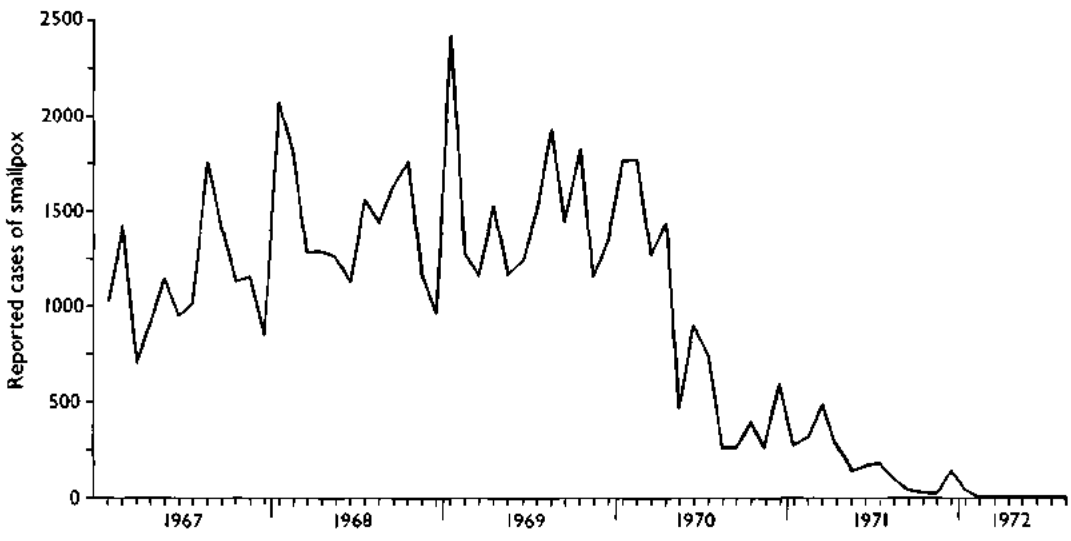

Fig. 13.7. Indonesia: number of reported cases of smallpox, by month, 1967–1972.

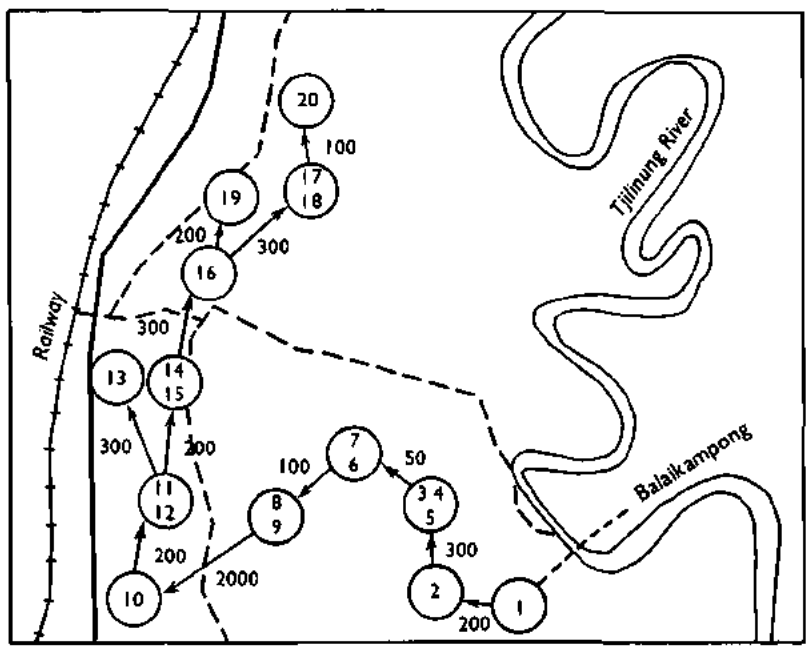
Smallpox Transmission in a Well-Vaccinated Area

An outbreak in Passar Minggu (population, 14 376), a densely populated section of Jakarta City, vividly illustrated the ability of smallpox to continue to be transmitted even in well-vaccinated areas. In August 1970, the investigation of a death due to smallpox led to the discovery of a chain of infection involving 20 cases extending over a period of 21 weeks (see the figure below). A scar survey in the area revealed that only 2% of children between 5 and 14 years of age were unvaccinated (see table). Overall, the proportion of susceptible persons in the area was only about 6%, almost none of whom were adults.

Passar Minggu: Vaccination Status of Children and Cases of Smallpox
(Emmet in WHO/SE/71.30)

Age group (years)	*Percentage unvaccinated*	*Number of cases*
<1	61%	2
1–4	20%	11
5–14	2%	5
⩾15	–	2

The cases spread from one house to the next, usually over a distance of no more than 300 metres (see illustration). Nine of the cases resulted from intrafamilial transmission; the remainder occurred through the visits of susceptible children to infected households.



1 Denotes the presence of a case in a household and the case number assigned to it.

200 → Indicates the distance, in metres, between households.

Similar occurrences of slowly spreading endemic smallpox in well-vaccinated populations were observed throughout the rural areas of West Java and, to some extent, of Central Java. In the other endemic areas of Indonesia, none of those which experienced smallpox after 1968 was so densely populated and smallpox there was far more easily contained.

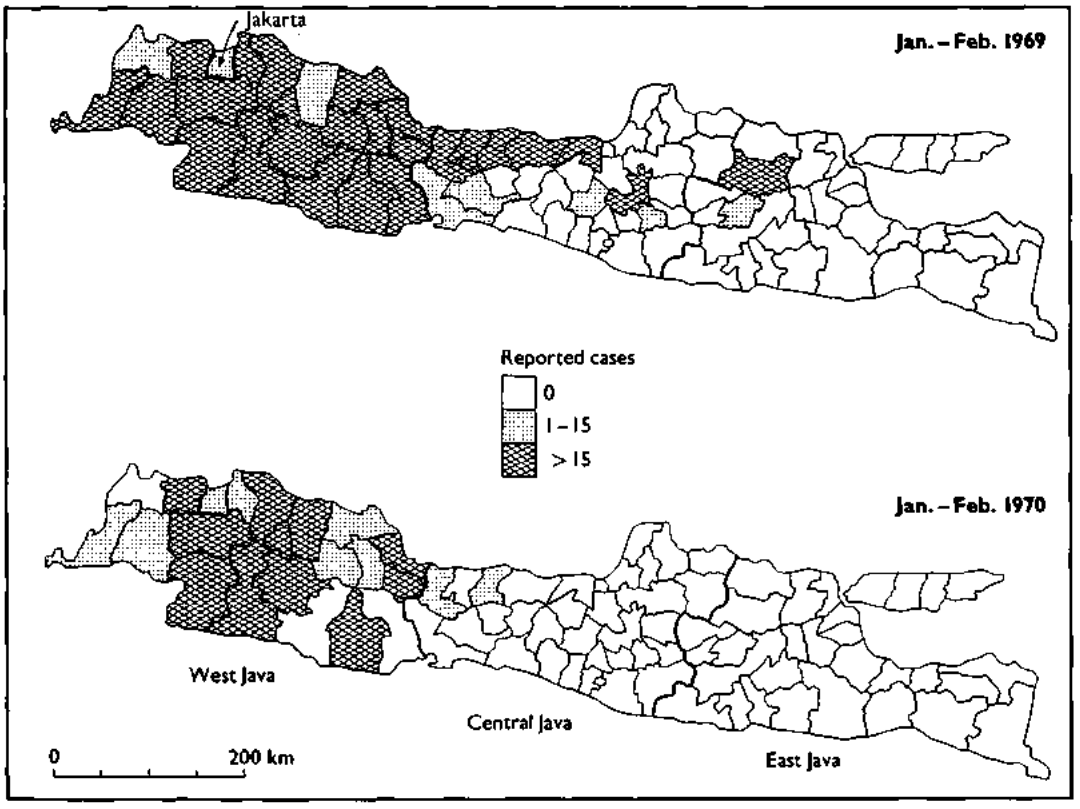


Fig. 13.8. Java: number of reported cases of smallpox, by regency, January – February 1969 and January – February 1970.

THE SURVEILLANCE–CONTAINMENT STRATEGY BECOMES FULLY ESTABLISHED

Despite the problems of the backlog vaccination campaign and the diversion of resources from surveillance–containment activities, progress was made in the "east-to-west" strategy in Java (Fig. 13.8). By February 1970, endemic smallpox remained solely in West Java. In Central Java, during 1970, only 28 cases were detected, all of which represented outbreaks due to importations. Meanwhile, programme activities were extended to the outer islands.

Reporting, which had been so incomplete and greatly delayed, improved markedly in 1970 following the assignment of a full-time medical officer, Dr A. Karyadi, to assume responsibility for surveillance and data collection. Simplified standardized reporting forms were adopted for the weekly reports and a goal was set for the receipt of reports with a delay of no more than 2 weeks from provinces in Java and of no more than 3 weeks from the outer islands (Karyadi in WHO/SE/71.30). Defaulting provinces were repeatedly contacted by letter, telegram, messenger and personal visits to promote compliance. Cooperation was sought from civil authorities as well. In the absence of an adequate postal service, many methods were utilized for the transmission of provincial reports, including couriers such as bus drivers, businessmen, special messengers and military personnel. Provincial authorities, with assistance from the smallpox eradication staff, sought to obtain promptly the weekly reports from regency medical officers and health units. To simplify reporting, the data requested were limited to the names of infected villages and subdistricts, the numbers of cases and deaths, the ages of cases, and the source of infection of each outbreak. Beginning in May 1970, a national weekly surveillance report was prepared which documented smallpox incidence and progress in the campaign. This was distributed to health authorities throughout Indonesia. In September 1970, Dr Karyadi was able to report that 95% of weekly reports were being received from provinces in Sumatra and Sulawesi within 3 weeks. Just one year pre-

[a] No cases were reported in Maluku, Kalimantan, Bali, Nusa Tenggara, West Irian or Jogjakarta during this period.

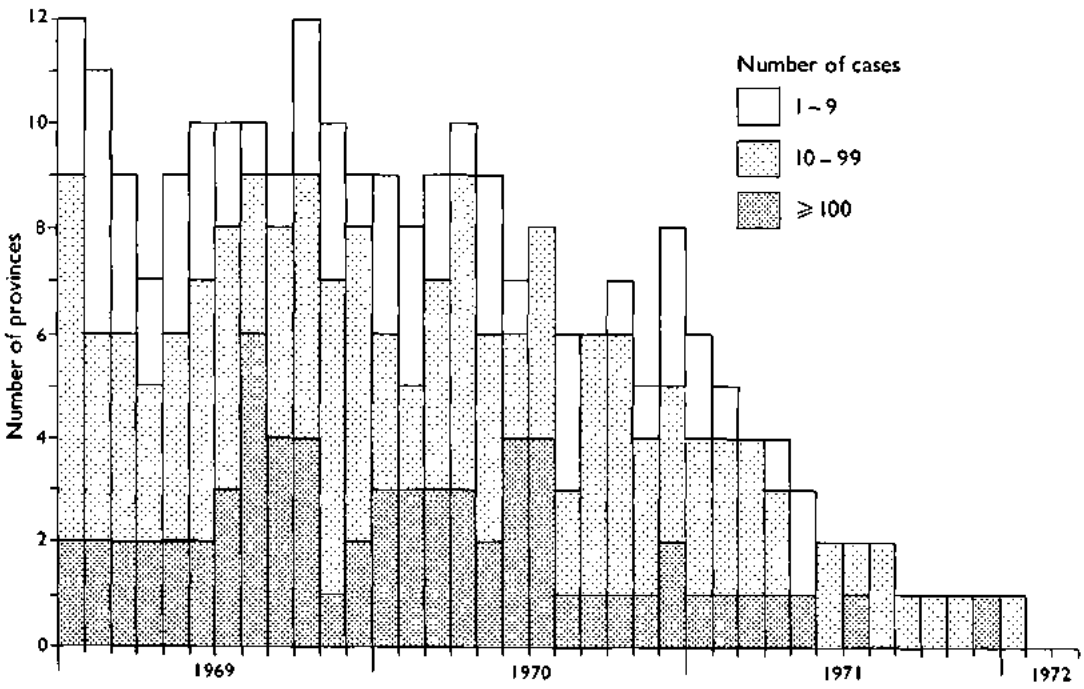

Fig. 13.9. Indonesia: number of provinces reporting cases of smallpox, by month, 1969 – 1972.

viously, only about half as many reports were being received, and then with delays of up to 21 weeks. An increasing number of cases began to be reported from Sumatra, reflecting better notification (Table 13.16). Despite improved reporting, the number of provinces reporting cases began to fall drastically as from the beginning of December 1970 (Fig. 13.9).

In West Java, 8 mobile surveillance–containment teams worked with regency teams in carrying out active search operations and outbreak containment. As the year progressed, area vaccinators devoted less time to routine vaccination and more to systematic searches to detect cases and to contain outbreaks, as was done in Tjirebon. Initially,

The Development and Use of the WHO Smallpox Recognition Card

Events which led to the development of the WHO smallpox recognition card and the use of schools in the search for cases in Indonesia occurred in Bandung. Among the many vaccinators engaged in search activities, there was one who recorded exceptional success in detecting outbreaks. Supervisors noted that, paradoxically, this vaccinator was considered to be one of the laziest workers—the last to leave for the field and the first to return home. When asked how he was so successful, he admitted that instead of visiting all the houses in a village, as instructed, he was visiting only the schools. There he showed children and teachers pictures of smallpox cases which appeared in a WHO teaching folder on smallpox diagnosis that had been prepared for Africa. Numerous case notifications were obtained with the minimum effort.

The teaching folder contained many different pictures of smallpox in African children. The photographs were small and the smallpox rash on a black skin appeared to differ somewhat from the rash on the skin of Indonesians, which was much lighter in colour. Nevertheless, most children had recognized the disease. Programme staff suggested the preparation of a single large picture of an Asian child with smallpox for use as a recognition card. Thus, the WHO smallpox recognition card was first prepared, encased in plastic for durability, and widely distributed around the world.

vaccinators were requested to search house by house, but because of the small numbers of vaccinators available, they were subsequently asked to contact specific persons and the staff of various facilities who would be the most knowledgeable regarding the existence of smallpox cases: (1) health units such as clinics, hospitals and aid posts; (2) civil officials, notably village chiefs, who in Indonesia had considerable authority in their designated areas; and (3) schoolchildren and teachers. Maps were prepared for each area, showing the principal sites and persons to be visited. A tour schedule was established to ensure that each was visited at least once a month. It was during these operations in West Java that the concept arose of printing smallpox recognition cards, depicting in colour a case of smallpox, which could be shown to those being contacted. This idea, which was proposed by Indonesian field staff to WHO regional office and Headquarters staff, was adopted and eventually tens of thousands of such cards were printed and distributed widely in Indonesia and other endemic countries throughout the world (see Chapter 10).

Containment activities were ever more rigorously defined and performed. In each outbreak, the "fire-fighting" or advance teams ensured that patients were isolated in their houses; the names of all villagers were recorded and everybody was vaccinated; the source of infection was identified and investigated; and the teams remained in the village at least overnight to ensure more complete vaccination of those working in the fields or absent during the day at the market or in school.

STRENGTHENING OF PROGRAMMES IN THE OUTER ISLANDS, 1970

Until 1970, resources and energies were principally directed to the containment of smallpox in the heavily populated island of Java. With the number of cases declining rapidly in Java during 1970 (from 1160 in January to 210 in June and to 49 in December) additional resources could be diverted to the two outer islands still harbouring smallpox—Sumatra and Sulawesi.

Sumatra had the higher priority because of the extensive inter-island boat traffic with Java. The programme in Sumatra had begun in July 1969 with an intensified vaccination campaign conducted by 567 vaccinators and 73 supervisors. As in Java, this had little effect on smallpox incidence. During 1970, more resources were made available to the programme (*Wkly epidem. rec.*, 1970d), notably transport and assistance from national campaign staff, and the strategy shifted from intensive vaccination to surveillance–containment. Smallpox spread less rapidly in the

more sparsely populated Sumatra and successful containment was easier, but this advantage was counterbalanced by a less-developed health structure and poorer supervision. In Sumatra, priority was given to the southern provinces, those nearest Java, to minimize the risk of importations. In October 1970, South Sumatra recorded its last cases, but the northern provinces (North Sumatra, Jambi and Riau) did not become smallpox-free until August 1971.

Sulawesi also began its programme in July 1969, with 355 area vaccinators and 38 supervisors. Endemic smallpox, however, was found only in South Sulawesi (population, 5 million). Progress was slow: the rugged mountainous terrain made travel difficult; communication with villagers was a problem because 15 different dialects were spoken there; and the civil and health infrastructure, after prolonged and devastating civil disturbances, was less developed than in Sumatra or Java. The interruption of transmission in Sulawesi was to require the best skills of experienced national and WHO staff and the most effective application of now well-defined techniques for case search and outbreak containment.

Only 59 vaccination staff worked in South Sulawesi—less than half the number planned. Throughout 1970 comparatively little progress was made. However, early in 1971, with smallpox transmission all but interrupted in Java and with incidence rapidly diminishing throughout Sumatra, senior national staff and WHO advisers transferred to Sulawesi, and additional automobiles, motor cycles and bicycles were assigned to the programme. The WHO smallpox recognition card began to be used in contacts with schools and civil authorities. In March 1971, a planned programme of meetings with village chiefs and other civil administrators was instituted in order to acquaint them fully with the programme and to solicit their help in the prompt reporting of suspected cases. Many conscientiously fulfilled this responsibility through special search programmes which they independently organized. Isolation of patients in their houses, containment vaccination, both by day and by night, search for the sources of outbreaks and identification of

[a] No cases were reported in Kalimantan, Bali, Nusa Tenggara, West Irian or Jogjakarta during this period.

exposed individuals who had left infected villages were more rigorously executed. With improved surveillance and containment measures and heroic efforts by national and WHO staff, smallpox transmission came to an end in South Sulawesi in November 1971 (Table 13.17).

Immediately after the apparent detection of the last case, the 1208 vaccinators in Sulawesi, Sumatra and Kalimantan searched village by village during a 4-month period, reaching 18 205 (73.5%) of the 24 781 villages in the process. Although 920 suspected cases were examined and 76 specimens were taken, none revealed the presence of smallpox (WHO/SE/74.63, Cuboni et al.).

In the island of Kalimantan (population, 5 million) and in the other provinces of Sulawesi, provincial and local health staff, without significant additional support from national or WHO staff, had unexpectedly succeeded in interrupting transmission as early as November 1969. How this was achieved is not fully documented. Kalimantan had experienced a major epidemic of smallpox, with large numbers of reported cases, during 1965–1967. The epidemic may have begun before 1965, although no earlier data are available. Because reporting was so incomplete, it is probable that the actual number of cases may have been 100 times or so greater than the number recorded.

Programme staff at the time speculated that natural immunity induced by the epidemic, combined with extensive vaccination, had so reduced the number of susceptible persons that transmission was interrupted even though the surveillance–containment programme was much less effective than in other areas. However, a high level of immunity was not the primary explanation for the interruption of transmission in Kalimantan and in Central, South-east and North Sulawesi, as was shown in a February 1974 survey. At that time, Indonesian staff conducted random cluster sample surveys among children throughout these provinces (Table 13.18) (WHO/SE/74.66, Cuboni et al.). In most provinces, more than one-third of all children remained susceptible. Immunity levels were substantially below those in most of Java, in which health services were far more extensive.

Important to the interruption of transmission was the fact that the populations of Kalimantan and Sulawesi were concentrated in discrete areas, primarily along the coast. Communication between these population centres was much more difficult than in Java or Sumatra. In effect, they were more like a series of comparatively small island populations than a land mass over which travel was easily accomplished. Many outbreaks undoubtedly terminated spontaneously and others responded to comparatively perfunctory containment and vaccination activities, as was the case in much of Africa, for example. After transmission had been interrupted in an area, smallpox was reintroduced only infrequently.

INDONESIA'S LAST OUTBREAK, 1971

After the last cases occurred in Sulawesi in November 1971, 4 weeks elapsed during which no smallpox cases were reported in Indonesia. It appeared that transmission had been interrupted, but on 14 December 1971, the Director of the Smallpox Eradication Programme received a report from Tangerang Regency (one of the 24 regencies/municipalities in West Java) of 45 cases and 6 deaths in Sepatan Subdistrict, only 28 kilometres from Jakarta. Tangerang (population, 1 million) had recorded its last cases in February 1971, fully 10 months earlier. A village-by-village search had been conducted in West Java between June and August 1971 in the subdistricts which had reported cases during 1970–1971; lack of personnel had precluded a search in all subdistricts. Sepatan Subdistrict had not reported cases during this period and thus had not been searched.

On investigation, it was found that as early as December 1970, a whole year earlier, many cases in Sepatan had begun to be reported to the health centre by the subdistrict's vaccinator. The medical officer of the health centre periodically organized ineffectual mass vaccination campaigns to control the outbreaks but deliberately suppressed the reports of smallpox, fearing that he might be punished for incompetence. In mid-December 1971, a provincial mobile surveillance and supervisory team visited the area on routine tour and was informed of the outbreaks by the local staff (Cuboni et al. in WHO/SE/76.85).

Search and containment activities were immediately instituted. In the realization that the suppression of reports might be widely prevalent, the decision was made to offer a transistor radio to any person who reported an active case of smallpox. This, so far as is known, was the first occasion in the Intensified Programme when a reward was offered for case reporting. It proved to be highly effective. Numerous suspected cases with illnesses of all types were reported by people throughout the area. Eventually, 160 smallpox cases with 15 deaths were confirmed in 3 villages (total population, 7982) of Sepatan Subdistrict; nearly one-third were unprotected when containment vaccination had begun (Table 13.19).

The outbreak had started in Sarakan village in December 1970 (Fig. 13.10), 1 year previously, as a result of an importation from West Jakarta. Smallpox spread slowly, only 14 cases occurring between December 1970 and May 1971. Eventually, the outbreak was contained by a local vaccinator. Meanwhile the disease had spread to Sangiang village in May 1971 and, in September, numerous cases began

Table 13.19. Sangiang, Sarakan and Gaga villages, Sepatan Subdistrict: number of vaccinations performed during containment operations, 1972

Village	Population	Number of vaccinations			Percentage unprotected[a]	Number of cases
		Primary vaccination	Revaccination	Total		
Sangiang	3 106	1 142	2 013	3 155	36	131
Sarakan	1 904	307	1 371	1 678	18	17
Gaga	2 972	917	1 627	2 544	36	12

[a] I.e., those receiving primary vaccination as a percentage of the total vaccinated during the containment phase.

to occur. In all, 131 persons eventually developed smallpox in this village of 3106 persons. At the end of November the disease was reintroduced into Sarakan village and, in December, it spread to nearby Gaga village. Finally, late in December, an outbreak of cases developed in a village 80 kilometres distant. The last 2 known cases in Indonesia occurred on 23 January 1972, one of them in Gaga village, and the other in Kupahandap village.

Concerned that other hidden foci might be present elsewhere in Indonesia, the programme staff decided in May 1972 to offer a reward of 5000 rupiah (US$12) to anyone reporting a case. This was widely publicized. The following month, teams from throughout Indonesia began an active search programme. Numerous rumours were investigated and many specimens were examined, but no further cases were found. A summary of the numbers of specimens examined in laboratories during 1969–1973 (Table 13.20) indicates the extent of this activity.

MORBIDITY AND MORTALITY PATTERNS

Smallpox in Indonesia exhibited two unusual features: (1) an exceptionally large proportion of cases among younger children; and (2) case-fatality rates which were often lower than those observed elsewhere in Asia.

In June 1969 the Joint WHO–Indonesia Assessment Team analysed the age distribution of 3823 cases in selected areas and during periods when reporting was considered to be reasonably complete (Table 13.21). The age distributions were similar in West and Central Java and Jakarta, in which smallpox was then endemic. Cases in East Java occurred primarily in outbreaks following importations and the patients were generally older, as was the case in other non-endemic areas. Excluding the data for East Java, 68% of cases occurred in children aged 0–4 years, a group which comprised only 18% of the population of the country. A surprisingly high incidence—about 12%—was found in infants under 1 year of age, twice the proportion recorded in India.

Smallpox spread in Indonesia more readily than in most parts of the world and transmission occurred throughout the year with no apparent seasonal pattern. The facility of spread can be attributed to the high population density and the custom in Indonesia of carrying sick children to visit relatives, thus exposing many more susceptible individuals.

The reported case-fatality rates in many years and during most outbreaks appeared to be lower than those in the Indian subcontinent. This is the converse of what might have been expected, because cases in Indonesia were proportionately more numerous in the very young, among whom case-fatality rates are customarily higher. The question whether case-fatality rates in Indonesia were substantially and uniformly lower than those in the Indian subcontinent was never resolved. The reporting of both cases and deaths was grossly incomplete throughout Indonesia before 1968. The degree of underreporting of cases compared to that of deaths undoubtedly differed from year to year. This probably accounted for such discrepancies as a case-fatality rate of 10% in 1950 and one of 44% only a year later. With the commencement of the national programme, the reporting of cases gradually improved, more rapid pro-

Table 13.20. Indonesia: laboratory examination of specimens, 1969–1973

Year	Number of regencies submitting specimens	Number of specimens	Number positive for variola virus	Number positive for vaccinia virus
1969	19	235	74	0
1970	37	250	55	0
1971	38	150	15	0
1972	113	1 009	12	1
1973	109	599	0	6

gress being achieved in some areas than in others. However, as in other countries, few efforts were made to improve the completeness of the notification of deaths. Since the programme's goal was to interrupt the transmission of smallpox, it was more important to know where and how many cases were occurring than to be aware of how many deaths had taken place.

In containing outbreaks, especially in 1970–1971, the smallpox eradication staff carefully enumerated cases, and because teams remained in the infected areas, the numbers of deaths (which usually occurred 1–2 weeks after the onset of illness) were also known fairly accurately. In those outbreaks, case-fatality rates of 5–10% were often observed, about half as high as the rates in the Indian subcontinent. Data from Jakarta, however (Fig. 13.11), consistently showed much higher case-fatality rates. Jakarta had had a reasonably complete system for the notification of deaths since 1965 and for the reporting of cases since 1968. The case-fatality rates were twice as high as those of West Java, a province which surrounds it and across whose borders residents moved freely. In other respects, the populations were essentially similar with regard to nutrition and general health. If it is assumed that the virus strain in Jakarta was the same as that in West Java, the obvious explanation for the lower rates in West Java would be incomplete notification of deaths. And yet the case-fatality rates in West Java were similar to those observed later in some well-studied outbreaks elsewhere in Indonesia. The observations were never reconciled.

CONCLUSIONS

Smallpox transmission in Indonesia was interrupted just 3 years and 7 months after the programme began in July 1968. This was a remarkable achievement considering the country's size, population and the limited international resources provided. The experience in Indonesia had a profound effect on other programmes during the succeeding years. Among the innovations were the WHO smallpox recognition card, the offer of a reward for reporting a case, a procedure for the systematic search for cases throughout a wide area, and the demonstration of the efficacy of a search based on contact with teachers and schoolchildren. More important, the success of the surveillance–containment strategy was forcefully communicated by Indonesian programme staff to their counterparts in the Indian subcontinent through papers and seminars. Of particular significance was a specially convened WHO interregional seminar in New Delhi in December 1970. One of the papers, contributed by Dr Koswara, the Indonesian programme's director (Koswara in WHO/SE/71.30), was

entitled: "Is Routine Vaccination a Necessity in a Smallpox Eradication Programme?" The author concluded that proper surveillance–containment action had brought smallpox under control in a short period, while routine vaccination and mass vaccination campaigns had had little effect in interrupting transmission. Many participants at the conference severely criticized this view, which they considered tantamount to heresy. At that time, Indonesia had not yet stopped transmission in Java, let alone in Sumatra or Sulawesi. Because of this, few of the participants were persuaded by Dr Koswara's arguments. However, with the occurrence of Indonesia's last case in January 1972, it was apparent that the 11-year-old programmes in India and Pakistan had much to learn from the Indonesian experience. A strong stimulus for change was provided.

Plate 13.8. Misah Bin Inang (**A**), one of the last two smallpox patients in Indonesia, became ill on 23 January 1972. Facial pockmarks are apparent in this picture taken in 1979, but many persons (**B**) were more severely afflicted.

INTRODUCTION

In 1967, endemic smallpox in continental southern Asia extended over a contiguous block of countries from Afghanistan through West Pakistan, India, Nepal, Bhutan, and East Pakistan. Epidemiologically, this area could be subdivided into two parts: a western part consisting of Afghanistan and West Pakistan and an eastern part that included India, Bhutan, Nepal and East Pakistan. Separating these two parts was the heavily guarded border between India and West Pakistan. Few persons travelled across this border and, so far as is known, no cases of smallpox were imported across it after 1966. The health programme of West Pakistan functioned quite independently of that of East Pakistan, and in December 1971, when the latter province became the independent state of Bangladesh the two programmes were, of course, entirely separate. The programme in East Pakistan/Bangladesh is described in Chapter 16 and the programmes in India, Bhutan and Nepal in Chapter 15.

West Pakistan and Afghanistan were epidemiologically closely linked because numerous travellers moved freely across their long common border (Fig. 14.1), including several hundred thousand nomads who lived in Pakistan in the winter and in Afghanistan in the summer. Smallpox spread easily across this border.

Pakistan and Afghanistan are both Muslim countries but differ greatly in most other respects—politically and geographically, in historical and socio-economic development and in the manner in which their smallpox

Fig. 14.1. Afghanistan and Pakistan and adjacent countries.

eradication programmes evolved. A WHO-assisted vaccination campaign had begun in 1963 in Afghanistan. By 1967, encouraging reports from programme staff made it seem reasonable to expect that systematic vaccination in the towns and cities and a national outbreak-containment programme would rapidly interrupt transmission. This optimistic view faded a year later, when it was discovered that itinerant hereditary variolators were active throughout much of the country, particularly in the extensive remote mountainous areas, spreading smallpox as they travelled. Because Afghanistan was a country with few roads, a primitive health infrastructure and orthodox religious practices which impeded vaccination, it was feared that transmission might be sustained in isolated, virtually inaccessible areas despite the best efforts at control. As late as 1971, WHO senior staff believed that Afghanistan might be the endemic country most likely to thwart the ultimate goal of global eradication. An extraordinary programme and a heroic effort by Afghan and WHO staff were to produce yet another surprise when, in September 1972, Afghanistan succeeded in interrupting smallpox transmission.

Pakistan, in contrast to Afghanistan, had a comparatively well developed health infrastructure, extending throughout most of the country, and a population which generally could be easily reached by the relatively extensive network of roads. A programme of routine smallpox vaccination had been established since the late 19th century; variolation was rarely practised. The epidemiological behaviour of smallpox in Pakistan had been characterized during 1966–1967 in a unique series of studies whose findings were to prove significant in shaping the strategy of eradication programmes in other countries. An important observation was that urban centres played a crucial role in sustaining smallpox transmission, especially during the summer and autumn, when the incidence was low. The investigators discovered, however, that even during the months of highest incidence and in what was considered to be a heavily infected district, the number of outbreaks was sufficiently small to require only a few teams to detect and contain them. Because they found the levels of vaccinial immunity to be already high in Pakistan, the investigators recommended that priority should be given to detecting and containing outbreaks, especially in urban areas and during the season of lowest incidence. Paradoxically, however, Pakistan was among the last countries to adopt a strategy based on these recommendations. Until 1973, national and WHO programme staff persisted in executing a mass vaccination campaign which was indifferently supported and not satisfactorily conducted. Despite the many factors favouring smallpox eradication, transmission was not interrupted in Pakistan until October 1974.

Meanwhile, there was little communication and virtually no coordination of activities between the programmes in the two countries. Numerous cases of smallpox were imported into Afghanistan from Pakistan and special surveillance programmes had to be developed to combat the threat they represented, which became all the more serious when Afghanistan succeeded in interrupting transmission more than 2 years earlier than Pakistan. The two programmes differed greatly and are discussed separately in this chapter.

AFGHANISTAN

Few of the endemic countries posed as many difficult and unusual challenges as did Afghanistan. In 1967, this isolated, landlocked country was in an early stage of economic and institutional development. The government structure was rudimentary, and in some remote areas the central authority was

not recognized. The population—90% of which was illiterate—is estimated to have been 11.9 million in 1968 (United Nations, 1985), although no census had ever been taken.

The Hindu Kush mountain range, with peaks as high as 7500 metres, extends from the extreme north-east border with China towards the south-west, much of central Afghanistan having an altitude of more than 2000 metres (Fig. 14.2). Because of snow, this area was largely inaccessible for almost half the year. The south-western part of the country is mainly desert, where the extreme heat precluded most programme activities during summer. Except for a single paved all-weather road that circled the country, with occasional branches to provincial capitals, the roads were extremely poor, challenging even heavy-duty vehicles. There were no navigable rivers, no railway, and only limited air connections. Programme operations and efforts to communicate with the population were hampered by illiteracy and by the use of 3 different major languages—Dari, Pushtu and Uzbeki.

Most of the population lived in the 20 000 villages in rural areas and less than 15% in the main cities of Kabul, Kandahar, Herat and Mazar-i-Sharif. Religious practices were strict among the predominantly orthodox Sunni Muslim rural dwellers, and religious leaders were highly influential. Of importance to smallpox eradication was the observance of purdah, whereby women were secluded within their homes and the male heads of household refused to permit them to leave the house for vaccination or to be vaccinated by male vaccinators.

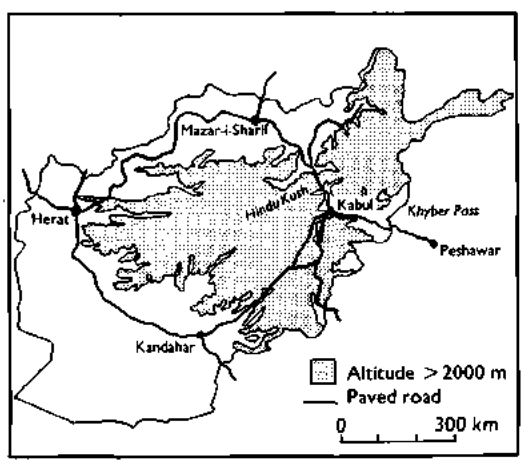

Fig. 14.2. Afghanistan: topography and principal roads.

The health structure was rudimentary. In 1965, there were reported to be 19 primary health centres and 60 hospital-clinics staffed by physicians who were responsible for both curative and preventive services, although few offered even the most elementary preventive measures (World Health Organization, 1965b).

Smallpox Control before 1963

For centuries, variolation had been practised throughout Afghanistan by traditional variolators, the technique usually being communicated from father to son. Many variolators travelled considerable distances in the course of their work. A fee of 10–15 afghanis (US$0.15–0.20) was the usual charge. Scabs (rarely pustular material) from a patient were collected and ground with a mortar and pestle, and the powder suspended in a liquid. The suspension was inoculated by scratch or by pinprick on the forearm or near the wrist. Variolators usually obtained fresh material each year, and therefore variolation tended to be performed during the autumn and winter months, after the number of cases had begun to increase.

Vaccination was all but unknown in Afghanistan until 1936, when a campaign was organized that succeeded in vaccinating 3 million persons over a 3-year period; liquid vaccine produced at a laboratory in Kabul was used (Berke, 1956). This laboratory continued to produce small amounts of vaccine which, during subsequent years, was primarily used in and around Kabul. Because the vaccine was of questionable potency, as well as being thermolabile, vaccinial immunity in 1967 was probably not high, even in Kabul.

In 1949, Afghanistan began to keep records of the number of cases of smallpox. Between 1949 and 1968, the annual total ranged from a low of 66 cases in 1966 to a high of 2179 cases in 1952. However, the figures had little meaning since the only cases reported were those which were diagnosed in the country's few health centres. A simple calculation provides an approximation of the probable extent of underreporting. In a population of 10 million, each year about 300 000 would survive the perinatal period to constitute a new group of susceptible subjects. Because

Plate 14.1. For hundreds of years, variolation had been widely practised throughout Afghanistan by hereditary variolators using kits such as these. Scabs were collected from a recovering patient and kept in a container such as a metal box (**A**) or horn (**B**). Before inoculation, the dried scabs were ground up, usually in a primitive mortar and pestle (**B**). A liquid such as honey or water with spices was added and a drop of the suspension was applied to the skin. This was then inoculated into the superficial layers of the skin, using a needle or lancet. Sometimes a special strip of cloth (**B**) was used, and reused repeatedly, to bind the site of the incision until a pustule formed.

few individuals were successfully vaccinated, almost all would eventually become infected with smallpox. Thus, on average, 300 000 persons would experience smallpox each year, either by natural infection or as a result of variolation—i.e., more than 350 times the average of 840 cases reported annually between 1949 and 1963.

Commencement of a WHO-assisted Vaccination Campaign, 1963

Following the Twelfth World Health Assembly's resolution in 1959 to embark on the global eradication of smallpox, Afghanistan sought and obtained assistance from WHO to begin a special campaign. It was one of only a few countries to receive technical and material support from WHO for field activities in smallpox eradication during the period 1959–1966. A WHO adviser was assigned to Kabul in 1962; in March 1963, a vaccination campaign began in the capital. During the following year, the campaign was extended to 9 provinces (World Health Organization, 1965b). Freeze-dried vaccine provided by the USSR and locally produced liquid vaccine were used. By the end of June 1964, 392 026 of the 400 000 residents of Kabul were reported to have been vaccinated by a staff of 139 male vaccinators and 7 female vaccinators and auxiliary midwives. Twenty-five of the vaccinators were then kept in Kabul "to carry on the maintenance phase and to fight epidemics", as the WHO adviser reported. The remainder were assigned to the provinces to work under the direction of provincial medical officers. Although large numbers of people were subsequently reported to have been vaccinated, the reports were thought to be greatly exaggerated.

In 1965, 3 additional groups, each composed of 70 vaccinators, were trained and dispatched to Kandahar, Ghazni, Wardak and Bamian Provinces (see Fig. 14.3). Young physicians, conscripted for government service, were assigned to supervise each group but few were willing to leave Kabul. What was achieved is unknown because no records were kept.

During the following 3 years, additional resources were provided by WHO, but little progress was made. At the end of 1968, the uncoordinated and poorly supervised series of activities could scarcely be characterized as a programme. The physician in charge of smallpox eradication was also responsible for all the country's communicable disease control activities and could therefore devote little time to the smallpox eradication programme. Young medical graduates, carrying out their compulsory service, continued to be assigned to provide direction but few spent more than a month or two in the field before arranging to be transferred. In the staff hierarchy there were only a few sanitarians between the programme director and the vaccinators, and the turnover among them was almost equal to that of the physicians. The problems were further compounded by inadequate government funds and a complicated financial system which typically resulted in delays of 3 months or more in the payment of salaries and, frequently, a lack of funds to purchase petrol. Within the government structure, the execution of even simple tasks was time-consuming. For any purchase, for instance, 3 responsible individuals were required to visit the bazaar to bargain, to obtain a receipt for the purchase, and then to report to an administrative section where the transaction could be recorded.

The support provided by WHO contributed little. The WHO smallpox adviser devoted most of his time to the preparation of letters advising his Afghan counterpart as to what should be done and to the compilation of monthly reports. He rarely travelled out of Kabul. Two WHO nurses, assigned to the programme in 1967, likewise travelled little and, although sharing an office with the adviser, received most communications from him in the form of typed memoranda. Eighteen vehicles had been provided to the programme of which 9 were not sufficiently roadworthy to leave Kabul and 7 had been coopted for the use of various officials in the Ministry of Health.

In April 1968, a medical officer responsible for smallpox eradication in the WHO Regional Office for South-East Asia reported in despair that no one knew where the provincial vaccinators were stationed or what they were doing. No records were kept, in part because most of the vaccinators were illiterate. The group of vaccinators in Kabul was periodically dispatched to the field when a report of an outbreak was received. They travelled in a large flatbed truck to the site with orders to vaccinate everyone in the area. After some days or weeks had elapsed, they gradually filtered back to Kabul. No report was prepared on what had been accomplished.

Meanwhile, the USA had been approached by the Afghan government and asked to send female volunteers to assist in vaccinating women throughout Afghanistan. Women, it was said, could not be vaccinated by male vaccinators nor could they leave their dwellings in most areas. The volunteers would be expected to work with Afghan women counterparts as members of teams vaccinating from house to house. The concept was attractive but unrealistic. A small contingent of United States volunteers could themselves vaccinate no more than a fraction of the population, and given the religious strictures of the country, the recruitment of Afghan women was all but impossible.

The unsatisfactory vaccine then being used presented no less of a problem. Although liquid vaccine production had ceased in Kabul, the freeze-dried vaccine provided through bilateral assistance did not meet accepted standards, as was attested by protocols provided by the production laboratory itself. Moreover, all vaccine was then being stored at room temperature, which caused it to deteriorate even further.

Finally, the scope of the smallpox problem itself was not comprehended. Early in 1967, the WHO adviser, noting that only 72 cases had been reported in 1965 and 66 cases in 1966, confidently estimated that in the entire country there probably were not more than 300 cases each year, most of them in children. If indeed there were so few cases, it could be inferred that there were comparatively few chains of transmission. Geneva staff, who were ignorant at that time of the moribund state of the programme, hopefully proposed an alternative strategy to country-wide vaccination: (1) intensive containment of known outbreaks by special teams; and (2) a programme of primary vaccination of children in the cities and towns. This, it was felt, might serve to concentrate resources in priority areas and alleviate the problem of supervising vaccinators so widely dispersed over the countryside. No action was taken, however.

When Henderson and Dr Jacobus Keja, of the WHO intercountry team advising on smallpox eradication, visited Afghanistan in October 1968, the full array of problems became apparent. Not only did they discover that the programme existed in name only, but they found that conditions in Afghanistan differed substantially from the situation described in reports and were far more serious than had hitherto been thought. Even with the woefully inadequate notification system, 334 cases were recorded in 1967 and 739 in 1968. Smallpox was far more widespread than had been supposed. Variolation was found to be common and some, perhaps many, of the outbreaks resulted from this practice. The fact that variolators were most active in the least accessible parts of the country was of particular concern. They retained infected scabs for 1–2 years and travelled considerable distances to perform inoculations. Moreover, because the government had begun to discourage the practice, villagers usually refused to identify the variolators, fearing that they would be punished. On the basis of these observations, it was suspected that smallpox transmission, perpetuated by variolation, might persist indefinitely among a remote, comparatively small population of susceptible persons. The optimistic outlook in 1967 that Afghanistan might soon interrupt transmission gave way towards the end of 1968 to fear that the country might prove to be the world's last and possibly permanent reservoir of smallpox.

The previously suggested strategy of vaccinating the more accessible members of the population, coupled with the search for cases and the containment of outbreaks, could not solve the problem caused by variolation. Special efforts would be needed to educate villagers about the hazards of variolation and to identify variolators and persuade them to stop their practice. It was recognized, however, that such efforts would be only partially successful because the identity of variolators was kept secret. Other measures were required. The only possible approach, apart from outbreak containment, appeared to be that of vaccination of the population at large to diminish the number of susceptible individuals available to variolators as clients and as a source of scabs. This would be particularly important in the remote areas in which variolation was most prevalent. Meanwhile, special efforts would be required to characterize epidemiologically all outbreaks so as to uncover evidence of variolation. Considering the poor record of achievement of the programme during the 6 years 1963–1968 the task appeared formidable, perhaps impossible.

Changes in the Strategy and Structure of the Eradication Programme, January 1969

During extended discussions between government officials and Henderson and Dr

Keja, a new plan of operations was formulated. The key Afghan officials who provided the essential impetus in the design and implementation of the programme were the perceptive and energetic Dr Sayed M. Saidi, President of Preventive Medicine, and Dr A. Omar, Deputy Minister of Health. An agreement was signed by the government on 12 December 1968 and by WHO 3 weeks later. The plan called for the appointment of a full-time Afghan medical director who was to be given sufficient authority and responsibility to direct the programme and the establishment of 4 operational zones (Fig. 14.3)—Kabul, Kandahar, Kunduz and Herat—with a zone office in each. A full-time medical officer and 3 sanitarians, assisted by a WHO adviser, would be assigned to each office. Each zone director was to be delegated full responsibility for the programme in his zone, with authority to discipline personnel and to recruit and train replacements, to requisition fuel for transport and pay for repair and maintenance, and to make all necessary travel arrangements for staff within the zone. Although the recommendations were administratively sound, such responsibilities had not previously been assigned to supervisory staff outside Kabul. Despite a conscientious effort to achieve the requisite delegation of authority, the lack of decentralized authority plagued the programme throughout its existence.

Personnel needs were identified and a budget was drawn up (Table 14.1). With only 4 motor vehicles and 6 motorcycles then available, it was recognized that the programme could not become fully operational until at least August 1969, when the delivery of an additional 44 vehicles, provided by WHO, was expected. Each province was allotted 1 vehicle each for the zone director, the WHO adviser, an outbreak-containment team and an assessment team, and 5 vehicles for the vaccination teams. Other vehicles were to be kept in reserve.

The plan called for vaccination teams to move systematically from village to village

[a] Excluding supplies of vaccine.

and from house to house, preceded 3–10 days earlier by a visit of the team's leader to inform village leaders of the programme and to instruct them about the hazards of variolation. Instead of the name of each vaccinated person being recorded, vaccinations would be tabulated by age group on a tally sheet. An assessment team would visit a sample of children in the villages 1–3 weeks later to assess vaccination status, take rates following vaccination and the prevalence of variolation scars. Surveillance–containment teams would visit civil and health authorities in their respective zones to seek cooperation in reporting and to investigate and contain outbreaks.

In addition to miscellaneous supplies such as refrigerators and office equipment, WHO agreed to provide up to 4 million afghanis (about US$60 000) each year for travel allowances for headquarters and zone staff and for petrol and vehicle maintenance and repairs. Eventually WHO provided Afghanistan with more than US$1.4 million in support of the programme (Table 14.2), an amount equivalent to about US$0.12 per head of population. In addition, freeze-dried vaccine was provided by the USSR and from contributions received by WHO.

In February 1969, Dr A. G. Rangaraj, a newly recruited senior WHO adviser on smallpox eradication, joined the programme, replacing the previous incumbent. Dr Rangaraj had served with distinction in the Indian Army Medical Service and brought to the programme a unique expertise and capability in programme organization and logistics. With the 2 WHO nurses already assigned, Miss Khin Mu Aye and Miss Ludmila Chicherukina, and later an additional epidemiologist, Dr V. V. Fedorov, an exceptionally effective WHO advisory team was created. In May 1969, the Afghan goverment appointed a no less determined and energetic full-time programme director, Dr Abdul Mohammad Darmanger, who ably fulfilled this role for the next 5 years.

Establishment of zone offices and effective field activities

Most of the Afghan smallpox eradication programme staff lived in Kabul, and the attractions of urban life discouraged prolonged work in the field. It was felt that a second base of operations, outside Kabul, with staff recruited from the local area, would facilitate field work. An office-cum-dormitory was rented in Kandahar and some work began from this base as early as November 1968. The staff initially consisted of an Afghan medical officer as director, 6 sanitarians, 44 vaccinators, 3 drivers, a cleaner, several volunteers from the USA and the 2 WHO nurses. Work was frequently interrupted, however, because of numerous national and religious holidays and periodic strikes by Afghan staff when they failed to receive salary or travel allowances because of the complicated payment system. Another hindrance was the frequent change of zone medical

Plate 14.2. **A**: Sayed M. Saidi (1923–1970), President of Preventive Medicine in the Ministry of Health of Afghanistan, provided a new impetus to the programme in 1968. **B**: Arcot G. Rangaraj (b. 1917) became the senior WHO adviser on smallpox eradication in Afghanistan in 1969 and, with Abdul Mohammad Darmanger, his Afghani counterpart, directed Afghanistan's first, and highly effective, nation-wide health programme. He later served with the smallpox eradication programmes in Bangladesh and in the Arabian peninsula.

directors (3 in the first 8 months alone), few of whom were anxious to undertake field work, or to live outside Kabul. Nevertheless, by June 1969, almost the whole population (742 000) of Kandahar, the largest province in the zone, had been vaccinated. Assessment showed that more than 90% of the population had been protected.

It became apparent during this period that, contrary to previous ideas, the 30 United States women volunteers were not essential to the work of vaccination. It was found that when village leaders were properly informed about the nature of the programme, women were usually permitted to be vaccinated by male vaccinators, although sometimes on the forearm or wrist rather than on the upper arm, the customary site of vaccination. From the investigation of outbreaks, it also became apparent that few cases occurred among women, most of whom by the age of puberty had experienced smallpox or had been variolated or vaccinated. Thus, even if some were missed during the vaccination campaign, only a small proportion would remain susceptible. Accordingly, the volunteers were reassigned to assessment and surveillance teams and some helped to establish the necessary administrative and support structure at headquarters and zone offices. They were a dedicated group and made important contributions to establishing the new programme, but when any of them left they were not replaced. Their number had dwindled to 9 by 1970 and to only 1 by 1971.

In July 1969, a third office was established in Baghlan Province, for Kunduz zone, with 2 team leaders, 2 sanitarians and 17 vaccinators. One of the WHO nurses was transferred to Baghlan and several United States volunteers were deputed to work in this office.

Not unexpectedly, a reorganization and reorientation of activities of the magnitude proposed in the plan of operations caused serious difficulties. A joint Afghan–WHO assessment team made an inspection visit in August 1969 and detailed in their report continuing major problems:

- The national programme office had no telephone, secretarial assistance, stationery, files, forms or records. Sanitarians appointed (as administrators) had neither the background nor the skills necessary to discharge their duties.
- The director had no apparent authority—i.e., he had no direct access to a defined budget, no authority either to establish or to enforce personnel policies and no authority to deploy assigned resources (e.g., vehicles, subsistence allowance) without individual written authorization by his immediate superior. Indeed, his superiors appeared to act independently with smallpox eradication programme resources without prior consultation.

- Only 1 team in 5 in Kandahar zone had worked at all from mid-June to early August and then for only 1 week. In August, 13 of the 53 team members in Kandahar had been sent for military service. Field allowances were not being paid nor were funds available for petrol. These factors were responsible for a strike by vaccinators in Kunduz zone.
- The director's lack of authority was illustrated by his inability to dispatch a truck to the airport to pick up a vaccine shipment; this resulted in the vaccine remaining in a hot unventilated shed for 8 days.
- The director had been unable to obtain maps for field operations although the Malaria Institute could do so and tourists could buy them from the Cartographic Institute.
- All teams in Kabul zone had been assigned throughout the summer by Ministry officials to perform cholera vaccination.
- No provincial vaccinators were working with the teams, contrary to prior agreements.
- In Kabul zone, there was no zonal administrative structure and no defined plan of action.
- Vehicles had been out of operation for extended periods and reassigned to other programmes; 2 of 7 large vehicles provided by WHO could not be located, nor could one-third of the motor cycles provided.

The assessment team travelled widely throughout Afghanistan in August 1969, talking with health staff and others and conducting surveys for evidence of pockmarks and vaccination scars. There were encouraging findings. Everyone with whom they spoke reported that variolation had markedly diminished in recent years, and of 4999 persons examined in their survey, only 3 were found who had been variolated within the preceding 3 years. The reporting of cases was known to be incomplete but, despite intensive search, the team could find no cases not already known to the programme staff. In areas in which the systematic vaccination campaign had been completed, only 7% of the population remained unprotected (Table 14.3); variolation scars were found in only 5 out of 363 children under 5 years. Even in areas in which a systematic vaccination campaign had not yet been conducted, almost half of the people had vaccination scars and only 23% were unprotected. In nomadic groups, however, only 25% had vaccination scars, nearly 40% had scars of variolation, and 29% remained fully susceptible. The results were encouraging but, at the same time, they had to be interpreted with reservation. Because of time constraints, the assessment teams conducted their surveys in the more accessible areas. Thus, the data undoubtedly indicated a higher level of protection and less variolation activity than might have been expected in the more remote mountainous areas.

Table 14.3. Afghanistan: results of scar surveys in 13 provinces by the WHO assessment team, by age group, August 1969

Type of scar	% previously infected with vaccinia or variola virus, by age group (years)					
	<1	1–4	5–14	⩾15 (males)	⩾15 (females)	Total
Areas in which systematic vaccination campaign had been completed

Number examined	19	86	137	111	107	460

Many recommendations were made by the assessment team and gradually, over the next 6 months, order began to emerge. The system of payments improved, greater authority was given to the director of the programme and the pace of operations in the zones increased. Nevertheless, zone directors came and went every few months; the turnover of vaccinators remained depressingly high, as they were regularly summoned for military duty or left for other jobs; efforts to utilize the vaccinators assigned to provinces proved futile.

Methodology of the vaccination campaign

The vaccination campaign was simple in concept but required imagination to execute. Five-man vaccination teams moved systematically through the country, completing their task district by district and province by province. The teams worked for a period of 24 consecutive days, followed by 7 days' holiday. The senior supervisor, moving in advance of his team, contacted each district and subdistrict political head and, finally, each village chief to explain what the teams were doing and to solicit their cooperation in ensuring that on the day of the team's visit, the male heads of household would be at home and would agree to let the adult females and children in their household be vaccinated. In most parts of the country, it was possible to vaccinate families only if permission was given by the male heads of household and such vaccination had to be done in the house. The supervisor also explained the hazards of variolation and endeavoured to seek out practising variolators. Variolators, when identified, were sometimes recruited as vaccinators or offered a free supply of vaccine to be used in place of scab material.

A performance goal of 100 vaccinations per vaccinator per day was established. The number was not large, but reasonable considering that many villages could be reached only after hours on foot or horseback, after which each household head had to be individually contacted and his permission obtained to perform vaccination. By the end of 1969, the goal had been achieved by most teams. Initially, the numbers of vaccinations performed were tallied by age group and sex but the vaccinators found it inconvenient to carry paper and pencils and to tally each vaccination performed. A simpler method was adopted. When a team completed work in a village, it simply counted the number of needles used and recorded it, along with the date and the name of the village. The completeness of coverage by age group was determined 1–3 weeks later by an assessment team.

To conduct a systematic vaccination campaign such as this required accurate and detailed maps, but it was soon discovered that the maps provided by the Cartographic Institute and the Malaria Institute omitted many villages and misplaced others. To cope with this problem, the team leader asked each village leader to identify each neighbouring village and its location. These were then added to the map and the map redrawn when necessary.

Methodology for the assessment of vaccination coverage

Assessment of the performance of the vaccination teams played an especially crucial role in the success of the Afghan programme. An assessment team composed of 2 persons visited a 10% sample of the villages 7–10 days after vaccination to determine the proportion of people vaccinated. Assessment was a new concept that was not readily accepted by the national health authorities. It seemed wasteful to them to assign 2 responsible supervisory staff merely to check the performance of others. They argued, moreover, that if assessment was to be carried out, all persons in every village would need to be examined, an impossible task given the limited resources available. Only with difficulty was it possible to persuade the health authorities of the value of a sample assessment which measured the overall performance of a team in a geographical area.

If only some villages were to be visited, which ones should be selected? One approach would have been to use standard statistical sampling methods, which require that every person has an equal chance of being included in the sample. The correct procedure would then have been to take into account the size of the population in each village in drawing the sample. Given the educational level of the staff, this was considered too complex. Another approach would have been simply to ask the teams to assess 10% of the villages in each geographical area. If this had been done, only the most accessible villages would have been checked, and these would have been the villages that the vaccination teams would also have visited. Not only would a falsely high level of vaccination coverage have been

recorded but remote villages in which variolation was prevalent would have been missed. Another scheme was adopted. The name of each village in which vaccination had been performed was written on a piece of paper that was then placed in a box. The assessment team leader drew from the box a number of papers equivalent to 10% of the total, and each of the villages thus selected was then assessed. The process itself was readily understood and it helped to ensure that at least some of the less accessible villages were checked.

To facilitate assessment, a simplified form (Plate 14.3) was developed by Dr Keja and Henderson with the assistance of Mr Svend Brøgger, a WHO statistician assigned to the Public Health Institute in Kabul. It was decided that in each village chosen for assessment, 85 children under 15 years of age and 60 adults should be examined. Children were the more important group, because it was among them that most cases were occurring. They were also the age group more likely to be encountered when the team visited a village. Because adult levels of immunity were found to be consistently higher owing to previous smallpox or to variolation or vaccination, the assessment of adults was later abandoned. The recording form had 145 boxes, 10 for the age group under 1 year, 30 for the age group 1–4 years, 45 for the age group 5–14 years and 60 for the adult group aged 15 years and over, a distribution roughly approximating to the age distribution of village populations.

The assessor was instructed to begin at one end of the village and to proceed house by house until a sufficient number of persons had been examined so that each box would contain a mark. In examining an individual, he looked first at the face. If there were pockmarks, he recorded a "P" in the box and proceeded to examine the next person. If there were no pockmarks, he looked for a variolation scar on the forearm or wrist. If it was present, he marked a "V" in the box. If neither was present, he looked for a vaccination scar and if he found one recorded an "X", or "XX" if it was a primary take. If none of these scars was present, he recorded a "O". He then asked each individual whether he or she had been vaccinated by the team. If the answer was affirmative, a dot was placed within the "O". When assessment was complete, the numbers of different symbols were summed and a simple calculation was performed. Absentees were tallied at the bottom of the sheet; if they were found to be numerous, the assessment was considered invalid. Experience showed that each team could carry out assessments in 2 villages every day.

With this assessment technique, it was possible to determine the immunity level in the village, the proportion of successful vaccinations, the extent of variolation and the past history of smallpox. The work sheet as well as the final report filled up only one side of a sheet of paper. From the physical condition of the report sheet, it was possible to know whether or not the team had actually performed the assessment: a clean form with all symbols neatly inscribed suggested that the data were contrived.

The method of assessment was not what a traditional statistician would have prescribed and the sample was certainly not "statistically valid". However, it was understandable to field staff and provided important information. As such, the sample came to be known as "operationally valid". Eventually, it was adapted for use in many other countries.

Operationally, the goal was established that at least 95% of primary vaccinees should show evidence of a successful vaccination and that not more than 20% of the children under 5 years of age should remain susceptible after a team had vaccinated in a village. Invariably, much higher levels of protection were found among individuals over 5 years of age. Thus, if fewer than 20% of those under 5 years remained susceptible, the overall proportion of susceptible people in the village would be much lower than this, usually less than 10%. If the assessment team found that more than 20% of children under 5 years were susceptible or that the proportion of successful vaccinations was unsatisfactory, the vaccination team was obliged to return to the area to revaccinate the population of all the villages, but its members were not paid a travel allowance. Within months after the assessment teams began work, the proportion of susceptible young children remaining after mass vaccination dropped abruptly from a range of 20–40% to consistently less than 10% and often less than 5%.

Progress in the Vaccination Campaign

Because of the host of administrative problems and the lack of transport, progress in the vaccination campaign remained unsatisfactory during 1969 (Table 14.4). Only

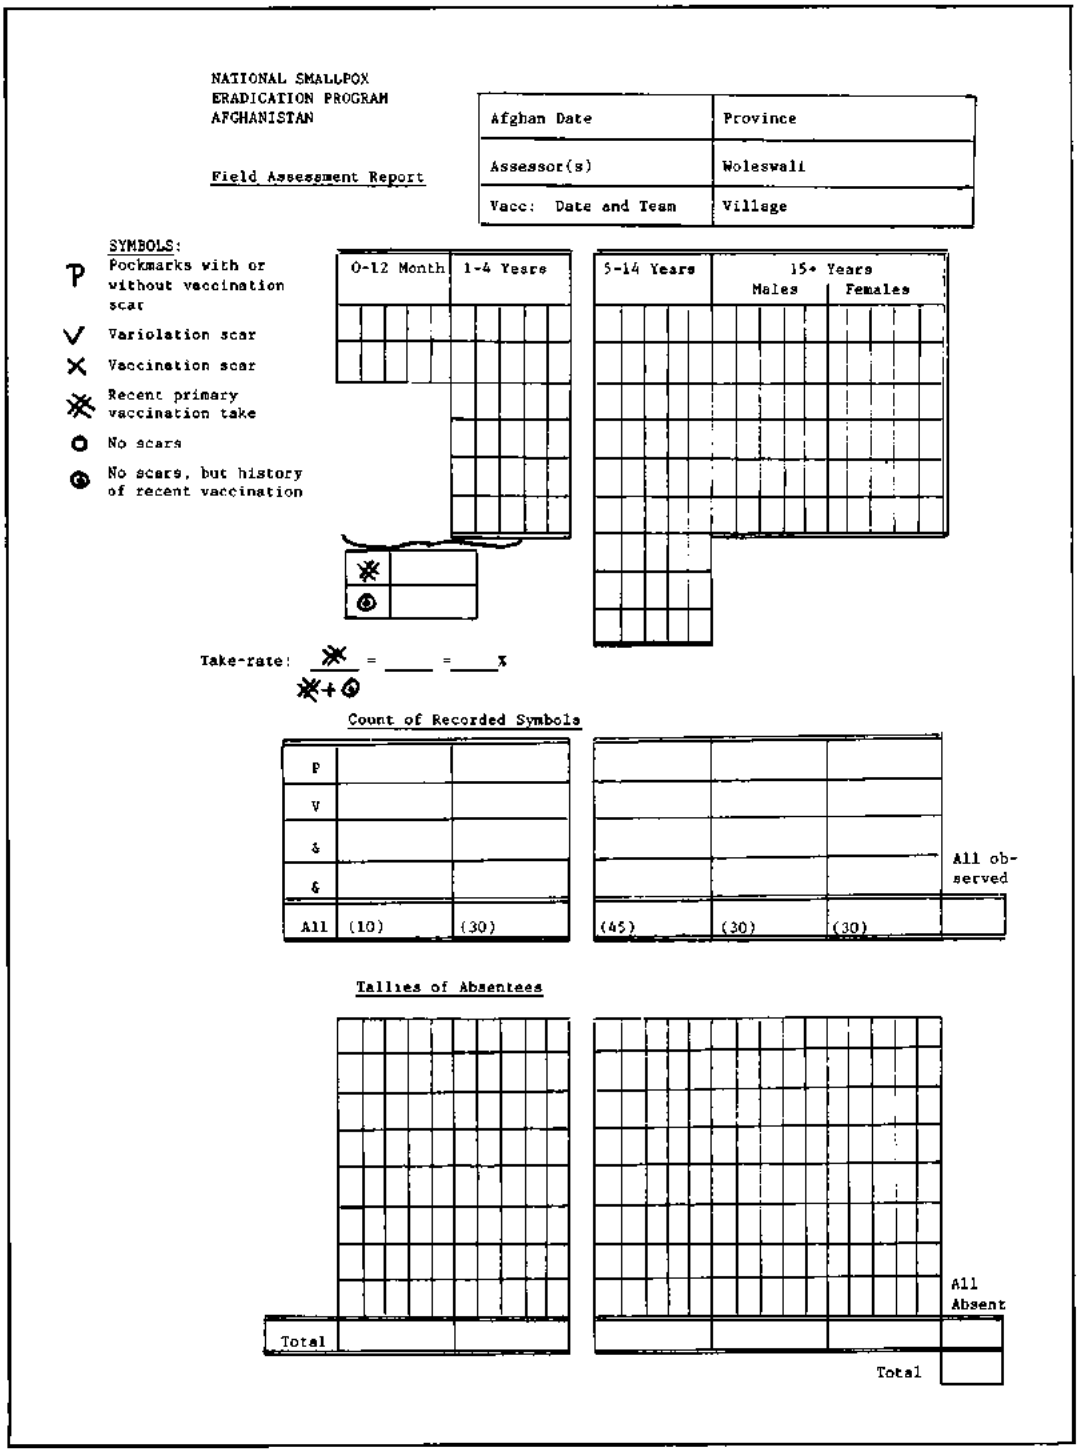

Plate 14.3. Afghanistan: field assessment form, 1969.

545 885 persons were vaccinated during the year, two-thirds of whom were in the Kandahar zone. Vaccination was completed in only 3 provinces (Fig. 14.4). However, as systems improved and operations in the Kunduz and Kabul zones got under way, the pace accelerated. By July 1970, more than 300 000 people were being vaccinated each month. During

1974	1 621 774		(Third round of vaccination)		

Table 14.5. Afghanistan: number of programme staff, by category, April 1971

	National medical officers	WHO advisers	Sanitarians	Vaccinators	Drivers	Total
Headquarters	1	1	3	1	1	7
Kabul zone	1	1	8	81	12	103
Kunduz zone	1	1	3	65	10	80
Kandahar zone	1	1	3	57	10	72
Herat zone	0	0	3	28	5	36
Total	4	4	20	232	38	298

1970, 3 541 643 vaccinations were performed and work was completed in 10 provinces (Fig. 14.4). Activities extended to Herat, the 4th zone, in 1971 and 4 676 442 vaccinations were performed during the course of the year. By the end of 1971, campaigns had been carried out in all but 4 provinces, and by June 1972, the first round of vaccination had been completed. In all, 10.5 million people had been vaccinated by a staff which at its maximum numbered only 298 persons (Table 14.5). The population of Afghanistan in 1972 was estimated by the government to be 17 million but, in the absence of a census, the actual number was unknown. The data of the smallpox eradication programme suggested that a population estimate of no more than 12–15 million persons would be more realistic.

On completion of the first round of vaccination, it was decided to undertake a second round, but to vaccinate only those under 15 years of age. The objective of this round was not so much to improve the immune status of the population as to ensure the continued mobility of the vaccination teams, who could both search for cases and detect the presence of variolators in the course of their work. The second round of vaccination was completed in 18 months, during which 5.4 million persons were vaccinated (see Table 14.4). The shorter time required reflected, in part, more efficient programme operations; of greater significance was the fact that village leaders were far more helpful and the villagers more receptive. After the second round of vaccination had been completed, it was decided to perform yet a third round, again to ensure a continuing search for cases and the detection of variolators. During the third round, only children under 5 years of age were vaccinated. This phase of vaccination was completed in just over a year, during which 1 621 774 individuals were vaccinated. Cooperation had progressed to such an extent in some areas that villagers assembled young children at collecting points, thus obviating the need for vaccinators to visit each house.

The nomadic and semi-nomadic Kuchis, who were estimated to number more than 2 million, presented a special problem. Entire families wintered in lowland pastures in southern Afghanistan and Pakistan, and, with their herds, moved to upland pastures in the spring. On the way, they travelled in large bands along comparatively well established routes, but once settled, they scattered widely, often in virtually inaccessible areas. Although, when settled, they readily accepted vaccination, they resisted it while travelling, fearing reactions to the vaccine. Many were vaccinated during the course of the systematic campaign but, as shown in a survey of Kuchis in Helmand Province in 1971, vaccinial immunity differed greatly from one group to another (Table 14.6). To ensure more complete coverage, a special summer programme was conducted during 1973 in Ghor and Bamian Provinces, in which the largest proportion was settled.

At the conclusion of the second round of systematic vaccination in 1973, the overall levels of vaccinial immunity in Afghanistan were assessed during a special programme. The levels of protection were among the highest found in any country (Table 14.7).

A Smallpox Surveillance Team

The investigation of a rumoured outbreak in November 1970 in the mountainous province of Oruzgan illustrates the pride and dedication that the teams developed. A team was sent on horseback to elicit information about the outbreak. On its way up a mountain, it encountered metre-deep snow and was forced to turn back. The team then approached the area by another route. Again, it encountered snow; the horses were abandoned and the team members continued on foot for 4 days to get to the villages. They stayed in the villages, moving from one to another to vaccinate. In all they spent 6 weeks vaccinating the inhabitants of villages in the middle of winter in the Oruzgan mountains. When it was possible to carry out a thorough search of the area in the spring, no cases of smallpox were found.

The Elimination of Smallpox: Epidemiological Patterns, 1969

Given the many problems and obstacles, the rapid development of a highly effective campaign of systematic vaccination was an extraordinary achievement. Programme staff, however, undertook at the same time an equally effective effort to improve reporting and to investigate and contain outbreaks. They decided that from September 1969, every reported case of smallpox would be investigated by a zonal containment team, usually accompanied by senior national and WHO staff. The Afghan programme was one of the very few in which both mass vaccination and surveillance–containment measures were simultaneously and successfully conducted.

To improve reporting, provincial medical offices were directed by the Minister of Health to report any suspected case by telephone or telegraph either to the national smallpox eradication office in Kabul or to the zone office. At the same time, the President of the Malaria Institute directed all malaria workers to report cases of smallpox. Meanwhile, programme staff began regular visits to each hospital, health centre and clinic to explain the programme and to ask that every suspected case or rumoured outbreak of smallpox should be reported promptly. Because only 69 out of 326 subdistricts had a health unit and because the malaria programme was not operational throughout the country as a whole, and not notably effective, additional measures were required. Zonal surveillance teams began systematic visits to the subdistrict civil authorities, the *maliks* and *arbabs*, to solicit their help and to visit the few existing schools. Each report of a case was investigated promptly by a surveillance team. The promptness of response provided tangible evidence to those reporting that the programme personnel were genuinely interested in receiving reports, and this gradually became widely known. Indeed, some villages which sought vaccination sent false reports, knowing that the report of a case would quickly bring a surveillance team to the village.

During the last 4 months of 1969, 22 reports of smallpox were received, of which 20 were verified to be outbreaks. In all, 79 cases were reported but the surveillance teams found an additional 171 cases during investigation (Table 14.8). In the course of 1970,

Table 14.8 Afghanistan: number of reported cases of smallpox and number of additional cases discovered by programme staff, 1969–1973

Definition of a Case of Smallpox among Variolated Persons

All persons who had been successfully variolated should properly have been recorded as cases of smallpox since they had been infected with variola virus. If all such individuals had been counted as cases, the recorded incidence in Afghanistan would have been high indeed, because in some outbreaks variolators performed upwards of 100 inoculations. To decide whether a person had been successfully variolated, however, was not a simple matter. The primitive technique of variolation often produced serious bacterial infections and it was impossible to tell whether or not variola virus had grown in the skin. For Afghanistan, and similarly for Ethiopia (see Chapter 21), it was agreed by WHO and the national authorities to record as cases only the variolated individuals who exhibited smallpox lesions on other parts of the body as well as at the site of variolation. It was recognized that some who were succesfully variolated would have a lesion only at the site of variolation and thus there would be an underenumeration of cases. However, because the probability of smallpox transmission was correlated with the extent of rash, such individuals were much less likely to transmit infection and therefore less important epidemiologically.

with reports being received from many additional sources (Table 14.9), the number increased to 1044 cases in 83 outbreaks. This was the highest total of cases recorded in Afghanistan since 1955. Cases were recorded in 21 of the 28 provinces (Table 14.10) and, as was the case in other countries, the apparent epidemic of smallpox (Fig. 14.5) alarmed the national authorities and fostered substantially greater support for the programme.

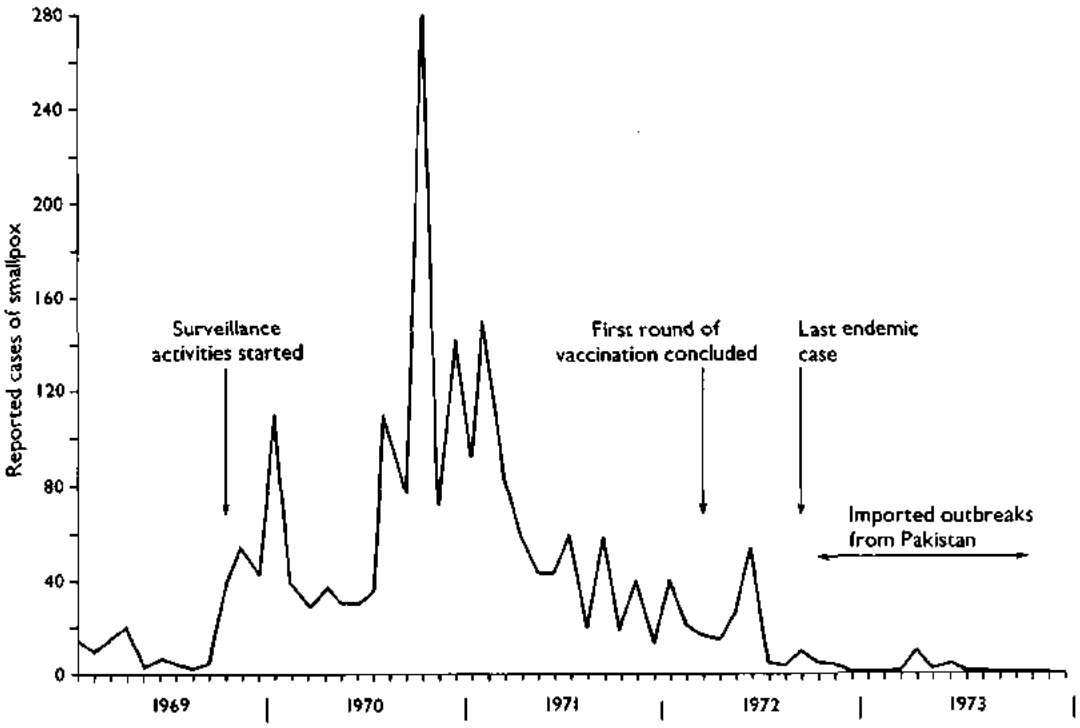

Fig. 14.5. Afghanistan: number of reported cases of smallpox, by month, 1969–1973.

Special concern was caused in 1970 by the increasing number of cases in the city of Kabul, and a number of outbreaks in other provinces which were traced to this source. In all, 156 cases (15% of all cases in Afghanistan) were reported from Kabul, most of which occurred in the congested poorer quarters of the city in which visitors from rural areas often stayed. Originally, vaccination in Kabul had not been planned since extensive vaccination campaigns had repeatedly been conducted there between 1962 and 1968. Because of the outbreaks, however, a special campaign was carried out during the winter months of 1970–1971. As in many other cities, the infectious diseases hospital itself proved to be a problem, 5 of the outbreaks resulting from the spread of smallpox within the hospital. One of the people infected was a Danish student, admitted because of suspected typhoid fever, who developed smallpox after returning to Copenhagen (see Chapter 23). This problem of hospital infection was eventually solved when smallpox eradication staff were assigned to the hospital to ensure the isolation of patients and the vaccination of all people admitted, for whatever reason. With these measures, Kabul and its infectious diseases hospital ceased to be a problem.

The number of outbreaks increased from 83 in 1970 to 107 in 1971, but only 736 cases were found on investigation, substantially fewer than the 1044 cases recorded in 1970.

In 1972, outbreaks were reported in only 11 provinces and the numbers of cases and outbreaks diminished rapidly. Between January and June, 10 provinces recorded 196 cases in 39 outbreaks. After June, smallpox was detected only in the southern provinces of Oruzgan, Kandahar and Zabul, the last indigenous cases occurring in Oruzgan in September, just 36 months after the surveillance–containment programme began. Later in the year, 1 outbreak occurred in Zabul and 2 in Kandahar whose sources of infection were, respectively, the towns of Pishin and Quetta, both in Pakistan.

The Final Outbreaks

Between October 1972 and April 1973, no evidence of endemic smallpox was found despite active search and the investigation of many rumours. However, 3 more outbreaks were yet to be discovered: 2 in April and 1 in June. The following brief descriptions of these outbreaks and how they were dis-

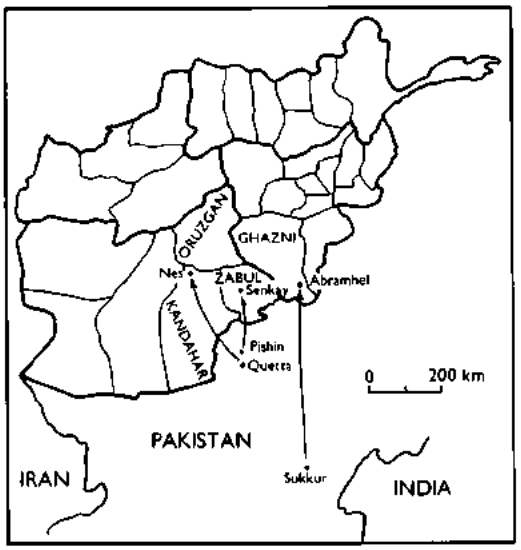

Fig. 14.6. Afghanistan: sources of infection and location of outbreaks, 1973.

covered, investigated and contained illustrate some of the challenges experienced by the Afghan staff.

Ghazni Province, Abramhel village

On 10 April 1973, a mobile vaccination team heard rumours from villagers of suspected cases in Wor Subdistrict, 85 kilometres away. The team leader and his supervisor went to the area the following day and in the village of Abramhel, 5 kilometres from a barely motorable road, found 3 active cases and 3 close contacts with fever, and learned of a person who had died of the infection. The village, consisting of 9 households and 56 persons, was one of a number of small, widely scattered villages situated on barren mountain slopes rising above an arid plain. A search of this and 12 neighbouring villages began immediately along with containment vaccination. In all, 2411 persons were vaccinated. Systematic vaccination had been conducted throughout the area 3 years earlier but this group of villages had been missed. The first case was that of a 23-year-old man who had travelled some 600 kilometres to the town of Sukkur in Pakistan in search of work (Fig. 14.6). He arrived back in his village after more than a year's absence, became ill with smallpox and died. In all, 13 cases eventually occurred, 2 of whom had old variolation scars and 7 of whom were vaccinated during the incubation period. Three of these persons died.

Zabul Province, Senkay Woleswali (*district*)

Fearing that Kuchi nomads might reintroduce smallpox during their spring migration from Pakistan, smallpox eradication teams in 1973 endeavoured to intercept groups of Kuchis in order to detect cases and vaccinate the others. On 29 April, a surveillance team found a 10-year-old child with smallpox among a group which was travelling from Pishin in Pakistan to its summer home in the mountainous province of Oruzgan. Only 5 of 140 persons in the group had not been vaccinated; the patient was one of the unvaccinated. The boy and his mother were isolated in the zone office and 2 vaccinators were assigned to travel with the Kuchis to detect any further cases that occurred. The Kuchis, who were smuggling cloth, feared that they might be reported and left silently, leaving the mother and child and 2 sleeping vaccinators. Angered by this, the mother revealed the intended route and destination of the band, and a vaccination team again intercepted them to keep them under surveillance for 6 weeks. No further cases occurred.

Kandahar Province, Nes Subdistrict

As happened in several countries, the final outbreak was marked by delays and failures in reporting in what was then thought to be a reasonably effective system of notification and containment. On 3 July 1973, the zone office in Kandahar was informed that a number of deaths had occurred in a Kuchi nomad camp some 90 kilometres to the north. Five days had elapsed since the commandant of police at Nes had telephoned this information to police headquarters in Kandahar. The provincial medical officer was notified the same day and he immediately sent a laboratory technician to investigate. The technician returned on 30 June to confirm that the outbreak was smallpox. Instead of directly informing the zone office, a few blocks away, the provincial medical officer wrote a letter to the office on 2 July which was received late the next day. On 4 July, the zone team went to Nes, where they found a Kuchi camp of 45 persons living in 7 tents. In all, 11 cases with 5 deaths had occurred. Surprisingly, a local malaria surveillance agent had visited the camp several days earlier, vaccinated a few people and departed without notifying anyone. Meanwhile, on 2 July, a variolator who lived in Nes had visited the camp, gathered scabs from one of the patients, variolated 10

persons and departed for another province. The team conducted an immediate search and vaccinated the population of the subdistrict, performing some 2300 vaccinations in all. Nine of the 11 cases were among adults. Systematic vaccination had been completed in the subdistrict only 3 months before, but at the time of the team's visit, only the children and a few women had been in camp, the men having gone far ahead to prepare the next campsite. The first case in the outbreak had been that of a 35-year-old man who had accompanied his uncle to a hospital in Quetta, Pakistan, and had developed smallpox after his return. A cable to Quetta confirmed that at the time of his visit, cases were present in the hospital. Thus, the last known outbreak in Afghanistan was traced to infection probably acquired in a hospital; the report of the outbreak and its containment were delayed by a full 5 days because of poor communication; a health worker who should have reported the cases failed to do so; the men in the camp who should have been vaccinated only 3 months earlier were missed because they had travelled to another area; and a variolator was given the opportunity to acquire scabs. Despite extensive search the variolator was never found nor was another case of smallpox detected in Afghanistan.

Conclusion of the Programme

The last outbreaks in Afghanistan were cause for celebration, but with smallpox still endemic in Pakistan and with the spectre of its possible recurrence through the practice of variolation, programme staff could not relax their efforts. The tens of thousands of nomads who began their annual trek northwards out of Pakistan in late February and March were of particular concern. In 1973, the number of surveillance teams in southern Afghanistan was increased and a special programme was begun to intercept nomads during their travels. During this period, different surveillance teams succeeded in intercepting some nomadic groups so often that the leaders of the groups protested against the harassment. To deal with the problem, it was decided to issue a special certificate to the leader after all members of a group had been examined, provided that they all accepted vaccination. When subsequently intercepted by another surveillance team, the group leader simply presented the certificate, assuring the nomads of the right of passage without further examination. Happily, the procedure was well accepted.

Meanwhile, the systematic vaccination campaign was continued, primarily to sustain a continuing search for cases but also to keep the number of susceptible persons as low as possible and so diminish the chance of variolation being revived. In fact, as late as 1976, evidence of attempted variolation was found, but no successful variolations are known to have occurred following the last outbreak in 1973.

Finally, after the interruption of smallpox transmission in Pakistan in October 1974, a reward of 1000 afghanis (US$18) was offered to anyone reporting a case. The number of rumours and reports of suspected cases increased dramatically but, on investigation, none proved to be smallpox.

Epidemiological Data

Data on age and vaccination status are available for 2258 of the 2291 cases that occurred between 1969 and 1973 (Table 14.11). Of the total, 360 cases (16%) were among persons infected through variolation. Only 83 (4%) occurred among those who had been vaccinated before exposure.

Because of the isolation of so many villages and areas in Afghanistan and the difficulty of movement from place to place, it was expected that a much larger proportion of cases would be found among adults, but in fact the proportion was not much greater than in

Throughout much of the Indian subcontinent, the leaves of the *neem* tree were believed to have special healing powers over smallpox.

Indonesia (11%), with its dense population, and far smaller than in Pakistan (37%). The paucity of susceptible adults reflects the extent of previous smallpox and variolation.

The overall case-fatality rate of 13.8% (313 deaths among 2258 cases) understates the severity of natural infection, including, as it does, 360 cases infected by variolation, among which the case-fatality rate was often 2-3%. Discounting variolation, the case-fatality rate was about 16%, a figure approximating to that found in the Indian subcontinent.

The source of infection of the 237 outbreaks that occurred from 1970 to 1973 is shown in Table 14.12. Of the 201 outbreaks for which a source could be identified, 45 (22%) represented importations from Pakistan and 47 (23%) resulted from variolation. During this 4-year period, the teams investigated a further 345 outbreaks reported to be smallpox but which, on investigation, proved to be chickenpox (202), measles (51) and other skin infections (43). The remainder were rumours without apparent foundation.

Unknown	20	12	4	0	36
Total	83	107	44	3	237

Outbreaks which resulted from importations, with one exception (in Badakshan Province), occurred in areas south of the Hindu Kush mountain range in provinces near or on the border with Pakistan. Similarly, outbreaks traced to the nomads (except those in Badghis Province) who migrated from Pakistan to Afghanistan were in these same areas (Fig. 14.7).

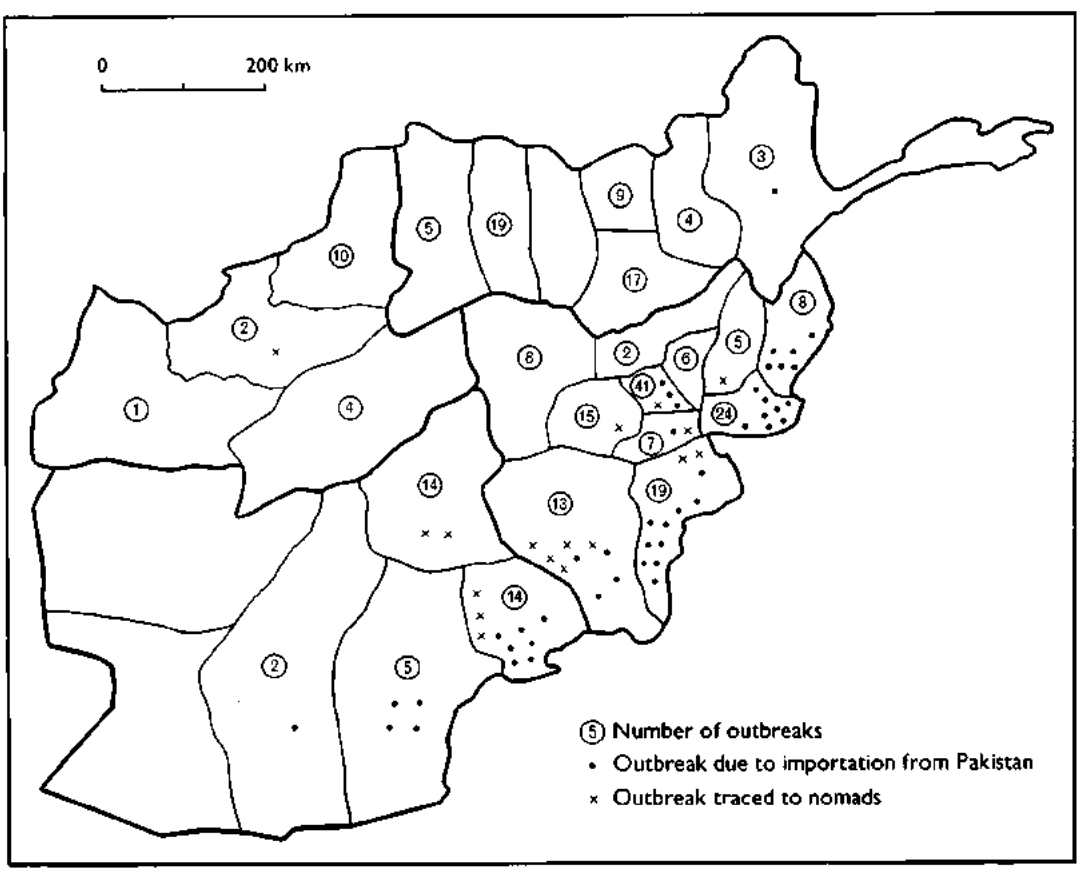

Fig. 14.7. Afghanistan: number of outbreaks by province and location of those caused by importations from Pakistan and those among nomads, 1969–1973.

Delays in the detection of outbreaks (Table 14.13) were a problem throughout the programme. The mean interval was just under 4 weeks, the delays being as great in 1972 as they were in 1969–1970. After the outbreaks had been found, however, further transmission did not continue for long. In only 6 out of 224 outbreaks did new cases occur more than 2 weeks after containment had begun, even though many of the outbreaks were on a large scale (Table 14.14).

The Problem of Variolation

Variolation had been thought to be a major, perhaps insoluble, problem. The practice was most widespread in the more remote mountainous villages and among the nomadic Kuchis, its extent being in inverse relation to the people's ease of access to vaccination. Among the adults in some areas, upwards of 50% bore the scars of variolation. For some, variolation was the only available protection against naturally occurring smallpox and many continued to pay to have variolation performed, even when free vaccination became available. Variolation was a familiar procedure to them and they regarded it as providing permanent immunity.

Priority was given to the identification of variolators: to characterize them, learn about their practices, obtain variolation material from them and persuade them to abandon the practice or to accept vaccine for use instead of variola virus. This was difficult, however, because they feared punishment if they were discovered. Between 1969 and 1973, 61 variolators were contacted and persuaded to abandon the practice. Later, in 1976, a special search for variolators revealed 36 others. The location of the variolators by province is shown in Fig. 14.8. Undoubtedly the numbers found represent only a small fraction of the total.

The variolators performed variolation only on the request of a village or a family, and usually for a fee. Many were farmers and some were religious leaders; other practitioners who were identified included a tailor and 4 women. In almost all cases, the variolator's father and grandfather had also been variolators and usually only the eldest son was engaged in the practice. Scabs—rarely pustular material—were collected from a recovering patient, preference being given to patients with many lesions who could therefore provide a greater amount of material. None of those interviewed said that they selectively sought to obtain scabs from less severe cases on the assumption that virus from such cases might result in less severe reactions. The scabs were usually kept either as such or in a powdered form. Sometimes, a liquid (e.g., honey or spices in water) was added either soon after the scabs had been obtained or immediately before inoculation. Because variola virus is exceptionally stable when dried, especially if kept in a cool place, efforts were made to learn from the variolators how long they believed they could satisfactorily store the virus. Most of them stated that it was necessary to obtain new material each year. A few observed that material could be retained for as long as 2 years, but they noted that such material was not reliable and often did not induce the desired infection.

Table 14.13. Afghanistan: number of outbreaks according to interval between first case and notification and between beginning of containment and last case, 1970–1973[a]

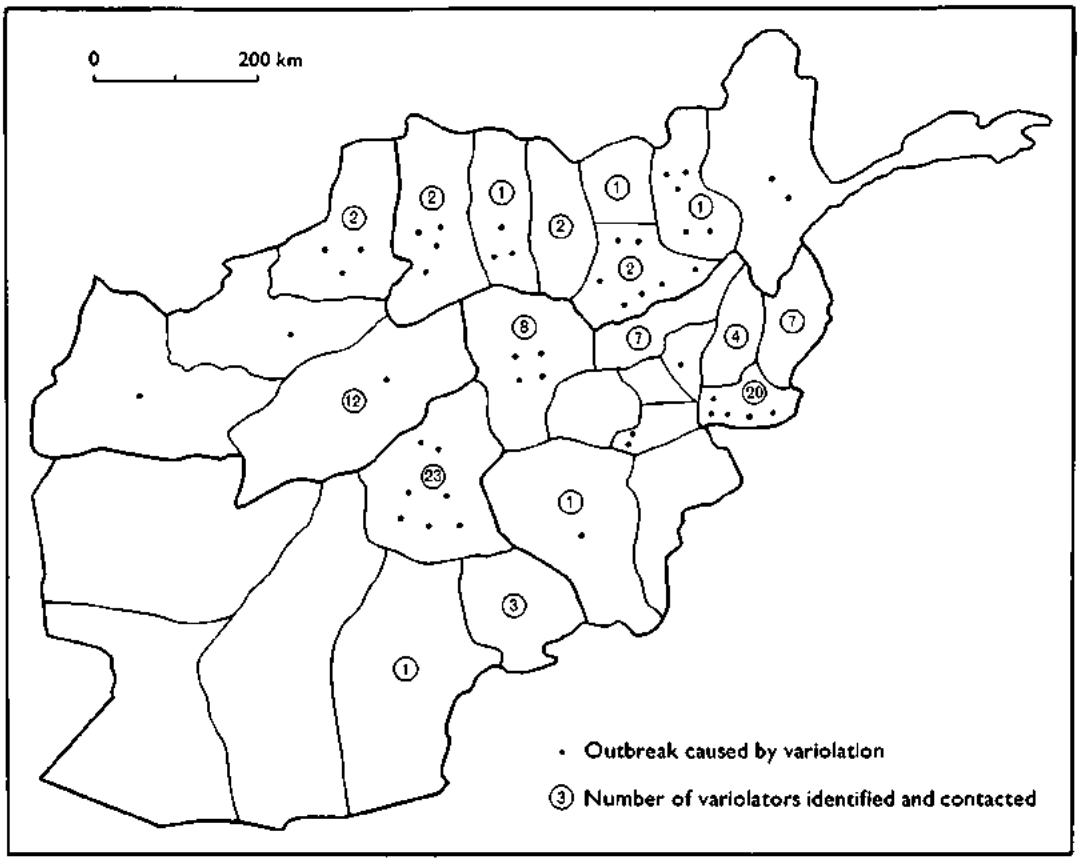

Fig. 14.8. Afghanistan: location of variolators who were identified and of outbreaks caused by variolation.

The variolators kept the scabs in all manner of jars and boxes, usually in their houses. A particularly interesting case was that of a variolator who kept the material in a horn, stored in a cave at a high altitude, quite far from his home. Although storage in a cold environment such as this should have served well to preserve the virus, the variolator reported that the material he collected was not very effective if more than a year old.

Six specimens were obtained and tested in WHO reference laboratories. Variola virus was isolated from 4 of them, of which 2 had titres that were presumably high enough to induce infection if inoculated (Table 14.15). The 4 specimens from which virus was isolated were collected between March 1969 and April 1970. One specimen collected in April 1976 consisted of scabs said to have been obtained in Pakistan in October 1974. In this specimen, virions were seen by electron microscopy but the virus did not grow on egg membrane.

Variolators were usually known to villagers throughout a subdistrict or district and were summoned only when smallpox began to occur in the area. However, some variolators travelled considerable distances, offering their services to the headman of each village visited. Sometimes, all the susceptible individuals in an entire village were systematically vaccinated, ensuring that none would remain to be exposed to natural infection acquired from those who had been variolated. This was the exception rather than the rule, however.

The usual method of variolation was to suspend the powdered scab material in a paste and to inoculate it either on the dorsum of the forearm or on the wrist, adjacent to the extensor tendon of the thumb (referred to by physicians as "the anatomical snuffbox"). Some did this by superficial linear scratch using a knife and some by multiple puncture using a small bundle of needles. A bandage was then placed over the area. Fever began on

Table 14.15. Afghanistan: results of laboratory testing of specimens collected from variolators

Number	Type of specimen	Date of collection	Age of specimen	Technique			Titre (pock-forming units/ml)[a]
				Electron microscopy	Gel precipitation	Variola virus isolation	
1	Fluids	March 1969	?	*b*	*b*	+	2 500

about the 4th or 5th day and a lesion appeared on the 7th day. Many of those inoculated developed lesions elsewhere on the body and, although the variolators who were interviewed usually denied that any of their patients had more than 100–200 lesions, surveillance teams found some with more extensive rashes and learned of others who had died.

Between 1970 and 1972, 47 out of 237 outbreaks were caused by variolation. These occurred primarily in provinces lying north of the Hindu Kush range and in the central mountainous provinces of Bamian and Oruzgan (Fig. 14.8). As is shown in Table 14.16, 714 cases occurred in outbreaks which had been initiated by variolation—i. e., more than one-third of all cases in Afghanistan during this 3-year period.

Certainly, variolation was a problem, but considering the large number of traditional variolators, it was less serious than had been

WHO/P. ALMASY

Plate 14.6. A variolator demonstrates the traditional way of binding the site of inoculation after variolation. The picture was taken in Afghanistan in 1970.

Table 14.16. Afghanistan: number of cases of smallpox due to variolation, 1970–1972

	1970	1971	1972
Number of outbreaks initiated by variolators	23	21	3
Number of cases due to variolation	120	200	16
Number of additional persons infected in the outbreak	213	158	7
Total number of cases directly or indirectly due to variolation	333	358	23

Proportion of cases related to variolation	32%	49%	10%

expected. Because vaccination was known to most of the population—though it was not always easily available—variolation had already begun to disappear by the time the programme in Afghanistan commenced. The efforts of the surveillance teams to contact all village and subdistrict leaders and to explain to them the adverse consequences of variolation undoubtedly helped to diminish the practice. The immediate response of the surveillance teams to any reports of smallpox cases was also important: vaccination was made widely and freely available before the variolators were able to initiate their activities.

PAKISTAN

Pakistan and its smallpox eradication programme presented a contrast to the situation in Afghanistan. Most of West Pakistan's 60.5 million people (1967) lived in the vast Indus river plain and in the Himalayan foothills, where population density was high. The government structure throughout this area was comparatively sophisticated, health services were much more extensive and health personnel were far more numerous than in Afghanistan. A network of roads, as well as train and air connections, and postal and telegraph services facilitated communication. Throughout this area, a programme of smallpox vaccination had been in operation for nearly 100 years; vaccinial immunity was high and variolation was all but unknown. Some remote, sparsely populated areas, however, presented problems almost as formidable as those in Afghanistan. In the northern mountainous areas of Gilgit and Azad Kashmir, in the mountainous districts bordering on Afghanistan and in the vast western deserts of the Baluchistan plateau, government and health services were less well developed, health personnel were few, vaccination had been less extensively practised and a few persons were still being variolated. The inhabitants of such areas, however, constituted no more than 10–15% of the country's total population.

In 1967, Pakistan consisted of the provinces of West Pakistan and East Pakistan, separated by the breadth of India and, each essentially autonomous so far as health programmes were concerned. In July 1970, the government decided to divide West Pakistan into 4 provinces and 2 federal regions. Health continued to be a provincial responsibility, the Federal Ministry of Health retaining authority only for health policy, the direction of medical research, standards of medical education and relationships with international organizations. A single smallpox eradication programme in West Pakistan thus became 4 separate and autonomous provincial programmes and 2 federal regional programmes which differed greatly in their methods of operation, rate of progress, and degree of political commitment to eradication. What little coordination existed between the programmes was achieved primarily by the WHO advisers. In December 1971, East Pakistan became the independent country of Bangladesh, whose programme is described in Chapter 16. The present chapter deals only with West Pakistan, designated, since 1971, as Pakistan.

Because of the availability of resources and the more sophisticated government and health structure, the eradication of smallpox appeared to be more feasible in Pakistan than in Afghanistan. Surprisingly, transmission was not interrupted until October 1974, 2 years later than in Afghanistan. Even when the last cases were being detected, the case notification procedure and surveillance system were still so inadequate that many months were to elapse before either national or WHO staff were persuaded that eradication had been achieved. Adherence to traditional mass vaccination, erratic political commitment and poor management were to characterize the programme throughout most of its course.

Smallpox before 1967

As in Afghanistan, only variola major, the severe form of smallpox, is known to have

occurred in Pakistan; and in past centuries, variolation had been widely practised. Smallpox control through vaccination began during the colonial period, before British India became the independent countries of Pakistan and India, and was widely practised throughout the more populous areas until the late 19th century. In the former province of Punjab, which constitutes a major part of Pakistan, a large-scale programme of vaccination began in 1875 under a General Superintendent of Vaccination, who employed 29 supervisors and 121 vaccinators. A Vaccination Act was passed in 1880, and in 1888 local government bodies were created which were responsible for vaccination programmes in their own areas. Indeed, throughout the 1970s, vaccination by "local body vaccinators" (personnel paid by local government authorities) continued in most parts of Pakistan. Liquid vaccine produced at the Punjab Vaccine Institute in Lahore was used. The extent of vaccination is illustrated by data from the former Punjab Province for the period 1933–1938. Each year, 3.1–5.8 million vaccinations were recorded in the province, whose population was only 24.8 million (1935) (Table 14.17). Nevertheless, the number of notified cases of smallpox remained high and major epidemics recurred every 4–6 years.

Table 14.17. Punjab Province of British India: number of vaccinations performed and number of cases of and deaths from smallpox, 1933–1938

Year	Number of vaccinations	Number of cases	Number of deaths
1933	3 206 356	22 571	11 626
1934	3 113 487	3 595	1 962

1968	62 166	13 946	22.4	1 836

[a] Population estimates from United Nations (1985).

Although the vaccination campaign undoubtedly had an impact on the incidence of smallpox, the effect was not impressive in comparison, for example, with that of the campaign in Indonesia, in which smallpox was eliminated during the same period. This was probably due to the fact that the vaccine used in Punjab was the thermolabile liquid product rather than the dried, heat-stable variety employed in Indonesia.

Following independence, local body vaccinators continued to vaccinate using the liquid vaccine. In the period 1959–1968 the reported number of vaccinations performed each year represented a proportion of the population ranging from 14% to 38%; moreover, the number of primary vaccinations reported to have been performed was greater than the number of newborn infants. In view of the fact that, in 1968, there was 1 vaccinator for every 40 000 persons, the numbers of reported vaccinations are believable. None the less, smallpox continued to occur, with peaks in incidence every 4–6 years (Table 14.18). As later studies were to show, the number of reported cases was only a fraction of the total that actually occurred. However, the once widely prevalent practice of variolation ceased in all but a few remote, less populous mountainous and desert areas, where it continued to exist until the end of the programme.

Programme Strategy

Immediately after the decision of the Nineteenth World Health Assembly in 1966 to intensify the smallpox eradication programme, the Director of WHO's Regional Office for the Eastern Mediterranean, who fully supported the programme, had recruited the energetic Dr Ehsan Shafa, a veteran of Iran's successful smallpox eradication programme of the early 1960s, as the regional adviser on smallpox eradication. In March 1967, Dr Shafa first consulted government officials in Lahore to discuss the development of a programme. Separate schemes were drawn up for East and West Pakistan. The

Plate 14.7. After a vaccination session, Pakistani schoolchildren hold their sleeves away from their arms to allow the remaining vaccine lymph to dry off. This was the customary practice with liquid vaccine in most countries, although vaccinations were equally successful if the excess moisture was wiped off immediately. In many countries in which mass campaigns were conducted, only a small proportion of the children attended school but they were often vaccinated at 6-month intervals by vaccinators eager to fulfil the quotas set for them.

plan of operations was signed by WHO in August 1967 but not by the government until April 1968.

The procurement of supplies began in the hope that the programme might be launched by the end of 1968. A WHO adviser was assigned in September 1968 and supplies were delivered that autumn. However, the programme did not commence until June 1969. Five more years were to elapse before smallpox transmission was finally interrupted. A host of administrative problems hampered the programme from its inception, and during 1971, activities everywhere were curtailed because of the civil war. However serious these problems, the principal deterrent to progress was the protracted delay in taking cognizance of the findings of a group of investigators at the Pakistan Medical Research Centre in Lahore and of the strategy worked out by them.

The Lahore centre was supported by the government of Pakistan and the United States National Institutes of Health; it was one of four international centres for medical research and training in which United States and local scientists collaborated in medical research programmes. The investigators themselves decided which studies should be undertaken; those in the Pakistani centre decided to study the epidemiology of smallpox in West Pakistan. In May 1966, they began a 1-year study of smallpox in a rural district with a population of 1.2 million near Lahore and later undertook additional studies in urban Lahore and in other districts better to define the epidemiology of the disease (Ali & Heiner, 1971; WHO/SE/69.13, Heiner et al.; Heiner et al., 1971a,b; Mack et al., 1970, 1972a,b; Thomas et al., 1972). The studies, which are described in the next section, were the most comprehensive to be undertaken during the whole global eradication programme. The principal investigators (Dr Ashgar Ali, Dr Nusrat Fatima, Dr Gordon Heiner, Dr Muzaffar Khan, Dr Fred McCrumb, Dr Thomas Mack and Dr David Thomas) prepared a series of important papers which were distributed to WHO smallpox eradication programme staff throughout the world beginning in 1968; most of these papers were published in scientific journals between 1969 and 1972. The data argued persuasively for giving the highest priority in Pakistan to the detection and containment of outbreaks, especially during the season of lowest incidence, and to special vaccination campaigns in urban areas. The applicability of the strategy was soon supported by observations in western Africa, Brazil, Indonesia and East Pakistan, as programmes throughout the world gave increasing emphasis to surveillance and containment. Ironically, West Pakistan was among the last to commit itself fully to this strategy.

In most countries, but especially those in the Indian subcontinent, the belief that it was necessary to vaccinate every member of the population to achieve eradication was accepted doctrine. That the development of reporting and surveillance systems was at least equivalent in importance to mass vaccination was an alien concept. In West Pakistan, the principal WHO advisers up to 1971 were veterans of the successful eradication programme in Iran in the early 1960s. There, smallpox transmission had been interrupted through a large-scale vaccination campaign;

surveillance was an unknown quantity. However rational the surveillance–containment strategy might be, it was extensive vaccination to which they were committed and to which they devoted their principal energies.

Before describing the programme and its evolution in West Pakistan, it is of interest to review the findings of the group from the Pakistan Medical Research Centre, which document the status of smallpox and its epidemiology in West Pakistan at the time the programme began.

Studies of Smallpox in West Pakistan, 1966–1967

Investigators from the Pakistan Medical Research Centre first studied the occurrence and patterns of transmission of smallpox over a 1-year period, beginning in May 1966 in a single district. Their stated objective was to determine the best strategy to interrupt transmission (Mack et al., 1970, 1972a,b; Thomas et al., 1972). Sheikhupura District, an agrarian area of 2312 square kilometres and a population of 1.2 million, of which 85% lived in 1700 villages, was selected for study. Since 1946, the district had recorded about 50 smallpox cases per annum with occasional years during which several hundred cases were reported. During the 1-year period of study, cases were identified by the epidemiologists through the field investigation of reports to the district health officer and rumours received from civil servants and travellers and through routine inquiries in villages. Control measures, if conducted, were performed by the local health authorities.

During the year of study, 146 cases in 23 villages were officially reported to the district health officer. The investigators, however, discovered 1040 cases in 121 outbreaks and subsequently estimated, by sample survey, that an additional 40 outbreaks and approximately 180 cases had occurred that had not been detected. Thus, even in this district, which had a reasonably extensive health structure, little more than 10% of all cases were being reported. The true incidence was about 1 case per 1000 population, a figure far higher than that recorded in the most highly endemic countries during this period and an incidence substantially greater than was detected subsequently in any year in any district of West Pakistan.

Data regarding the age and outcome of illness were reported for 1034 of the patients. The age distribution and case-fatality rates were similar to those observed elsewhere in the Indian subcontinent: 29% of cases occurred among children under 5 years of age and a similar percentage (28%) among persons aged over 15 years (Table 14.19). In all, 16% died, but among infants (under 1 year) case-fatality rates reached more than 50%.

Despite the substantial number of cases, sample surveys of 15 villages showed a remarkably high proportion of persons who had previously been vaccinated. Among 6000 persons examined, 88% had either vaccination scars or the pockmarks of smallpox (Thomas et al., 1972). Three-quarters of the cases had occurred among the 12% who had not been vaccinated before exposure (Table 14.20). Among the unvaccinated household contacts of cases, 88% developed smallpox, compared with only 7% of people who had been vaccinated at some time.

Table 14.19. West Pakistan, Sheikhupura District: number of reported cases of and deaths from smallpox and case-fatality rates, by age group, 1966–1967[a]

Age group (years)	Cases		Number of deaths	Case-fatality rate (%)
	Number	%		
<1	68	7	38	56
1–4	232	22	32	14
5–14	445	43	46	10
⩾15	289	28	46	16
Total	1034	100	162	16

Within preceding 10 years	115	5	4
Previous smallpox	27	0	0
Total	250	51	20

[a] Based on Mack et al. (1972a).

Studies of smallpox transmission in 6 rural districts showed that vaccinated persons who experienced infection transmitted the disease to others only one-fourth as often as did unvaccinated persons with smallpox (Heiner et al., 1971b; see Chapter 4, Table 4.10).

In brief, smallpox transmission was sustained primarily by perhaps 150 000 persons of Sheikhupura District's 1.2 million residents. Pakistan's vaccination campaign had been more effective, at least in this district, than had been thought. A later study, done in Lahore Municipal Corporation, showed even higher levels of protection. In Lahore, 93% of all persons surveyed showed vaccination scars or the pockmarks of smallpox. Even among infants under 1 year of age 39% were protected, and among children aged 1–4 years 84% were protected (WHO/SE/69.13, Heiner et al.; Ali & Heiner, 1971).

The seasonal fluctuation in incidence was significant (Fig. 14.9), the peak occurring during the colder, drier months of November to the end of March. By September, at the end of the hot summer monsoon, smallpox had all but vanished (Thomas et al., 1972); in the first week of September 1966, only 1 village in the entire district was infected. However, even at the peak of the transmission season, not more than 50 of the 1700 villages in the district were infected at one time.

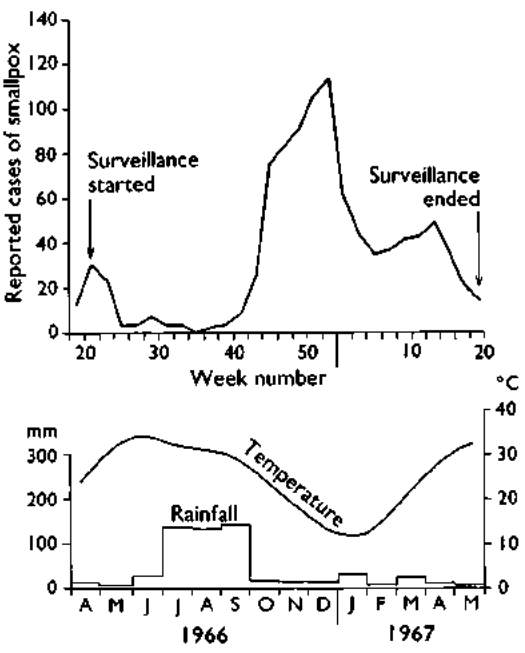

Fig. 14.9. Pakistan, Sheikhupura District: number of reported cases of smallpox in relation to meteorological data, by 2-week intervals, 1966 – 1967.

The outbreaks were often small and most terminated spontaneously. Smallpox was found to spread far less readily than measles or influenza, for example. Nearly one-third of the outbreaks consisted of single cases and in only half of the 121 outbreaks did new cases develop more than 4 weeks after the first case had occurred (Thomas et al., 1972). Even when transmission did occur, an average of only 2.4 new cases was recorded during each 2-week period. The larger outbreaks were of greater epidemiological importance. More than 50% of outbreaks with 5 cases or more were identified as sources of other outbreaks, compared with only 15% of outbreaks with fewer than 5 cases.

Contrary to what many supposed, smallpox was rarely transmitted at large public gatherings or transferred from place to place by nomads. Most infections were acquired as a result of contact with the patient in his own home (Thomas et al., 1972).

A further significant observation was the identification of large urban areas as important foci for spread. Of 74 outbreaks for which a specific source of infection could be determined, 42 (57%) could be traced directly or indirectly to cities, in which only 19% of the Punjabi population resided (Thomas et al., 1972).

The group of investigators pointed out that if Sheikhupura District and the Lahore Municipal Corporation were representative of other areas with regard to vaccinial immunity levels, a mass vaccination campaign had, to all intents and purposes, already been carried out. They recommended that instead of conducting another mass campaign, attention should be focused on the detection of cases and the containment of outbreaks, especially in urban areas. Such an approach would be especially effective during the summer, when only a few localities were infected. Because the disease spread slowly within and between villages, they believed that few resources would be required to cope with the outbreaks. Even if the reporting of cases was not improved, the effective containment of those that did come to notice should have a significant impact, since, as had been found, the larger outbreaks were reported more often and were most frequently responsible for spread to other localities. Because of the importance of cities in transmission, it was reasoned that urban areas should be given priority in mass vaccination campaigns, if such were to be conducted, and that emphasis should be placed on primary vaccination.

The observations in Sheikhupura District were subsequently found to be applicable throughout most of Pakistan. Not all areas had as high levels of vaccinial immunity as Sheikhupura, but everywhere successful immunization had been far more extensive than anyone had believed and the epidemiological pattern of spread of smallpox was similar. The recommendations of the group of investigators proved to be sound when they were eventually put into practice in Pakistan in 1972.

Beginning of the Mass Vaccination Campaign, 1968–1969

The plan of operations was signed in August 1967 by WHO and in April 1968 by the government, in Islamabad. Planning, procurement of supplies and recruitment of staff took longer than expected, but in June 1969 field operations finally began. West Pakistan, in 1969, was divided into 6 health regions, each comprising about 8 districts. Each district had a population of 1–2 million. The plan called for systematic mass vaccination campaigns in 2 regions each year. When the mass vaccination campaign was completed in a region, maintenance vaccination would be introduced to vaccinate neonates and migrants and to revaccinate the entire population every 3–4 years (Table 14.21).

The inhabitants of the two most populous health regions of Sargodha and Lahore, in which Sheikhupura District was located (Fig. 14.10), would be the first to be vaccinated. The campaign was to be directed by 2 provincial medical officers assisted by the WHO adviser and, at each health region office, by 2 medical officers, plus supporting clerical staff. At the health region level, a unit composed of 10 vaccinators and a superintendent of vaccination were to undertake surveillance activities and to control epidemics. The primary operational unit was the district, in which the campaign was to be directed by a full-time medical officer, a district superintendent of vaccination and teams of 10 vaccinators. A complement of 50 vaccinators for every million persons was considered necessary. This number was determined on the assumption that each vaccinator would perform an average of 100 vaccinations a day over 200 working days each year. Each operational group of 50 vaccinators would have a group leader and 5 assessors to check performance; vaccination was to be conducted village by village and house by house, the inhabitants of each locality to be vaccinated systematically by an operational unit of 10 vaccinators. The units would continue work in a locality until a number equivalent to 85–90% of the estimated population had been vaccinated. As in Afghanistan, the plans called for the teams to spend 24 consecutive days in the field, followed by 7 days' leave. A 10% sample of the vaccinations performed was to be assessed 1 week after vaccination. In addition to the surveillance–containment unit at regional level, a 10-man surveillance and containment unit was to be established in each district. The projected manpower required and the number available as at December 1968 are shown in Table 14.22.

Table 14.21. West Pakistan: plan for mass vaccination campaign—number of vaccinations to be performed each year, (thousands)

Others	47	27	20
Total	1 412	1 237	175

WHO agreed to provide US$200 000 in support of the programme, for the purchase of 25 Land Rovers, 125 motor cycles, 1300 bicycles, 25 refrigerators, a stock of bifurcated needles, and miscellaneous supplies. (Eventually WHO provided approximately US$1.3 million to the programme, as well as 70 million doses of vaccine (Table 14.23).) Freeze-dried vaccine produced at the Institute of Public Health, in Dhaka, East Pakistan, was to be used. It was calculated that the government of West Pakistan would need to increase its budget for smallpox eradication from 1 334 650 rupees to 2 728 480 rupees (US$278 800–570 000) for each of the 3 years of the Intensified Programme. It was expected that the previous level of financing would be adequate to cover the maintenance phase.

The findings and recommendations of the research group from Lahore did not become available until shortly after this plan was drawn up in August 1967. Even so, sufficient resources were foreseen in the plan to permit surveillance and containment activities of the type recommended.

[a] Excluding supplies of vaccine (about 70 million doses).
[b] WHO records reflect support given to both West Pakistan and East Pakistan (which became the independent state of Bangladesh in December 1971). Approximately half of the total was provided to West Pakistan and these are the figures shown in the table.

By December 1968 major problems had become apparent. The government did not increase the budget but, in fact, decreased it by 30%—to 1 million rupees. The plan envisaged the use of local body vaccinators as part of the complement of personnel but they were responsible to their own union councils (administrative units each responsible for a population of about 10 000) and the councils, in turn, to the Ministry of Basic Democracy. As the WHO adviser was to report: "A number of vaccinators have been appointed under political pressure and many of them are recommended by influential persons and are engaged in other duties or private jobs." Likewise, vaccinators in the municipal areas were under an entirely different jurisdiction, and there was no coordination of their activities with those of the provincial or regional staff. The problems of programme direction were further complicated when supervisory staff indicated that they could not travel to the field because the government's travel allowance was too meagre to cover the cost of even the most austere board and lodging. Last but not least of the difficulties was that no provision had been made for the purchase from programme funds of freeze-dried vaccine from the government's quasi-independent Dhaka laboratory. Up to this time, liquid vaccine had been purchased by union councils with their own funds and no administrative mechanism existed to permit these funds to be diverted to the purchase of freeze-dried vaccine.

One by one, the problems were solved or partially solved by a variety of means. Because vaccine production at the Dhaka laboratory was found to be inadequate to supply more than East Pakistan, WHO provided freeze-dried vaccine which had been contributed by various donors, primarily the USSR. WHO agreed to provide funds to supplement the travel allowance of national supervisory staff to permit them to travel to the field. The Ministry of Basic Democracy was, with difficulty, persuaded to issue an order to the union councils directing local body vaccinators to work with the programme, an order which was subsequently ignored as often as it was respected. Eventually, the national government authorized additional funds to recruit the requisite staff.

The programme in the 16 districts began in June 1969, but outside these districts no effort was made to develop reporting or surveillance activities. Even in the 16 districts, the so-called "fire-fighting" and surveillance teams did little. Indeed, in Lahore, one of the principal urban centres, a surveillance programme was not established until May 1972.

In all, some 1600 government staff participated in the unnecessary mass vaccination campaign in the 2 regions. The campaign was completed at the end of May 1970. One million primary vaccinations and 22 million revaccinations were recorded in a population of 27 million persons. Between March and May, 313 000 persons in 546 localities were examined to determine the level of vaccinial immunity achieved. The survey revealed that only 3.7% of them had neither a vaccination scar nor the pockmarks of smallpox. Even making allowance for possible errors in the assessment, it was apparent that the residual number of susceptible individuals was small but, as the research group from Lahore had shown, the number of unprotected persons had not been large when the vaccination campaign began. The marginal improvement was confirmed by a study in a division in which the health services were the least adequate: before the campaign, 10.5% of the population were found to be unprotected; after its completion, 8% remained unprotected.

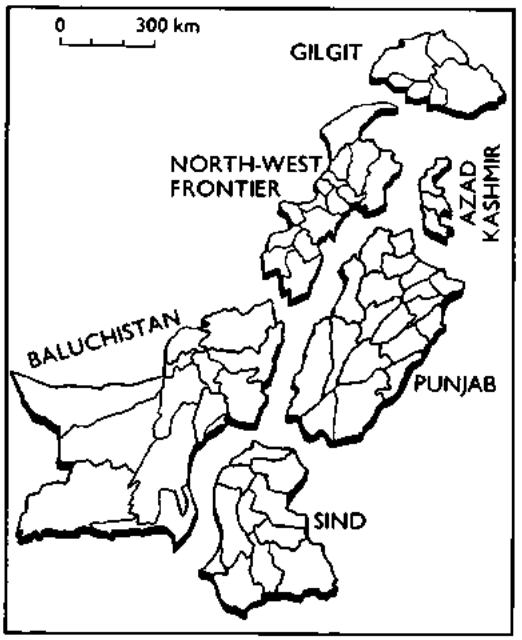

Fig. 14.11. Pakistan: provinces (or federally administered areas) and districts in July 1970.

One Programme Becomes Six, July 1970

On 1 July 1970, the administrative divisions of West Pakistan were abruptly changed by the government as part of the efforts to cope with increasing tensions in the relationships between East and West Pakistan. As has been mentioned above, the province of West Pakistan was divided into 4 independent provinces and 2 small, federally administered regions in the north of the country (Azad Kashmir and Gilgit) (Fig. 14.11). The populations of the provinces differed greatly in size: Punjab, 32.1 million; Sind, 11.9 million; North-west Frontier Province, 9.5 million; and Baluchistan, 1.6 million. The 16 districts in which the mass vaccination campaign had been conducted were all in Punjab Province, along with 3 additional districts. Early in the autumn of 1970, mass vaccination was completed in these 3 districts, during which an additional 200 000 primary vaccinations and 2.4 million revaccinations were reported to have been given. However, as shown in Fig. 14.12 and Table 14.24, the total of 25.6 million vacci-

[a] Mass vaccination campaign conducted during which 25.6 million vaccinations were performed.

nations performed in Punjab Province had little impact on the reported incidence of smallpox.

The failure of the campaign to have any apparent effect on the reported number of cases might be thought to reflect a better notification of cases, which masked the effect of the vaccination campaign. In fact, however, the surveillance teams functioned poorly and the notification system was not improved during this period.

Because of the subdivision of West Pakistan into 4 separate provinces and because each of the provinces was granted almost total autonomy in health matters, new provincial governments had to be persuaded of the need to undertake a smallpox eradication programme, to create some sort of organizational structure, to establish a budget and to recruit and/or assign personnel. In 3 of the provinces, no smallpox eradication activities had yet been undertaken. The national government and the national programme director had responsibility for the signing of agreements with WHO to permit advisers to be assigned and equipment to be provided, but had no authority over field activities except in the remote and sparsely populated Azad Kashmir and Gilgit.

The constraints on federal authority are illustrated by the frustration experienced in endeavouring to establish a vaccine production facility in the newly constructed national laboratories in the capital, Islamabad. In 1970 WHO offered to provide equipment for vaccine production and consultant assistance to establish a facility, which, it was hoped, would produce vaccine for the whole of West Pakistan. The federal government insisted that this could be done only if the government of Punjab transferred funds to the federal government that had previously been used to finance the now defunct liquid vaccine production unit at Lahore. After prolonged negotiation, agreement was reached and WHO ordered and delivered the production equipment. Because of Punjab's later refusal to honour the agreement, the equipment was never used. Vaccine for the programme continued to be provided by WHO, initially from various donors but after 1973, from the Pasteur Institute in Iran, which donated large amounts of vaccine to WHO.

In an effort to establish a programme encompassing the entire country, an interprovincial meeting was convened in December 1970 to seek the agreement of all provinces to undertake programmes. Two years had elapsed since the projected commencement of the programme in West Pakistan, but little had been achieved, except for mass vaccination in 19 districts. Meanwhile, the incidence of smallpox had remained virtually unchanged (Fig. 14.13). The lack of accomplishment after the expenditure of effort in districts with the most developed government and health structures and the greatest resources offered little encouragement for success at a national level.

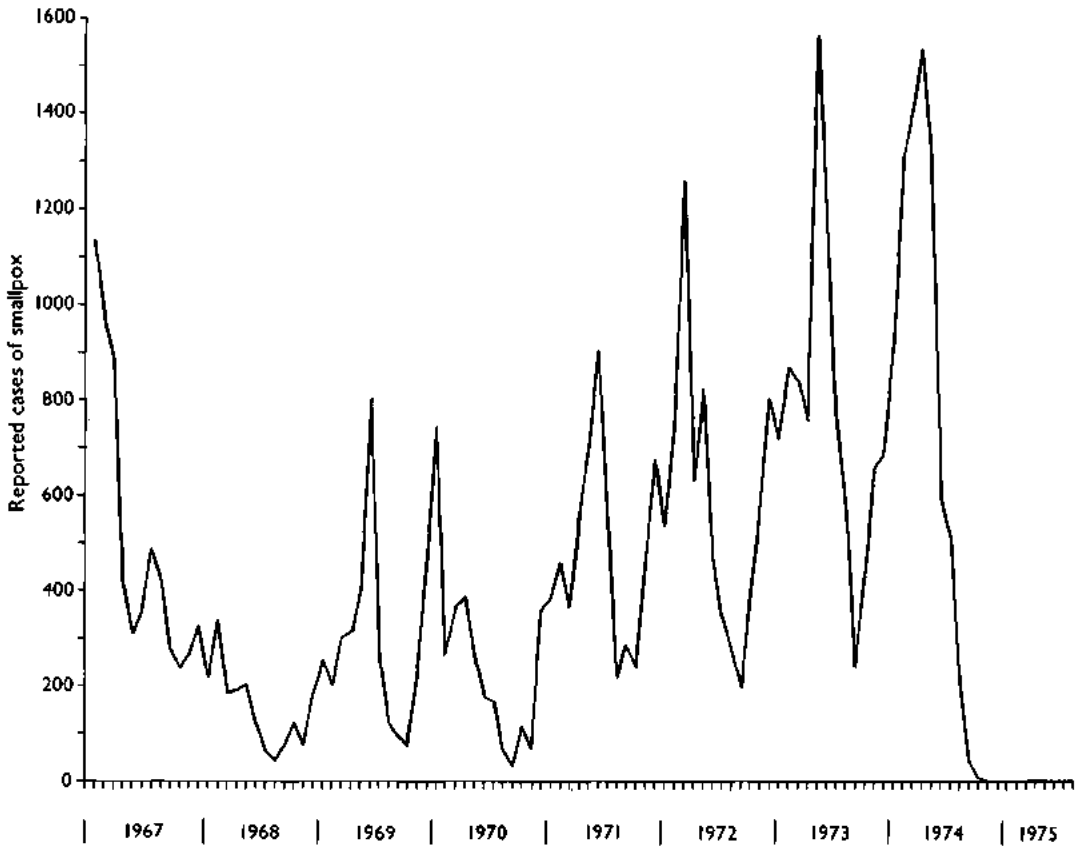

Fig. 14.13. Pakistan: number of reported cases of smallpox, by month, 1967–1974.

The Fourth Year of the Programme, 1971

At the meeting in December 1970, representatives of each of the provinces of West Pakistan agreed to give high priority to smallpox eradication: to create the necessary administrative structure, to develop a reporting and surveillance system and to seek the necessary funds for a systematic mass vaccination campaign. WHO agreed to recruit 3 additional advisers so that one could be assigned to each province, the senior adviser continuing in his capacity as national counterpart as well as adviser to the programme in Punjab. Additional supplies and equipment were ordered by WHO and travel allowances were provided for senior supervisors in all provinces. Meanwhile, because title to the vehicles and other equipment provided by WHO remained with the Organization, some supplies from Punjab Province were transferred to other provinces, an otherwise impossible action in the case of government-owned supplies.

It was agreed that interprovincial meetings would be held twice a year to coordinate the 4 separate programmes. However, each programme developed more or less independently, employing different strategies and achieving varying degrees of success. All of them encountered difficult obstacles, in the first instance because of the diversion of resources due to the civil war in East Pakistan, and then as a result of the tension between India and Pakistan at that time. In December 1971, when East Pakistan became the independent state of Bangladesh, these difficulties abated and additional resources were made available to all programmes. Three additional WHO advisers were recruited, arriving between March and June 1971. They were assigned, respectively, to Sind, North-west Frontier Province and Baluchistan. However, little was done during that year in Baluchistan, or in Sind except in the city of Karachi.

In 1971, Punjab Province appeared to be the best candidate to achieve the early interruption of transmission. Because 60% of the

population of West Pakistan lived in that province, it was believed that the interruption of transmission there would provide an impetus to the other provinces. A programme had been in operation for 3 years, the mass vaccination campaign had been completed, and few susceptible persons remained. The reporting system had improved little since 1968, but with the vaccination campaign finished, smallpox staff found themselves with few responsibilities other than to develop a surveillance–containment programme. In May, 8 assistant superintendents of vaccination and 19 vaccinators were trained in surveillance activities and began working in 2 teams under the direction of the Provincial Smallpox Eradication Officer, Dr M. B. Khawaja, who was succeeded by Dr Mohammed Rafique. In the summer of 1971, all district health offices were ordered to send weekly telegrams to report the number of cases discovered during the week. With 1407 health units (172 hospitals, 893 dispensaries, 39 rural health centres and 303 maternal and child health centres) in which cases might be identified, it was reasonable to expect that the reporting of outbreaks would be quite complete if a system could be developed.

Because there were only 2 large teams engaged in search and containment in a province of 32 million people, and because telegraphic reports were then being received from less than half of the districts despite the provincial order, many outbreaks continued to be overlooked. More important, little was done in urban areas—the chief foci for the dissemination of smallpox. Programmes in the urban areas were the responsibility of the municipal corporations, each of which had its own health structure, and these, independent of provincial policies and supervision, continued to carry out traditional routine vaccination campaigns.

During 1971, the Punjab surveillance teams investigated 81 outbreaks, in which 561 cases had been reported; an additional 1475 cases were discovered. Although the total of 2036 cases was the same as that recorded in 1969, when the vaccination campaign began, the number of cases declined sharply in the latter half of the year, only 20–90 being reported monthly between July and November.

Meanwhile, in North-west Frontier Province, an energetic WHO adviser, Dr G. P. Marchenko, arrived in March 1971. With the help of an able provincial medical officer, Dr Mohammed Ayaz Khan, the province launched a mass vaccination campaign in May in 4 of its most populous districts—Peshawar (the capital), Mardan, Hazara and Swat. In contrast to Punjab, case detection was specifically emphasized as an important component of activity. Numerous cases were discovered by the vaccination teams (Table 14.25; Fig. 14.14). By the end of the year, 2654 cases had been detected, most of which (2132) were in the 4 districts in which the campaign was being conducted. This was 5 times the number recorded during the preceding year. The

"epidemic" alarmed provincial authorities but stimulated political interest and support, which continued throughout the rest of the programme.

Commencement of Country-wide Activities, 1972

During 1972, smallpox eradication programmes were introduced in Sind and Baluchistan Provinces and activities at last extended throughout most of the country. The provincial programmes progressed at different speeds and encountered such different problems that each is described separately. The remarkably successful programme in North-west Frontier Province is dealt with first. Transmission was interrupted only 2 years after the programme had begun, but the area was inundated by importations from the other 3 provinces for more than a year thereafter. Next to be discussed is the programme in Punjab, with its large population and attendant operational problems, and then the inadequately supported and poorly organized programmes in Sind and the sparsely populated Baluchistan. Table 14.26 shows the number of reported cases by year for each of the provinces during the period 1970–1975.

North-west Frontier Province

North-west Frontier Province extends from the foothills and mountains of the Himalayas along the border with Afghanistan to the plains of the Indus river in the east and south-east (Fig. 14.15). About three-quarters of the population are traditionally independent Pathans, some of whom at that time enjoyed semi-autonomy in federally administered tribal areas in the mountainous districts of Waziristan, Khyber, Kurram, Malakand and Mohmand. Extensive vaccination campaigns had been conducted during the preceding years throughout the plains and foothills, as in Punjab, but in some sparsely settled mountainous and tribal areas variolation continued to be practised.

The house-to-house vaccination campaign, which began in May 1971 in 4 districts, was completed in June 1972. A staff of 350 persons vaccinated 3.6 million people (about 80% of the 4.4 million inhabitants of the area). Initially, the search for cases and the containment of outbreaks were limited to these 4 districts. In July 1972, vaccination campaigns were initiated in the districts lying in the Indus river plain (Kohat, Bannu and Dera Ismail Khan) and efforts were made to launch

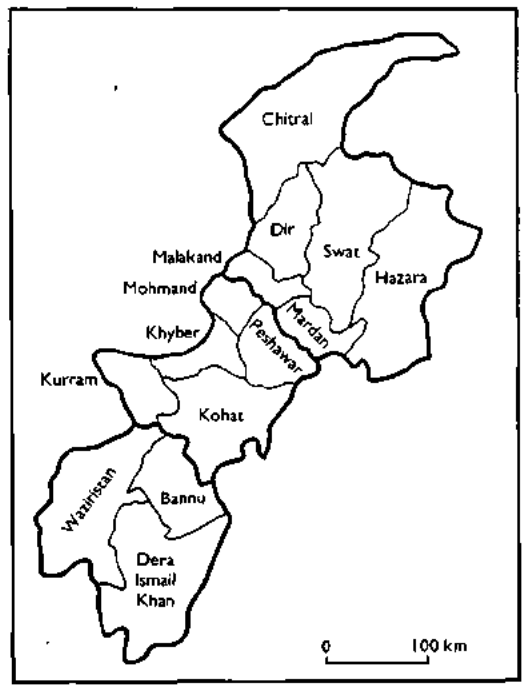

Fig. 14.15. Pakistan: districts of North-west Frontier Province, 1973.

campaigns in the tribal agency districts. The latter were soon abandoned, however, when it was discovered that frequently only 5% or less of the population would accept vaccination. Data on the efficacy of the vaccination campaign are available from surveys conducted in 1973 in 5 districts. The results were, in general, comparable to those in Punjab (Table 14.27).

Simultaneously with the beginning of a vaccination campaign in the Indus river plain, case detection and outbreak activities were extended throughout the province. Six "fire-fighting" teams, each with a vehicle, were trained and assigned responsibility for designated districts to improve case notification and to detect and contain outbreaks. Meanwhile, in Peshawar, the capital, 20 teams of 2 persons each began a house-to-house search for cases. When cases were discovered, an 8-man team carried out containment vaccination. For the first time in Pakistan, the strategy which had been recommended 5 years earlier by the Pakistan Medical Research Centre team was finally to be implemented.

The number of cases steadily decreased during the late spring and throughout the summer—the seasonal low point in smallpox transmission—and from October to the end of December, only 100 cases were discovered, of which 98 were in Peshawar District. The outbreaks all occurred near Peshawar City, in small villages frequented by smugglers from the tribal areas. None of the outbreaks was large but containing them proved difficult because the villages were considered to be dangerous, especially at night, and the villagers often refused to provide information about cases. Additional impetus was given to the programme, however, when in November a new WHO adviser arrived—Dr Reinhard Lindner, who had played an important role in developing the surveillance–containment strategy in Indonesia. Gradually, the problem in Peshawar came under control, and in April 1973 the last cases occurred in that district.

Table 14.27. North-west Frontier Province: results of vaccination scar survey in children under 15 years of age in 5 districts, August 1973

District	Number examined	% with scar, by age group (years)		
		<1	1–4	5–14

Peshawar	4 872	50	91	97
Mardan	4 032	69	94	98

Meanwhile, cases began to be reported in January 1973 in the tribal areas of Kurram and Khyber, probably introduced from Peshawar. The teams were permitted to enter the area only with a military guard and only after assuring tribal leaders that they would not vaccinate them but would merely document the numbers of cases and deaths. In all, 101 cases were recorded in the outbreaks. Fortunately, smallpox transmission ceased spontaneously, probably in response to the traditional practice in villages of isolating cases and permitting only those previously infected with smallpox to care for the patients.

During the first 6 months of 1973, the only cases detected in the entire province apart from those in Peshawar and the Kurram–Khyber tribal area were 2 imported into Mardan from Punjab Province in January, and 2 in Swat notified in May following an importation from Karachi. By May, it appeared that transmission had been interrupted. The vaccination campaign was stopped and the vaccinators were assigned solely to a search for cases. A reward of 25 rupees (US$2.50) was offered to anyone who detected a case. Numerous rumours were investigated but no cases were found. In October, the reward was doubled.

In November, however, importations began, primarily from Punjab but also from Sind and Baluchistan. Between November 1973 and September 1974, 35 outbreaks and 173 cases occurred. Of 34 outbreaks for which a specific source could be identified, all could be traced to Punjab, except 3 from Sind and 1 from Baluchistan. All but 3 of the cases were in the northern districts of Hazara (136 cases), Swat (26 cases), Dir (7 cases) and Mardan (1 case). The province's final outbreak of 3 cases occurred in the southern district of Dera Ismail Khan, the last on 7 August 1974. Subsequent extensive search and a reward which was progressively raised to 200 rupees, then to 500 rupees and finally to 1000 rupees failed to uncover further cases.

Only partial data are available regarding the age distribution and vaccination status of cases in the province (Table 14.28).

As in Afghanistan, only a small proportion of cases occurred among adults, of whom, however, one-third had scars indicating previous vaccination. Fifty-eight percent of the

cases occurred in children under 5 years of age, and although 10% were reported to have been vaccinated before onset, in some instances vaccination had been performed late in the incubation period during containment vaccination.

The achievements of the programme in North-west Frontier Province were notable. In April 1973, less than 2 years after the start of activities, transmission was interrupted, despite a health structure inferior to that of either Punjab or Sind Province, despite the greater difficulties of transport and communication and despite the existence of large population groups which refused vaccination. One might suppose that the authorities of other provinces would have found its programme and strategy instructive but, in fact, they openly doubted the reported results. In rancorous interprovincial meetings, they expressed scepticism and denounced the authorities of North-west Frontier Province for asserting that after April 1973 the only cases of smallpox that had occurred there had been imported from their provinces. Most adamant and vocal were representatives from Punjab Province.

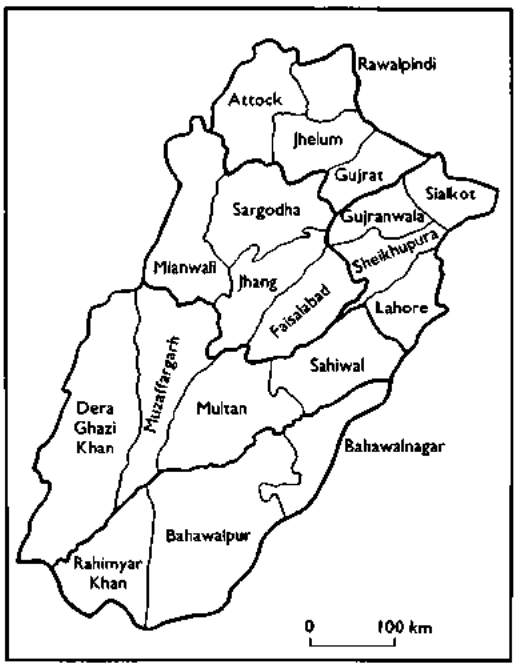

Fig. 14.16. Pakistan: districts of Punjab Province, 1973.

Punjab Province

During 1972, Punjab Province strengthened its surveillance programme. Instead of 2 large surveillance groups, more surveillance teams of smaller size were created, each of which travelled extensively to improve reporting from the districts (Fig. 14.16) and to search for cases village by village. In all, 1495 cases were detected, 500 fewer than in 1971, when reporting was far less complete. Outbreaks were detected and contained reasonably quickly—73% being detected within a month of onset and 97% within 2 months.

Little was done in urban areas, however, until May 1972, when special measures were taken to control smallpox in Lahore, the provincial capital. In the municipal corporation, 75 vaccinators were then working in 34 vaccination centres, only rarely leaving these centres to vaccinate people in the surrounding community or to detect and contain cases. It was agreed that a WHO adviser would be assigned to work in the corporation and, in May 1972, 6 sanitarians were trained in methods of case detection. One each was assigned to 4 sectors of the city and 2 were retained at headquarters to investigate cases brought to the infectious disease hospital.

Each of the 34 vaccination centres was designated a primary reporting unit, which would send reports weekly, and 51 of the 75 vaccinators were assigned to a house-to-house search for cases; a special containment team of 10 vaccinators was stationed at the provincial office. A report prepared in October documented 314 cases in 52 outbreaks in Lahore District, primarily in slum areas around the perimeter of the city. Almost one half (41.4%) of the cases were detected within 2 weeks of onset and 72% within 1 month. Only 4 outbreaks were traced to importations from other districts and these resulted in a mere 7 cases. However, numerous outbreaks, originating in Lahore, were identified during 1972 in other districts in the central and northern parts of the province. Indeed, between July and September, 37% of all cases in Punjab could be traced to Lahore. Cases in the city continued to occur primarily among unprotected persons, who had been found, in a 1969 survey, to constitute only 6.9% of the total population (Ali & Heiner, 1971). Although immigration may have increased the proportion of susceptible persons somewhat during the 3 succeeding years, a continuing vaccination campaign served to sustain vaccinial immunity. Attack rates among contacts in infected households substantiated the fact that those who had previously been vaccinated were at significantly less risk than the unvaccinated (Table 14.29).

The importance to the province of controlling smallpox in Lahore had long been pointed out and this was fully substantiated when an effective programme was finally begun. Coincidentally with a decrease in incidence in Lahore, the number of reported cases of smallpox in Punjab, as well as in neighbouring North-west Frontier Province, fell sharply during the summer of 1972 and continued to decline during the autumn and winter months.

The programme was so successful that during March 1973, at the time of highest seasonal transmission, only 2 cases were detected in Lahore and only 8 in the entire province of Punjab. The Provincial Director of Health Services decided that the programme had succeeded and decentralized the surveillance operation. The Provincial Director of the Smallpox Programme was informed that he should undertake no further field travel and the WHO vehicle assigned to him was given to another medical officer. Each of the 5 divisional deputy directors of health services was assigned responsibility for one of the surveillance teams, and they in turn directed the teams to undertake other duties, primarily cholera vaccination. Surveillance in Lahore effectively ceased.

Through late October, the reported incidence of smallpox remained low; in fact, from 2 September to 20 October, no cases whatsoever were reported in Lahore District. It was the calm before the storm (Fig. 14.17). In late October smallpox outbreaks were again detected in Lahore, although investigations revealed that the city had, in fact, never been free of the disease. During December small-

pox spread widely through the city and cases began to appear in other districts and in North-west Frontier Province. By the end of December, 8 districts of Punjab had recorded outbreaks.

Despite the enormous resources and energies that had been devoted to the programme in Punjab, the situation had deteriorated to such an extent that conditions were not much better than they had been before the initiation of the mass vaccination campaign more than 5 years earlier. As at December 1973, the provincial smallpox eradication programme, such as it was, consisted of 4 wholly independent and uncoordinated components: (1) the Provincial Smallpox Eradication Officer with 8 assistant superintendents of vaccination and 14 surveillance agents; (2) 5 divisional surveillance teams under the direction of deputy directors of health services; (3) 19 independent district health offices, each with supervisors and vaccinators—some 1200 persons in all; (4) the municipal corporations, with their separate staffs.

It had been demonstrated beyond question in North-west Frontier Province that smallpox transmission could be interrupted even in difficult areas if the available resources were effectively managed. The problem in Punjab was to obtain an adequate political commitment, an appropriate strategy and a stability of leadership for long enough to permit this to be done.

Three events ultimately provided the necessary stimulus to a political commitment. The first was the recording in 1973 of 9258 cases of smallpox, the country's highest total since 1948. Although this could be attributed to more complete notification, the political authorities were alarmed and began both to query the performance of health officials and to make greater resources available. The second event was the interruption of transmission in Afghanistan in 1972, which caused some embarrassment in Pakistan. Afghanistan, considered to be a far less developed country, pointedly and repeatedly indicated to the Pakistani authorities that all its cases since mid-1972 had resulted from importations from Pakistan. The third incident was India's decision in the summer of 1973 to mobilize its vast resources of health manpower to undertake monthly village-by-village searches to detect and contain outbreaks throughout the country. Optimistically, the Indian government forecast that the interruption of transmission would occur between January and June 1974. With Bangladesh and Nepal making excellent progress, it appeared that by late 1974 Pakistan might well be the last reservoir of smallpox in Asia.

Manpower in Punjab was not a problem but leadership and management were. A change occurred in February 1974 with the arrival of a new WHO adviser—Dr Omer Sulieman, the dynamic former director of the successful eradication programme in the Sudan. Within weeks, a moribund programme began to revive, and only 10 months later Punjab recorded its last case.

On his arrival in Lahore, Dr Sulieman reported on the situation: no plan or targets had been committed to paper; the concept of surveillance was accepted in principle but ignored in practice; officials continued to insist that vaccination targets should be met in all areas; there was no search for cases; containment was poor; and cooperation between different groups was so lacking that even data regarding cases were not forwarded to the provincial office.

The Secretary of Health extended full support and ordered district and municipal corporations to cooperate with the programme. A written document establishing guidelines and technical commitments was prepared and distributed; surveillance teams were reconstituted and trained; a reward of 10 rupees for each new outbreak reported was announced; and vaccinators were asked to search for cases among the groups of people they vaccinated. To intensify the search, population planning and malaria eradication staff were directed to undertake a house-to-house search for 1 week each month. When it was found that women were better received by the people and were more effective in searching for cases, 12 000 were employed between February and May; most of them were traditional birth attendants or municipal sweepers. In addition, during March, a special 2-day house-to-house search was conducted in Lahore by 50 000 schoolchildren and their teachers. They discovered 1800 persons with rash and fever of whom 13 were suffering from previously undetected smallpox.

Between February and May, substantial progress was made in the detection and containment of outbreaks but the smallpox incidence remained high. This was due, in part, to more complete reporting and, in part, to the high seasonal transmission. By June

1974, it was apparent that the cities of Lahore, Multan and Lyallpur (Faisalabad) were the key problems, accounting for the majority of cases and representing the source of infection of many rural outbreaks. In these cities, containment activities were strengthened, in line with the procedure then operating in India, by assigning a supervisor and 3 vaccinators to each outbreak to list and to vaccinate all residents and to stay in the area to vaccinate visitors until the outbreak was controlled. A vaccinator was also posted at each infected house until the last case had recovered. Efforts were also made to find and vaccinate all relatives, wherever they resided.

Whatever their instructions, some district health officers continued to rely on vaccination rather than surveillance and so, in June, routine vaccination was officially suspended and vaccinators were assigned solely to search and containment activities. To improve coordination, the Secretary of Health began to hold monthly meetings with all district health officers to emphasize his personal concern. In July, the health officers were relieved of other official duties in order to supervise a village-by-village search programme which covered one-third of the province's 23 692 villages each month. This programme was similar to that which had begun in India almost a year before.

With a declining number of cases and outbreaks—partly because of better control activities and partly because of the seasonal decline in smallpox incidence—it was possible to exercise better supervision in each remaining outbreak. Careful efforts were made to trace the source of cases and containment was tightened. Finally, on 16 October 1974, the last case of smallpox in Punjab, and in Pakistan as a whole, occurred in Multan City. The search continued, enhanced by the offer of a growing reward, but no further cases were found.

In Punjab, less than 10 months had elapsed since the introduction of the first well-coordinated province-wide programme of surveillance–containment and the occurrence of the last case. However, almost 6 years had passed since the beginning of the programme.

Baluchistan Province

Until 1972, little was achieved in the eradication programme in Baluchistan, the most sparsely populated and least developed of Pakistan's 4 provinces. It occupies 40% of Pakistan's land area and is composed of desert and rolling hills with few roads. Only 10% of the land was arable, most of it being in the eastern districts, in which the population was concentrated (Fig. 14.18). Baluchistan was a new province, created in July 1970, and the government structure was only beginning to take shape. Communication and travel were difficult; the postal service was all but non-existent; and fewer than 100 physicians were employed there. Vaccinial immunity in Baluchistan was substantially lower than elsewhere in Pakistan, as was demonstrated by a scar survey performed in 1976 in 3 of the districts in which health services were the best (Table 14.30).

A mass vaccination campaign began in 1971 in the more populous north-eastern area of Quetta, Pishin and Zhob, employing some 30 vaccinators and some 20 support and supervisory staff. In fact, little was achieved, the numbers of recorded vaccinations for the province actually showing a decline, from 549 000 in 1970, to 422 000 in 1971.

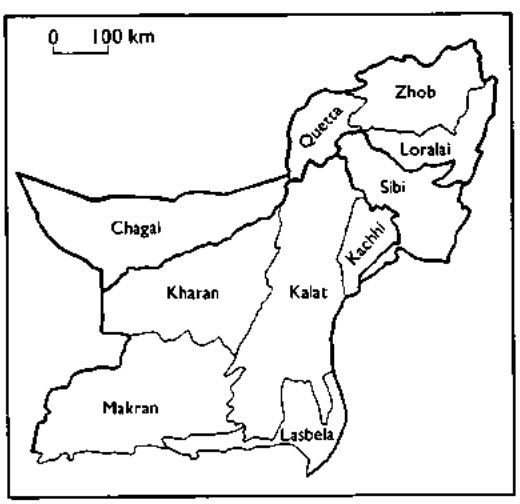

Fig. 14.18. Pakistan: districts of Baluchistan Province, 1973.

Table 14.30. Baluchistan: results of vaccination scar survey, in children 5 years of age and under, 1976

Quetta	6	78	0	29
Zhob	17	997	15	59
Total	42	1794	17	50

In May 1971, a WHO adviser was assigned to the province, but the difficulties of maintaining even a few vehicles in operation in the field proved formidable. In the latter part of 1971 and in 1972, some outbreaks were investigated and vaccinations performed in and around Quetta, the capital, but little progress was made until the summer of 1972, when it was decided that a mass vaccination campaign was not feasible and the effort was abandoned. Surveillance agents were then posted to each district and 5 mobile teams, each composed of 4 persons, were constituted; 2 of these undertook a search for cases and 3 performed vaccinations in what were considered to be vulnerable areas. The number of reported cases increased from 80 in 1970 to 291 in 1971 and to 559 in 1972 (Table 14.31). Cases were reported from each of the 10 districts in 1972, but most of them (444) were in Quetta and the nearby town of Sibi, in which the mobile teams were working. In all, the teams themselves detected 486 (87%) of the cases.

The surveillance programme futher improved following the arrival in February 1973 of an experienced WHO adviser, Dr P. R. Arbani, a national of Indonesia who had worked in the smallpox eradication programme in that country. By July, weekly reports of cases began to be received routinely from all districts. With improved training and increasing involvement of the few existing district and local health staff, cases were detected more quickly and were better contained. During 1973, 165 outbreaks with 801 cases were documented. With the exception of 2 cases in Chagai, all cases were reported from the more populous north-eastern districts.

Table 14.31. Baluchistan: number of reported cases of smallpox, by district, 1970–1974

Zhob	6	2	19	23	0
Total	80	291	559	801	202

By 1974, the surveillance programme was functioning far more effectively. Only 40 outbreaks with 202 cases were discovered during that year, of which 27 were detected within 2 weeks of onset; 30 of the 40 outbreaks consisted of only 1 or 2 cases (Tables 14.32 and 14.33). The last 4 outbreaks (of 2, 18, 23 and 65 cases respectively) occurred in Baluchistan in the summer of 1974 and were associated with variolation in Kalat District. Although the outbreaks were quickly detected, many cases among variolated children were already late in the incubation period before the team arrived.

Smallpox Transmission on Public Transport

Variola major was usually transmitted within the confines of a building, primarily in a household and sometimes in a hospital. Public transport was rarely implicated. This was because patients usually experienced a severe prodromal illness before developing rash and being able to transmit infection. Fortunately, few people travelled on public transport after first becoming ill but, if they did, infection could be disseminated rapidly and widely. One such episode occurred in Loralai District, Baluchistan, in July 1972.

On 21 July, a 4-year-old girl, accompanied by her mother, travelled 55 kilometres on a crowded bus to a medical clinic in Loralai town, returning home the same day. The girl had fallen ill with smallpox on 1 July and had become progressively worse, developing a confluent rash. She died only 2 days after the bus trip. On the bus, the girl and her mother rode in the front on one of 5 seats set aside for female passengers and separated by a partial partition.

Five persons, exposed on the bus, subsequently developed smallpox: the 60-year-old bus driver and 4 girls ranging from 3 to 8 years of age. Four additional persons, exposed at the clinic, also developed smallpox. As a result, outbreaks developed 2 weeks later in 12 different villages over a distance of 65 kilometres. Thirteen additional cases occurred before the outbreaks were contained. (WHO/SE/72.41, Suleimanov & Mandokhel.)

Table 14.32. Baluchistan: interval between onset of first case of smallpox and detection of outbreak, 1973–1974

Year	Number of outbreaks detected within:				
	1 week	1–2 weeks	2–3 weeks	≥3 weeks	Total
1973	50	47	21	47	165
1974	16	11	2	10	39[a]

[a] Information not available for 1 outbreak.

Table 14.33 Baluchistan: number of cases of smallpox in outbreaks, 1973–1974

Year	1 case	2 cases	3–10 cases	>10 cases
1973	76	24	52	13
1974	23	7	6	4

After April 1973, all cases and outbreaks occurred near Quetta, in which the isolation ward of the civil hospital served as the principal focus for the dissemination of infection. In addition to being the source of Afghanistan's final outbreak, mentioned earlier, the hospital was the focus of infection of 25 additional outbreaks over a 3-year period (including the last 4 outbreaks in Quetta), all of which were traced to patients who had contracted the infection there. Despite continuing efforts by provincial smallpox eradication staff to persuade the responsible hospital authorities to isolate patients and to vaccinate all persons admitted to the hospital, here, as at so many other hospitals, little was done until smallpox eradication staff were assigned to perform these duties.

Baluchistan recorded its last case on 30 August 1974. An extensive search was then organized throughout the vast, sparsely settled desert areas of its western provinces but no cases were found. Transmission had been successfully interrupted in less than 2 years after a surveillance programme had begun—and without benefit of a mass vaccination campaign. The costs were low. The total expenditure by the government over a 3-year period from mid-1971 to mid-1974 was 610 000 rupees (US$61 500), or US$0.24 per head of population.

Fewer than one half of the cases in Baluchistan were among children under 5 years of age; one-fifth were among persons aged 15 years and over (Table 14.34). The generally older age distribution of cases reflects the occurrence of smallpox in comparatively isolated population groups among whom, in contrast to the situation in Afghanistan, variolation had not been widely practised in recent years.

The Last Outbreak in Baluchistan

Four weeks had elapsed without the reporting of a case in Baluchistan, when, on 1 August 1974, the assistant commissioner of a subdistrict reported to the district health officer in Kalat that he had heard rumours of smallpox in the area. A team immediately went to investigate and discovered cases in 4 villages (population 585) located at the top of a mountain, accessible only on foot. The first case had been exposed at Quetta's civil hospital in May and had become ill on returning home. On 4 June, a variolator was summoned; he took scabs from the patient and variolated the residents of the 4 villages. Between 4 June and 15 August, there were 108 cases and 9 deaths, as shown in the following table:

Age group (years)	*Natural infection*		*Variolation*	
	Number of cases	*Number of deaths*	*Number of cases*	*Number of deaths*

None of those infected had ever been vaccinated. Although the inhabitants of the 4 infected villages had a low level of vaccinial immunity, 90% of the people in surrounding villages were found to have been vaccinated.

Sind Province

In Sind Province, which mainly comprises a flat alluvial plain, 40% of the population lived in urban areas, including the cosmopolitan city of Karachi (Fig. 14.19). It was comparable to Punjab in the extent of its health programmes and personnel and in the availability of transport and communication facilities. In all, Sind had 120 hospitals, 918 dispensaries, 103 rural health centres and subcentres, and 116 maternal and child health clinics. In 1972, vaccinial immunity was found by survey to be over 95% in Karachi, and although lower in the rural areas, generally speaking it was probably comparable to that in Punjab and much better than that in Baluchistan or in North-west Frontier Province.

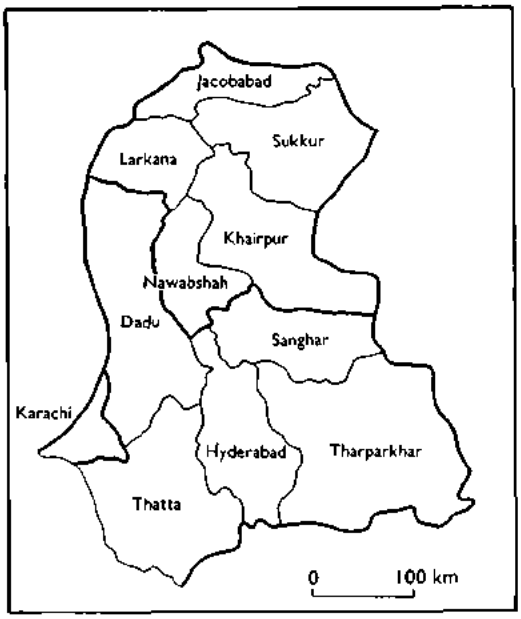

Fig. 14.19. Pakistan: districts of Sind Province, 1973.

Except in Karachi, the smallpox eradication programme was effectively ignored until the autumn of 1972. Early in 1971, the Karachi city authorities consolidated into a single organization the vast numbers of vaccinators who had been employed by a variety of different administrative jurisdictions, to undertake systematic vaccination and a programme of case detection. Three, later 6, surveillance teams and 3 containment teams complemented this effort, which proved so successful that between July and September 1971 no smallpox cases were found in the city. A week-long, city-wide search in mid-November confirmed the absence of cases. Karachi, however, was Pakistan's largest city and principal seaport and numerous travellers from all over the country passed through it. Most of them were from other parts of Sind in which the smallpox incidence was probably higher than anywhere else in Pakistan. Importations led to a number of cases (369 in 1972, 335 in 1973 and 252 in 1974), and some outbreaks in other parts of Pakistan were traced to Karachi. However, smallpox in Karachi remained a minor problem in comparison with the situation in Lahore.

Provincial health authorities exhibited little interest in the programme until the autumn of 1972. The existing smallpox eradication staff of 724 persons, including 644 vaccinators (1 for every 23 000 persons) continued a routine vaccination campaign during which 3–4 million people were reported to be vaccinated annually. Reluctantly, the provincial authorities had agreed to the assignment of a WHO adviser, Dr M. Chamsa, who arrived in June 1971. Efforts had been made to mount a special vaccination campaign but lack of government support soon caused the attempt to be abandoned, and attention was focused on surveillance. With only limited resources available, this commenced in the autumn of 1972. Outbreaks were soon detected in every district—727 in all, with 3661 cases (Table 14.35)—4 times the number of cases reported during the previous year. Even so, weekly reports were not received from all districts, nor was an active search for cases begun until late in 1972.

By the autumn of 1972, national and WHO staff had become increasingly concerned about the inadequacy of the Sind programme and the lack of interest on the part of the health authorities. By that time, the smallpox

incidence was declining rapidly both in Punjab and in North-west Frontier Province. The programme in Baluchistan was proceeding slowly, but since the population of the province amounted to only 1.9 million, it was of less concern. In Sind, which was much more densely populated, an effective programme was vital. Accordingly, in November 1972, WHO convened a special seminar in Karachi in which provincial officials from all over Pakistan participated, together with smallpox eradication officers from other countries in the Eastern Mediterranean Region. The site had been deliberately selected in the hope of awakening the interest of senior officials in Sind. Henderson observed in his opening remarks:

"As for Sind, the considerable delay in initiating the programme and the many administrative problems encountered leave more yet to be done in the Province than in the other three ... I can say honestly to you that in no other previously or presently endemic region are so many engaged in smallpox eradication; in no other endemic region are health services, transport and communications so well developed nor the populations so willing to accept vaccination." (SE/72.9, Henderson.)

Despite the fact that the surveillance system in Sind had improved little, the total of recorded cases in 1972 rose to unprecedented levels. This event, coupled with the conference, served at last to stimulate the health authorities to undertake a more effective programme.

Following the conference, activities were reorganized. Additional surveillance teams

were constituted for search and containment and soon the number of reported cases increased dramatically (Fig. 14.20), from 3661 in 1972 to 7848 in 1973. Even so, detection was greatly delayed and when outbreaks were found, containment was poorly executed. The problem was apparent from the observation that 43% of all outbreaks in 1972 and 24% in 1973 lasted more than 4 weeks (Table 14.36); 15% of all outbreaks in 1972 and 9% in 1973 had 11 or more cases (Table 14.37).

By the autumn of 1973, it was apparent that additional measures would be required. Whatever had been said about a change in strategy, district and local supervisory staff continued to be preoccupied with routine vaccination, undertaking case search and outbreak containment only with reluctance. Accordingly, in October 1973, activities were implemented that were similar to those which had been developed in India. To emphasize that the objective of the programme was to detect cases, vaccinators were redesignated "surveillance agents". Teams of 2–3 persons were scheduled to visit once a month all villages (usually 100–150) in 2–3 union council areas to detect and contain outbreaks. Activities

were supervised on the spot by a district superintendent of vaccination and a district smallpox eradication medical officer. Several provincial teams assisted in districts with the greatest problems. In Karachi, staff of the family planning and malaria control programmes participated in the search for cases. To encourage participation, a reward of 5 rupees (US$0.50) was offered to anyone finding a case. However, as a provincial surveillance officer observed, even this sytem of active search was poorly executed, the searchers devoting more time to obtaining the signatures of village leaders and teachers to prove they had been to the village than to searching for cases. The comparatively few special surveillance teams actually discovered more cases through questioning schoolteachers and persons encountered during their travel.

The results were dramatic nevertheless. Cases were discovered more promptly and were better contained. In 1974, 50% of all outbreaks consisted of only a single case and only 43 out of 1272 (3%) lasted more than 4 weeks.

During the summer of 1974, the number of cases fell steeply, from 1100 in May to 300 in June and only 55 in August. This corresponded to the customary seasonal decline in incidence observed throughout Pakistan, but with the momentum of search and containment achieved during the winter months, the few remaining outbreaks were more effectively contained. Finally, on 28 September, the last case occurred in Sanghar District, just prior to the beginning of the seasonal increase in transmission. However, programme staff remained sufficiently sceptical of the

adequacy of surveillance that months were to elapse before they expressed confidence that transmission had in fact been interrupted.

Cases and deaths in Sind for the period 1972–1974 are shown in Table 14.38. Half of all the cases were in children under 5 years of age and only 8% were in individuals aged 15 and over, a marked contrast to the situation in Baluchistan. The overall recorded case-fatality of only 9% was unusually low for the subcontinent. Data from the city of Karachi (Table 14.39) suggest that this probably reflected incomplete notification of deaths in a province in which surveillance was notably poor.

As noted before, surveillance in Karachi had been consistently better than in the rest of Sind since 1971 and the cases which occurred during 1973–1974 had resulted primarily from importations from other parts of the province. Even when standardized for age, case-fatality rates were substantially greater than for the province as a whole, almost certainly reflecting more complete documentation of deaths rather than a difference in virus strains. A similar phenomenon had been observed in Indonesia, in which case-fatality rates were far higher in the city of Jakarta than in the surrounding West Java Province.

Northern areas of Pakistan—Gilgit and Azad Kashmir

In the federally administered, sparsely populated areas of Gilgit and Azad Kashmir, no special programmes were launched until 1974. Because the problems in the more populous areas of Pakistan were so formidable, neither national nor WHO staff considered it desirable to divert resources to these areas before then. It was hoped that in these northern areas, in which the population density was low, the transmission of smallpox might terminate spontaneously or be interrupted by control measures if cases were introduced. This proved to be the case. The population in Gilgit, estimated to be 450 000, lived in 5 different valleys in scattered hamlets and very small villages. A single rough road, open only 2 days a week, connected this area with the large urban centre of Rawalpindi, located in Punjab Province; as for connections by air, the single daily flight was often cancelled owing to bad weather. Between 13 000 and 100 000 vaccinations were recorded each year by hospital and dispensary staff. A reporting system was all but nonexistent. To assess the status of this area, an extensive search was conducted in the summer of 1976 but no evidence of recent cases of smallpox was discovered. Two unreported outbreaks were documented: 1 person in the eastern part of the region had developed smallpox and died in 1972, a week after returning from Karachi; and, in January 1971, 37 cases had occurred in the town of Gilgit, the largest urban centre in the region. Following the Gilgit outbreak, health staff, assisted by army personnel, had vaccinated nearly 150 000 persons. No surveys were done to document the levels of vaccinial immunity but it is doubtful that they were high.

Azad Kashmir, like Gilgit, is sparsely settled (population in 1975, 1 558 000), the people living in villages widely scattered over about 11 500 square kilometres of mostly hilly terrain. Many of the men travelled outside the area for work and, as a result, smallpox was introduced sporadically. In 1973, a special vaccination campaign was conducted by personnel of the 184 stationary health units, during which 1 381 294 persons were reported to have been vaccinated. Because of the lack of supervision or assessment of the programme, this figure was thought to be exaggerated. No information regarding cases was available before 1974,

Table 14.40. Dera Ghazi Khan, Bahawalnagar and Rahimyar Khan: results of variolation scar survey, by age group, 1976

Type of area	District	Number examined	Number variolated, by age group (years)					
			0–2	3–4	5–14	⩾15	Total	% of total examined

when an epidemiologist was assigned to the area. Between February and June, he documented the occurrence of 14 cases in 7 separate outbreaks, the last case occurring on 11 June 1974. No data were collected concerning the source of infection although it is assumed to have been the neighbouring province of Punjab. Extensive search in 1976 by special teams assisted by malaria control staff and local health personnel confirmed the absence of smallpox.

Variolation in Pakistan

Variolation continued to be practised in isolated areas in Pakistan throughout the duration of the programme but it was far less extensive than in Afghanistan or Ethiopia and did not significantly affect progress. As has been noted above, the last cases in Baluchistan occurred in an isolated desert area of Kalat District, but evidence of recent variolation was also observed in the southern desert of Punjab and in mountainous tribal areas bordering Afghanistan.

Variolation in Punjab was limited to the Rahimyar Khan desert near the borders with Sind and Baluchistan; this practice persisted through 1973, and one unsuccessful attempt was detected as late as 1974. A survey in 3 districts in this desert area revealed extensive variolation in the past but no evidence of it in the preceding 4 years except in Rahimyar Khan (Table 14.40).

In the tribal areas of North-west Frontier Province, variolation by traditional variolators, as in Afghanistan, had been common. An investigation was conducted in 1976 in one such area in Mohmand Agency during which the inhabitants of 31 villages were checked for the scars of variolation and the pockmarks of smallpox (Table 14.41).

More than three-quarters of the population over 10 years of age had variolation scars but surprisingly few had pockmarks. Evidence of variolation and/or pockmarks was seen only in children 3 years of age and older. This was supportive evidence that variolation had ceased, since it was usually performed when children were 1–2 years of age.

[a] Males only.

CONCLUSIONS

Following the occurrence of the last case of smallpox in Pakistan in October 1974, extensive searches were repeatedly conducted throughout the 4 provinces and 2 federally administered regions to confirm the absence of smallpox; a reward of 100 rupees, later increased to 5000 rupees, was offered to anyone reporting an outbreak. Because of the programme's earlier record of poor performance and the inadequacy of surveillance, uncertainty existed until the end of the year as to whether transmission had actually been interrupted. Only after several months of continuing search during the period of high seasonal transmission did national and international staff begin to feel reassured.

The situation in Afghanistan was entirely different. Since 1970, continuing efforts had been made to strengthen reporting and all outbreaks had been carefully investigated,

their sources traced and the outbreaks contained. Surveillance was sufficiently extensive that when cases ceased to be detected, the Afghan staff were confident within a matter of weeks that natural transmission had ceased. However, since smallpox was still widely prevalent throughout Pakistan, there was a serious risk of its being reintroduced into Afghanistan and becoming re-established there. Indeed, transmission was interrupted more than 2 years earlier in Afghanistan than in Pakistan. Importations did occur but an effective surveillance programme quickly detected and contained the outbreaks.

In Afghanistan, there were few resources and only a rudimentary health infrastructure. Nevertheless, a highly effective programme rapidly took shape once a national commitment to the programme was made. In Pakistan, the resources were extensive, immunity was already high and a sound scientific basis for a programme had been elaborated. That Pakistan required so much longer to interrupt transmission reflects the difficulties of endeavouring to replace entrenched traditional doctrine—in this case, "100% vaccination"—with an alternative strategy that called for the detection and containment of outbreaks. Progress was unquestionably impeded by the attitude of some WHO advisers who, for so long, were not completely persuaded that this approach was correct. The delegation of authority and responsibility for health policy and programmes from national to provincial level further compounded the problem. Although national authorities attended the World Health Assembly, discussed global health policies and made commitments on behalf of Pakistan, provincial authorities bore the responsibility for deciding policy and priorities within their own jurisdictions. Some supported an eradication programme while others exhibited little interest. National authorities could do no more than exhort and cajole. In consequence, a successful effort in North-west Frontier Province was jeopardized by the sudden collapse of the programme in Punjab, and both programmes were compromised by repeated importations of smallpox from Sind and Baluchistan, neither of which exhibited interest in smallpox eradication until late in the programme.

The question arises, in respect of Afghanistan, whether surveillance–containment measures alone might have succeeded, in view of the fact that transmission was interrupted so rapidly once these measures had been taken. Given the extent of variolation, it seems doubtful, in retrospect, that the staff could have dispensed with mass vaccination and the accompanying programme designed to educate village leaders and the villagers themselves about the dangers of variolation and the advantages of vaccination.

In 1968, the attainment of eradication in Afghanistan had been considered to represent the Intensified Programme's most difficult challenge. With the interruption of transmission there, senior WHO staff speculated anew as to which country or area might constitute the insuperable obstacle to global eradication. A few thought that it might be Ethiopia. Most, however, conjectured that it would be the populous country of India, which was generally believed to be the original home of smallpox and in which, perhaps, unique factors of climate, crowding, etc., permitted transmission to persist as in the case of cholera. In the next chapter we shall turn to the programme in India.

INTRODUCTION

The Indian subcontinent has long been regarded as the probable place where smallpox originated—its traditional endemic home. It was a disease described in early Indian writings and enshrined both in Hindu religious belief and throughout the country in temples to the smallpox goddess. Variola major, with a case-fatality rate of 20% or higher, was the only variety of smallpox found in India and, as recently as the 1950s, it is estimated to have killed more than a million persons annually. Many held the view that because of population density, or for other ill-defined socio-cultural or epidemiological

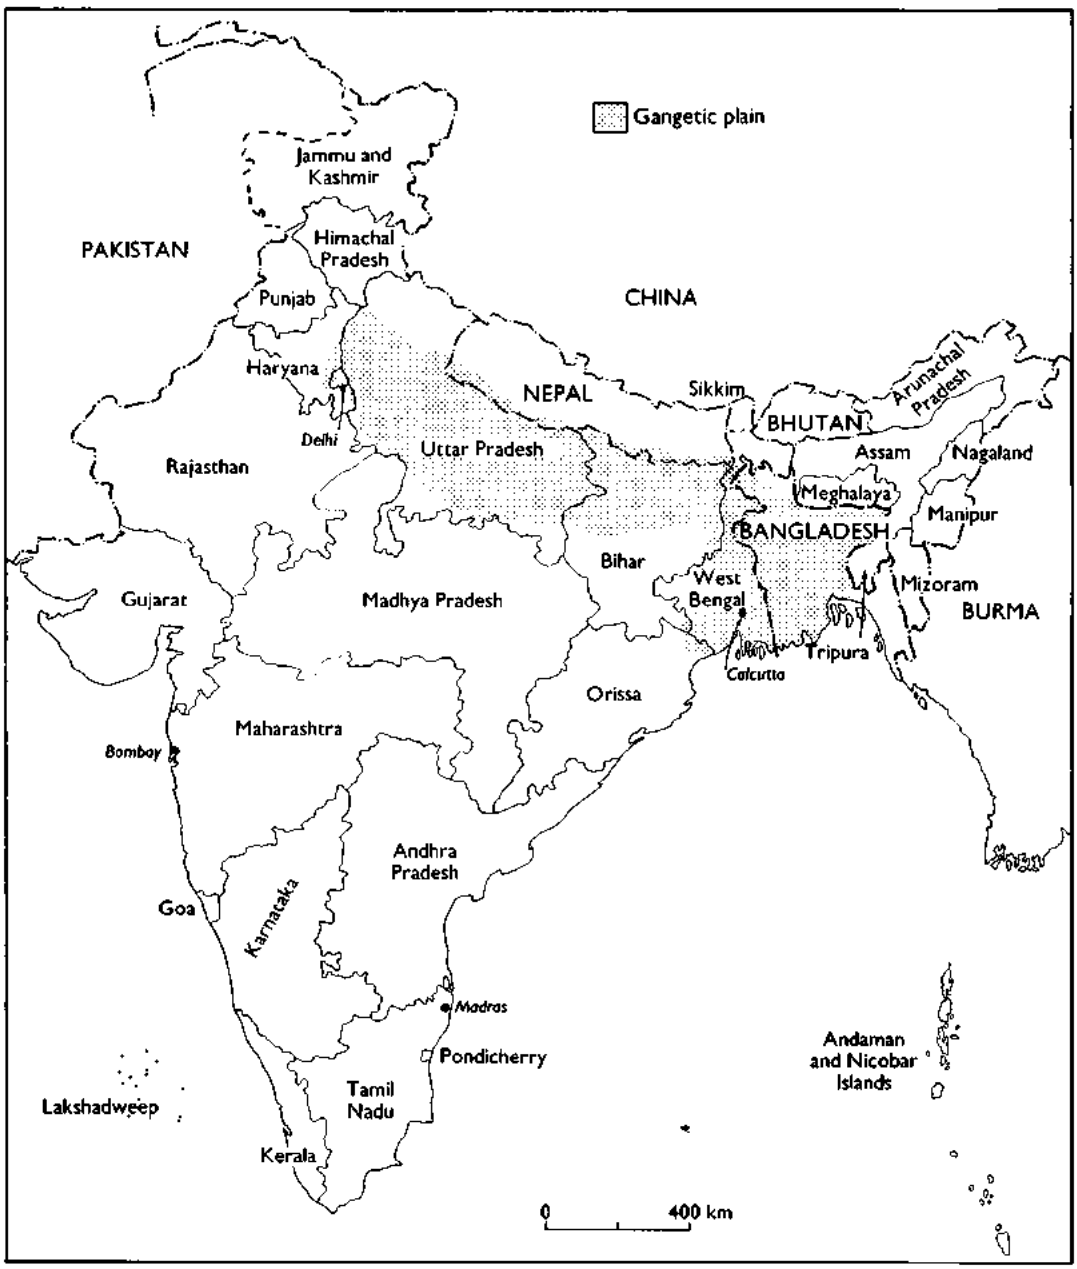

Fig. 15.1. Bhutan, the states and union territories of India, and Nepal. Many of the most densely populated areas in the region are in the Gangetic plain. In India, Karnataka was known as Mysore until 1973; Arunachal Pradesh was the North East Frontier Agency until 1971; and Sikkim became a state in 1975. Bangladesh was East Pakistan until 1971.

reasons, the eradication of smallpox in India would ultimately prove impossible. This belief had its roots in the behaviour of cholera, which for centuries had been confined to the riverine areas of the Indian subcontinent. In the 1830s, cholera spread across the world in the first of seven global pandemics, only to disappear over time, except from the Ganges river plain (Fig. 15.1). Although cholera was a bacterial disease with wholly different epidemiological characteristics, many believed that there were unique, yet unrecognized features of this area which would doom a smallpox eradication effort as certainly as an effort to eliminate cholera.

There were other reasons for pessimism. In area, India was the world's seventh largest country but second only to China in size of population. Of the 1100 million people living in areas which had endemic smallpox in 1967,

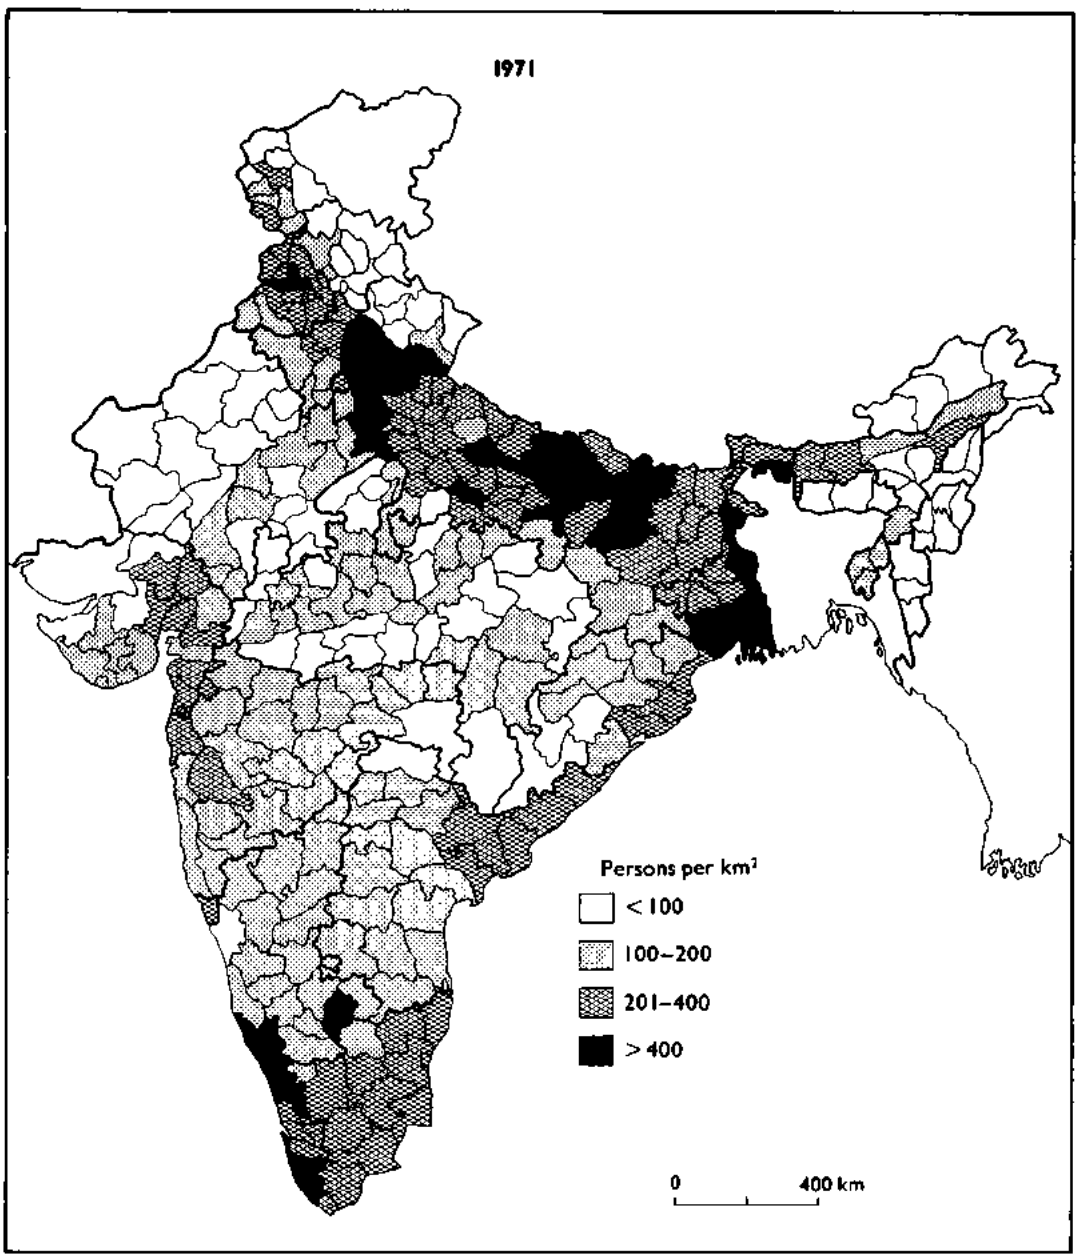

Fig. 15.2. India: population density, by district, 1971.

513 million (47%) lived in India. The most densely populated zone was the Ganges river plain in the north (Fig. 15.2), some 2400 kilometres long and 240–320 kilometres wide. Sharing borders with India and epidemiologically related to it were the 2 small Himalayan mountain kingdoms of Nepal (population 10.8 million) and Bhutan (population, 987 000), and the Indian protectorate of Sikkim (population, 196 000). (Sikkim became an Indian state in 1975.)

A smallpox eradication campaign had begun in India in 1962 (Fig. 15.3) but, despite an intensive and costly effort, smallpox was still widely prevalent in 1967 and substantially underreported throughout the country. A pilot smallpox control programme had been launched in Nepal in 1962, but cases continued to be reported from the only 3 districts which reported at all. Little was known in 1967 about the situation in Bhutan and Sikkim.

In 1967, the meagre resources available to WHO precluded the provision of meaningful support to all endemic countries in Asia. A programme was already established in India, although functioning poorly, and India at that time requested international assistance only to permit the acquisition of equipment for vaccine production. Thus, WHO's assistance in Asia was directed to the less populous endemic countries—Afghanistan, Indonesia, Nepal and Pakistan (which then included East Pakistan, later to become Bangladesh). It was hoped that successful programmes in these countries would eventually permit the release of significant resources in support of the Indian national programme if required. A joint India–WHO team assessed the Indian programme in 1967 and, subsequently, WHO staff from Headquarters and the Regional Office for South-East Asia in New Delhi held frequent meetings with Indian government staff. Until 1970, however, progress was slow. That year, a WHO–India agreement was signed which provided for WHO support for field activities. During the following 3 years considerable progress was made in the southern and western states but little in the northern, densely populated Ganges river plain. Meanwhile, country after country in Africa, South America, and Asia succeeded in interrupting smallpox transmission. By June 1973, only 5 endemic countries remained, of which 4 were adjoining countries in Asia (Bangladesh, India, Nepal and Pakistan) and the fifth was in Africa (Ethiopia).

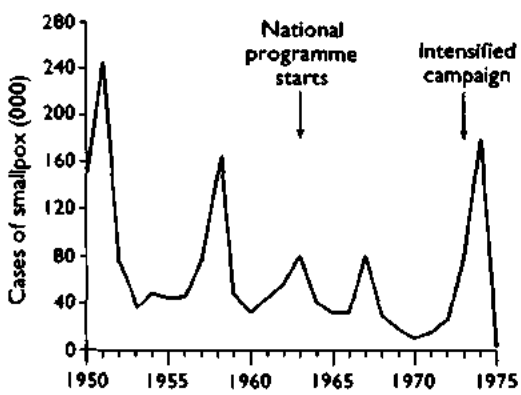

Fig. 15.3. India: number of reported cases of smallpox, by year, 1950–1975.

In June 1973, Indian and WHO staff decided on an ambitious campaign to involve more than 100 000 local health staff throughout India in a village-by-village search for cases. Such searches would be completed in 7–10 days and would be undertaken monthly in heavily infected areas and less often in areas in which few or no cases were being reported. Outbreaks, when found, would be contained by local health staff assisted by state and district surveillance teams. With this strategy, it was hoped that transmission might be sharply curtailed by January 1974 and perhaps interrupted as early as June 1974. The problems proved far more formidable than had been foreseen. Although the original optimistic target was not met, transmission was interrupted in May 1975, less than 2 years after the special programme had begun—a considerable achievement in so vast a country.

In sheer magnitude and scope, in innovation and adaptation to adversity, in dedication and enthusiasm, in the degree of international cooperation and understanding, the Indian programme from September 1973 onwards was one of the finest endeavours of the global campaign. It is impossible to do full justice to this vast programme in a single chapter. Fortunately, a number of publications describe the overall programme, focusing primarily on its concluding phase. Two books, *The Eradication of Smallpox from India* (Basu et al., 1979) and *The Management of Smallpox Eradication in India* (Brilliant, 1985), are particularly valuable. Special issues of the *Indian journal of public health* (January–March 1978) and *The journal of communicable diseases* (August 1975) also provide important information.

This chapter includes an account of the closely related and ultimately well-executed Nepalese programme, of which there is no published description. It concludes with such information as is available regarding activities in Bhutan and Sikkim, which experienced only infrequent importations after 1966.

INDIA

Background

India's immense size and vast population, of whom more than 80% lived in rural areas, was but part of the challenge. In India, as well as in East and West Pakistan, there was an extraordinary movement of population from place to place for purposes of business and attendance at marriages and funerals. Numerous religious pilgrimages and gatherings attracted huge crowds, sometimes amounting to millions of people. Uncountable hundreds of thousands travelled throughout the country on 10 800 daily trains. The state transport system, including buses and other motor vehicles, alone carried some 10 million passengers (about 2% of the population) each day. Reflecting the extent of internal migration, the 1961 census showed that a third of the population was enumerated outside their places of birth that year; during succeeding years, mobility substantially increased. This was important in smallpox transmission. Often, persons who were exposed to or became ill with smallpox would journey long distances to return to their home villages, disseminating smallpox when they arrived and sometimes in the course of the journey.

Also unique to the Indian setting was a belief among Hindus that attributed smallpox to the wrath of a goddess, called Sītalā (Shitala) mata although known by a number of different names among India's 15 major language groups and 250 regional dialects. It was not surprising that a deity was associated with smallpox, considering the antiquity of the disease and the large numbers of people it afflicted, of whom 1 in 5 died. Its severity was illustrated by the fact that as late as the mid-1800s, 13% of all recorded deaths in Calcutta were due to smallpox, and 75% of blindness in India at that time was attributed to the disease (Rogers, 1944). Some persons resisted vaccination, fearing that it would anger the goddess. Religious ceremonies in her honour were common at specially dedicated temples as well as in people's homes.

Finally, there were the complexities of the administrative structure. India, a parliamentary democracy, was divided into 21 states and 9 union territories. (In 1975, Sikkim became the 22nd state.) These were further subdivided into 393 districts and 5247 community development blocks (Table 15.1). Of the 575 721 villages enumerated in the census of 1971, approximately 319 000 had a population of less than 500; only 6333 had a population of more than 5000. There were only 4 cities with more than 2 million inhabitants: Calcutta (7 million), Bombay (6 million), Delhi (3.6 million), and Madras (3 million).

At the national level, responsibility for health programmes was shared by the Minister of Health, a political figure; the Secretary of Health, a non-technical administrative executive officer; and a technical Director-General of Health Services, who implemented health programmes. Substantive decisions required the collaborative understanding of all three. In each state the administrative structure replicated the national one. Although there was some variation in the type of organization from state to state, there were district health units in most, directed by a chief medical officer of health (or civil surgeon). In large states, several districts were grouped in divisions and, for each, there was a divisional medical officer. Districts were divided into basic health units termed primary health centres (corresponding usually to community development blocks), which attended to the health needs of 80 000–150 000 people living in 150–350 villages.

Smallpox in India before 1962

Vaccination had first been performed in India in 1802 and an organized vaccination programme was begun in Bombay in 1827 (Rogers, 1944). By 1868, some type of vaccination programme had been established in all provinces, although little was done in most of the 560 independent princely states, in which about a third of the population resided. With increasing numbers of vaccinations, the numbers of registered deaths from smallpox declined between 1878 and 1937, despite a progressively improving system for the regis-

Plate 15.1. The goddess of smallpox has long been worshipped throughout the Indian subcontinent. She is usually portrayed as a woman riding on an ass, carrying a broom in one hand and a waterpot in her other arm. In northern India, she was known as Śītalā mata, śītalā meaning the cool one, and mata meaning mother. Though worshipped primarily by Hindus and Jains, in Nepal she was incorporated in the Buddhist pantheon as Ajima, the mother of Gautama Buddha. Offerings were made at temples dedicated to her and to images in the home; annual festivals were held on her feast day. Beliefs and practices differed from place to place and the goddess was variously considered to have powers to prevent or cure the disease as well as to inflict it.

tration of deaths and a growing population (Table 15.2). Data comparable to those provided by Rogers could not be obtained for the period 1937–1961, but data for 1962–1971 are available—1962 being the year in which India commenced a special national smallpox eradication programme (see below). It is not known how complete the registration of deaths may have been at different times. However, studies conducted during the early 1970s showed that even then, the number of reported cases of, and presumably deaths from, smallpox represented less than 5% of the cases and deaths that had actually occurred.

Vaccination programmes were gradually extended throughout most of the country and, following India's independence in 1947,

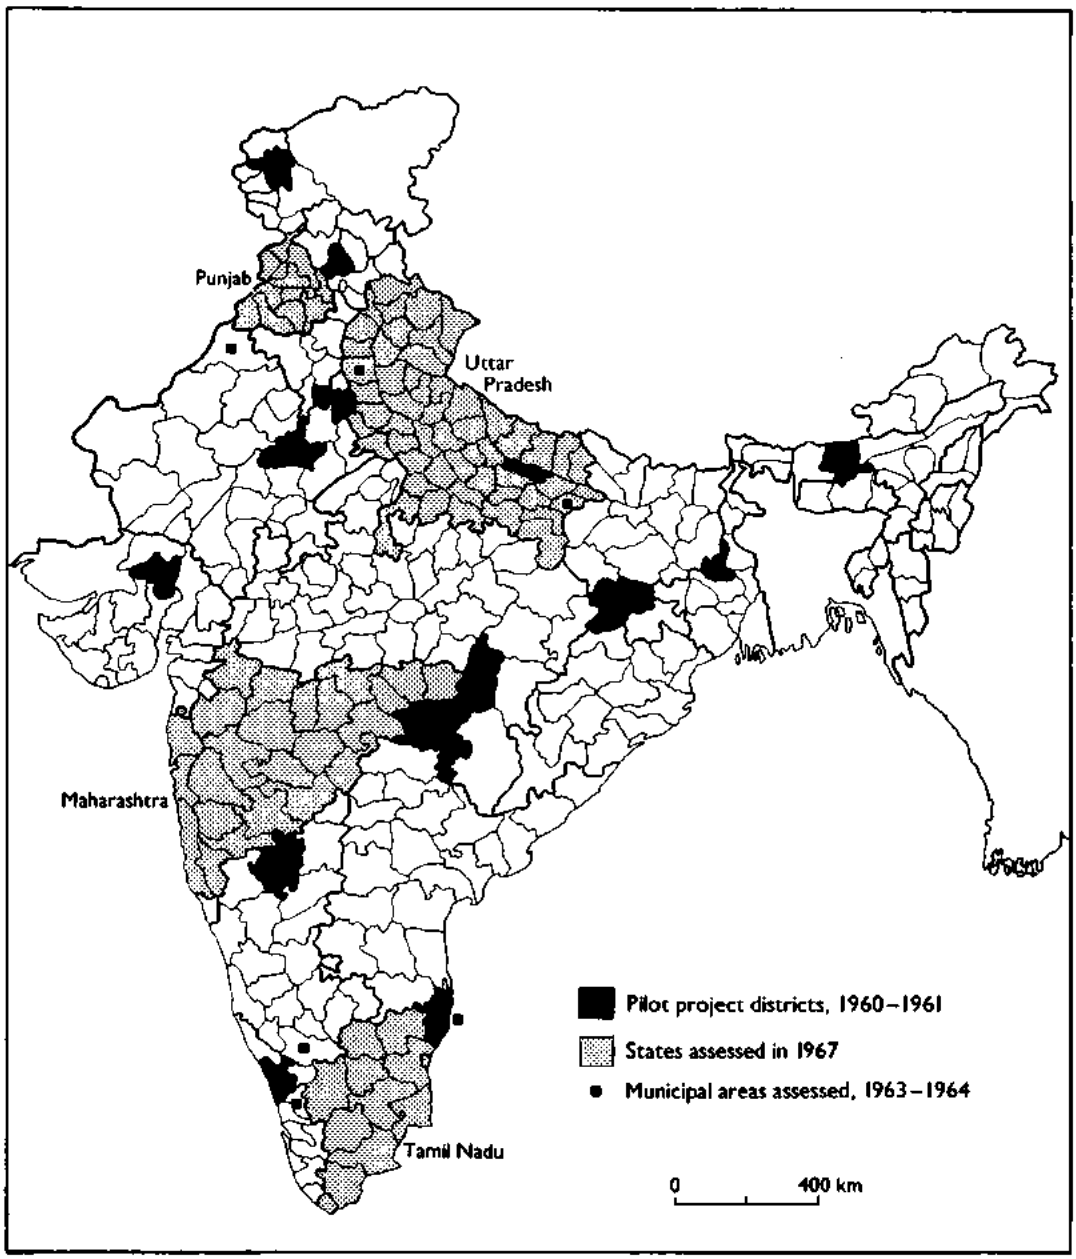

Fig. 15.4. India: pilot project districts for the National Smallpox Eradication Programme (NSEP), 1960–1961; state programmes assessed in 1967; and municipal areas assessed, 1963–1964.

to the remaining princely states. Thermolabile liquid vaccine was the only vaccine available and many of the vaccinations performed must have been unsuccessful. This vaccine was produced in 14 laboratories in 11 different states. As in Pakistan, vaccinators who were recruited and hired by the local administrative organization and termed "local body vaccinators" performed the vaccinations. The programme of vaccination provided only partial control of smallpox, but because vaccination was widely available and variolation was forbidden by law, the latter practice ceased and, by the late 1950s, was no longer a problem in India.

India's National Smallpox Eradication Programme, 1962

In June 1959, one month after the decision of the Twelfth World Health Assembly to undertake a global eradication programme, an Expert Committee of the Indian Council of Medical Research recommended that a National Smallpox Eradication Programme should be established. The vaccination campaign that resulted was of heroic dimensions and, although failing in its goal to eradicate smallpox, it served to extend vaccination to all but the most isolated villages and created an army of workers and a momentum which provided a foundation for the subsequently successful eradication effort.

Pilot projects were first developed in one district per state to work out methodology and to develop estimates of costs and personnel requirements (Fig. 15.4). The projects began in 1960 and concluded in March 1961 (India, Ministry of Health and Family Planning, 1966).

The essence of the strategy called for a specially recruited team to move systematically from house to house and from village to village throughout a district in an effort to vaccinate or revaccinate not less than 80% of the population. With this proportion vaccinated, it was expected that a sufficient number of persons would be immune so that smallpox transmission would terminate spontaneously. The vaccination team was preceded by enumerators, who listed in a large multi-page register the name of each person along with his or her address, age, sex and previous history of vaccination or of smallpox. One register was compiled for each village or defined area in a city and was intended to be used during the subsequent 20 years. After enumeration had been completed, the register was given to the vaccination team, which then endeavoured to vaccinate those who were listed. The register was next given to an inspector, who was to check each vaccinee to ensure that vaccination had been successful. Subsequently, local health unit vaccinators (1 for every 50 000–70 000 persons) were assigned responsibility to vaccinate those missed in the mass campaign ("mopping-up vaccination"), to maintain the registers, to revaccinate everyone every 5 years and to vaccinate contacts when cases were discovered. Performance in the pilot projects was poor. In a target population of 23 million, only 12 million (52%) were vaccinated. No evaluation of the programme was conducted nor was smallpox incidence monitored. Nevertheless, as happens only too frequently, the pilot projects were followed almost immediately by the introduction of a national programme.

The USSR offered freeze-dried vaccine, which was largely but not entirely intended to replace the thermolabile liquid vaccine; the United States Agency for International Development made a grant of rupees equivalent to US$2 million; and UNICEF pledged equipment for vaccine production. Eventually, the USSR provided 650 million doses of vaccine and the USA, between 1961 and 1967, contributed the rupee equivalent of US$23 million, which had been generated by the sale of foodstuffs provided to India (termed Public Law 480 funds).

Since health programmes in India are constitutionally a state responsibility, the principal administrative direction of the smallpox eradication programme was delegated to the states. Only 2 professional staff provided coordination at the national level. However, because smallpox was considered a national priority, the programme was "centrally sponsored"; the states were reimbursed by the central government for all non-recurring expenditures and for 75% of recurring costs.

The government created 152 units, each of which was expected to vaccinate about 3 million persons in an "attack phase" lasting 2–3 years. Each unit consisted of a supervising officer (usually a physician), a paramedical assistant, 60 vaccinators, 12 inspectors, 12 enumerators and 2 health educators. Each unit was assigned 3 vehicles. In all, more than 13 000 persons were employed, most of whom

Recommendations for Primary Vaccination in Early Childhood, 1963

The programme's recommendations for primary vaccination were taken from a publication of the British Ministry of Health and distributed in a circular to all administrative staff in 1963. It stated that primary vaccination "should be carried out some time before the age of two years, preferably during the second year" and listed as specific contraindications: "failure to thrive, exposure to infectious disease, septic skin conditions, infantile eczema and other allergic conditions, hypogammaglobulinaemia and corticosteroid treatment" (India, Ministry of Health and Family Planning, 1966). Although perhaps appropriate for the United Kingdom, where smallpox cases were only occasionally imported, the recommendations were inappropriate for India, where many children were exposed to smallpox from birth, where the risks associated with vaccinating most of those with the listed contraindications were much less than the risk of death due to smallpox, and where most vaccinations were performed by scarcely literate vaccinators who could not be expected to recognize many of the conditions noted. Indeed, if all the contraindications had been carefully observed in India, few children would have been vaccinated. Sensibly, the recommendations were largely ignored by most vaccinators, although some did not vaccinate children who were ill with fever or had skin infections. Throughout India, 3 months of age was generally respected as the lower age limit for vaccination. By 1970, a more realistic and appropriate policy had evolved. It called for vaccination from the time of birth and recognized no contraindications except one: vaccinators were instructed not to vaccinate seriously ill persons who might be expected to die over the succeeding day or two and whose death might thus erroneously be attributed to vaccination.

were newly hired and trained. The programmes were launched in 1962 and 1963.

Between 1962 and 1966, 440 million vaccinations were reported to have been performed. It was an impressive number but it did not signify that this many persons had been rendered immune. The first indication of difficulties was observed in New Delhi in the winter of 1963 (Gelfand, 1966). Between December 1962 and May 1963, 346 cases of smallpox occurred in an area in which the number of vaccinations performed was equivalent to more than 80% of the population. Sample surveys conducted in 18 representative areas revealed that, in fact, vaccinations had been given to only 63% of the population and that, of these, 86% had been successful. It was therefore concluded that only 54% of the population had been successfully vaccinated. This discrepancy between the number of vaccinations reported and the number of people actually rendered immune was attributed to a falsification of records and the repeated vaccination of readily accessible groups, particularly schoolchildren. The government was disturbed by these findings and asked India's National Institute of Communicable Diseases to undertake similar surveys in other states. Five were subsequently conducted in districts which reported that the number of vaccinations performed was equivalent to 80% or more of the population. In operational terms, this meant that the mass campaign "attack phase" had been completed or was about to be completed and the "maintenance phase" was due to begin; during the latter phase the established health services would assume the responsibility for sustaining levels of vaccinial immunity and for controlling outbreaks.

The findings of the National Institute's teams were not encouraging (Gelfand, 1966). The family registers—printed sheets sewn together in a large book—were supposed to include the name of each individual in a defined area and to provide a permanent record of vaccination status. Field assessment showed that many registers had already been lost or were so worn as to be unusable; many names had been omitted; and the clerical task of keeping the registers up to date was overwhelming. It was found, for example, that some individuals who had died as long as a year before were recorded as having just been successfully revaccinated. However in-

effective the family registers may have been, their use continued in many areas until the late 1960s.

The proportion of the population found to have been successfully vaccinated was less than the reported 80% in all districts, ranging from 54% to 73%. Substantially lower levels of vaccination coverage were found in urban districts than in rural areas. Although the numbers reported to have been vaccinated were probably somewhat inflated, the more basic problem was similar to that observed in New Delhi: the most accessible individuals—schoolchildren, for example—were being vaccinated as often as every 6 months, while pre-school children and persons in the lowest socio-economic groups, among whom smallpox was most prevalent, were not being vaccinated at all.

In areas which had entered the maintenance phase of the programme, the National Institute's teams evaluated performance by examining children aged 3–12 months for the presence of a vaccination scar. After the mass campaign, all children on reaching 3 months of age were supposed to be vaccinated by staff assigned to the local primary health centre. In one district, 88% of children 3–12 months old had vaccination scars, but in the remaining districts the corresponding proportions were, respectively, 2%, 9%, 23% and 38%. The National Institute's teams investigated reported cases of smallpox in the maintenance phase areas and in each district they found many other cases which had not been detected.

In view of the fact that the districts evaluated were among the few which had reported that they had achieved the target of 80% coverage, it was apparent that the programme had fallen far short of expectations. An internal document issued by the United States Agency for International Development in November 1964, justifying the programme's continued use of United States rupee funds, stated prophetically: "Eradication of smallpox in India ... is at least 10 years hence ..."

Despite the extensive vaccination programmes, 30 000–40 000 cases of smallpox were reported each year during 1964–1966 (Table 15.3). Because millions had been rendered immune through vaccination, a decrease in the true incidence of the disease is assumed to have occurred, although such a decrease might have been masked by a more complete notification of cases. However, no specific measures had been taken to improve the reporting system and little is known about its efficacy at this time beyond the recognition that only a small proportion of cases was officially recorded.

Serious deficiencies extended throughout the reporting network at each level responsible for data collection and transmission. In villages, cases of smallpox, as well as of plague and cholera, were supposed to be reported to the primary health centre by the village headman in most states or, in some, by the village watchman (chowkidar)—a poorly paid, sometimes illiterate employee of the village council. Some villages submitted reports but many did not. Health workers, assigned to primary health centres, paid little attention to the reporting of smallpox.

An additional problem was that villagers sometimes deliberately hid cases to avoid vaccination, to which they objected for religious reasons or because they feared the painful, infected lesions which so often resulted from the use of the rotary lancet. Some persons who had contracted the disease concealed themselves to avoid being taken forcibly to congested and understaffed hospitals. The cases that came to the attention of primary health centre personnel and district officials were frequently not reported by them to higher authorities because they were afraid of being punished by their supervisors. Many supervisory staff acted on the premise that the occurrence of cases in an area was prima facie evidence that the health staff had done an inadequate job of vaccinating the population and so deserved punishment.

At that time, the Central Bureau for Health Intelligence, the national statistical office, simply recorded data, showing little interest in whether the districts and states reported at all. Even the simple task of recording data was confounded by a system, unique to India, which required each district to report each week the number of cases detected according to the week of onset of the cases. This differed from the practice in other countries, in which a weekly report was compiled giving the number of cases of smallpox *detected* that week, irrespective of the date of onset. Thus, instead of receiving and recording one number for each of India's 393 districts, the Central Bureau received new reports of cases for each district extending back weeks or even months. All numbers were entered in a great ledger, past numbers corrected and new

Vaccination Using the Rotary Lancet

Until the bifurcated needle began to be used in 1970, vaccination was an elaborate and time-consuming ritual. Each vaccinator had a helper who carried a vaccination bag, and the pair proceeded from house to house to identify individuals to be vaccinated. When a candidate was found, the helper unpacked the bag and the following routine, prescribed by the Directorate of Health Services, was followed (India, Ministry of Health and Family Planning, 1966):

1. Check your kit bag to make sure that all the articles are there.
2. Perform vaccinations in a shady place to prevent exposure of the lymph to the sun.
3. Before vaccinating a person, wash your hands thoroughly with plain soap and water.
4. Sterilize both the scoop end and the toothed end of the rotary lancet in water brought to the boil beforehand and kept boiling. Hold the middle of the lancet with your thumb and index finger and dip the two ends in boiling water alternately for a minute each. If quick work is required, hold the two ends of the rotary lancet alternately over a naked flame. After sterilizing the lancet, keep it on a special wooden stand, taking care to see that the two sterilized ends do not come into contact with any other object.
5. Scrub the site chosen for vaccination thoroughly with plain soap and water. Wipe it dry with a sterile swab.
6. Take the vaccine tube from the ice container, unscrew its cap, take the lymph on the scoop end of the rotary lancet, recover the tube and put it aside on a special holder. Place the lymph on the required number of spots, on the outer surface of the middle third of the left upper arm for primary vaccinations, and on the front surface of the left forearm for revaccinations. Place the toothed end of the lancet on the skin through the drop of lymph. Rotate the lancet with gentle and even pressure so as to produce a light circular cut without drawing blood. After making the insertion, rub in the lymph into the scarified area with the scoop end of the lancet. Detain the person for 15 minutes so that the lymph may have time to get absorbed into the skin.

After one or several vaccinations had been performed at a house, the bag was repacked by the helper, and the vaccinator and helper proceeded to the next house.

Vaccinators who failed to permit the lancet to cool sufficiently or who were were too vigorous in pressing it into the skin inflicted painful lesions. Because the lancets were often contaminated, the vaccination lesions frequently became septic. The scars which remained sometimes resulted from the growth of vaccinia virus but sometimes were caused by bacterial infection alone. Not surprisingly, many vaccinators were offered money *not* to vaccinate.

Given the routine and the need to record the name of each vaccinee in a large register, it was unusual for a vaccinator to perform more than 25 vaccinations a day. When the bifurcated needle became available, the procedure was greatly simplified and both the special bags and the helpers gradually disappeared. However, the pace of vaccination, by then well ingrained, did not substantially increase.

totals compiled. Similar procedures were followed by district and state statistical offices. However, many of these offices did not forward reports of cases which had occurred several weeks or months previously, considering them not to be of current interest.

The National Smallpox Eradication Programme Advisory Committee held a meeting in November 1965 to decide what should be done when, in March 1966, the attack phase—the mass vaccination campaign—was scheduled to be completed and the programme throughout the country would enter its maintenance phase (India, Ministry of Health and Family Planning, 1966). The Director of the National Smallpox Eradication Programme, Dr K. M. Lal, expressed optimism that there would be a "further steep fall" in incidence in 1966–1967 but was concerned about the large number of persons who still remained unvaccinated. Because

independent assessments had shown that equating the numbers of recorded vaccinations with the numbers of persons successfully vaccinated was erroneous, it had been decided that a target of 100% vaccination coverage was necessary (a strategy endorsed by a WHO Expert Committee on Smallpox (1964) at Dr Lal's suggestion). Dr Lal doubted that a satisfactory maintenance vaccination programme could be conducted by the existing primary health centre staff, malaria workers, midwives and others. The 1963–1964 assessment had shown this. He favoured a plan which had been suggested to and approved by the Advisory Committee in 1963, whereby 1 smallpox vaccinator would be provided for every 10 000–15 000 persons in rural areas and for every 20 000 persons in urban areas. Such a scheme would be costly and, by any standard, would involve a generous deployment of manpower. Assuming that a vaccinator worked 200 days a year, he could theoretically vaccinate the entire population in a rural area during the space of a year by performing as few as 50–75 vaccinations a day.

Dr Lal and many members of the Advisory Committee were reluctant to end the attack phase with its mass vaccination units until cases had ceased to occur in a district. Various members proposed intervals of up to 3 years as the desirable time for an area to be smallpox-free before it entered the maintenance phase and vaccination was turned over to basic health staff or local body vaccinators. A special subcommittee was appointed to explore the question further. However, budgetary considerations intruded. The government was forced to decrease expenditure, and the attack phase programme, with its 152 mass vaccination units, was terminated. Special vaccinators for smallpox continued their work in most areas, but in a few, a handful of poorly trained and poorly supervised basic health workers were expected to add vaccination to other tasks.

Meanwhile, vaccine production institutes at Patwadangar, Belgaum, Guindy (Madras) and Hyderabad struggled unsuccessfully to produce the large quantities of freeze-dried vaccine required. By 1966–1967, they were producing only 1.4 million vials (enough to vaccinate about 20 million people). The USSR continued to provide approximately 500 000 vials each month, but even this was not enough. Emergency requests to other governments were regularly channelled through WHO, and several million additional doses were received from the Netherlands, Switzerland and the United Kingdom, but none of these sources could supply substantial quantities since none had laboratories equipped for the large-scale production required. Accordingly, the thermolabile, questionably potent, liquid vaccine continued to be used in a number of states since it was felt that unsatisfactory vaccine was better than no vaccine at all.

Table 15.4. India: numbers of reported vaccinations, percentages relative to population, and numbers of reported cases of and deaths from smallpox, 1962–1976

Year	Primary vaccinations		Total vaccinations		Reported number of cases of smallpox	Reported number of deaths from smallpox
	Number	% relative to population[a]	Number	% relative to population[a]		
1962	3 520 000	0.8	32 350 000	7.2	55 595	15 048
1963	16 350 000	3.6	138 720 000	30.2	83 423	26 360
1964	15 400 000	3.3	130 380 000	27.7	40 265	11 831
1965	17 390 000	3.6	109 840 000	22.8	33 402	9 058
1966	17 230 000	3.5	83 000 000	16.8	32 616	8 482
1967	18 560 000	3.7	96 450 000	17.2	84 902	26 225
1968	22 000 000	4.3	83 000 000	16.1	35 179	7 266
1969	22 700 000	4.3	76 870 000	14.6	19 281	4 156
1970	23 060 000	4.3	77 110 000	14.4	12 773	2 240
1971	24 190 000	4.4	91 680 000	16.7	16 190	2 706
1972	26 950 000	4.8	112 730 000	19.6	27 407	5 457
1973	24 840 000	4.4	112 340 000	19.8	88 114	15 434
1974	24 180 000	4.2	123 430 000	21.3	188 003	31 262
1975	19 025 474	3.2	86 718 634	14.6	1 436	176
1976	16 745 086	2.8	66 854 231	11.1	0	0

[a] The percentages provide an index of vaccination activity and are derived by dividing the reported total number of vaccinations performed by the estimated total population (from Basu et al., 1979). The figures do not provide a measure of the proportion of the population newly immunized or whose immunity was boosted. Vaccination was sometimes unsuccessful and some individuals were vaccinated two or more times in a year. Moreover, the reported total numbers of vaccinations performed were sometimes inflated.

The Herculean effort to eradicate smallpox through mass vaccination, launched so enthusiastically in 1962, had all but come to a halt by the time the Nineteenth World Health Assembly, in May 1966, decided to embark on the Intensified Smallpox Eradication Programme. The Indian delegate to the Health Assembly, commenting on the new initiative, pointed out that India would need 180 million doses of vaccine annually, of which it would never be able to produce more than 60 million doses, and expressed the hope that WHO could meet the projected deficit. He cautioned the delegates that unless good basic health services were developed "it would be very difficult indeed to maintain the immunological status temporarily reached" in a mass campaign (World Health Organization, 1966c).

In December 1966, Henderson, who had recently been appointed Chief of the newly constituted Smallpox Eradication unit at WHO Headquarters, arrived in New Delhi to participate in his first intercountry smallpox eradication seminar, attended by representatives from countries in WHO's South-East Asia Region. It was not an auspicious beginning, as India, which then accounted for one-third of the world's cases, announced at the seminar that it had terminated its attack phase and had reverted to a programme of maintenance vaccination.

The Intensified Smallpox Eradication Programme Begins, 1967

The advent of the Intensified Programme in India found a discouraged staff. Dr Lal, the director of the National Smallpox Eradication Programme since 1962, retired and, because the attack phase had been terminated, was not replaced. This left at the national level only one medical officer, Dr Mahendra Singh, a Deputy Assistant Director-General of Health Services. Although he was overwhelmed by the tasks of giving some sort of direction to the remaining smallpox control activities and of providing the necessary reports to Parliament among many other duties—Dr Singh tried valiantly to stimulate the host of vaccinators distributed across India. He dispatched numerous cables and letters asking state health directors to take action to control epidemics reported officially to him or, as often, through the press. Vaccination targets were established for each state and those who failed to meet their goals were given forceful reminders. The number of reported vaccinations diminished, however, from 139 million in 1963 and 130 million in 1964 to 96 million in 1967 (Table 15.4). Vaccine distribution was also Dr Singh's responsibility, and a continuing problem because reserves were few and requests to replenish vaccine stocks in state and district offices were often not forthcoming until supplies had been exhausted. Government regulations required that Dr Singh should travel by train or bus, often a 1- or 2-day trip to reach distant and populous state capitals. In each state, there was only one official responsible for smallpox, and he was usually assigned responsibility for one or more additional programmes. The smallpox eradication programme and its still extensive complement of vaccinators laboured under a severe shortage of senior, responsible staff.

Assessment of the Programme in India, October 1967

In 1967, smallpox incidence rose dramatically, eventually reaching a total of 84 902 cases, more than had been reported in any year since 1958. Concerned by this turn of events, the Indian government agreed that a joint India–WHO assessment team should

Plate 15.2. Medical officers at a primary health centre in Maharashtra State. *Right*: Mahendra K. Singh (b. 1928), a Deputy Assistant Director-General of Health Services, who was the only medical officer at the central level in India's National Smallpox Eradication Programme from 1966 to 1972 and sustained the momentum of the work until additional senior Indian and WHO staff could be assigned. He continued with the programme until the eradication of smallpox in India had been certified in 1977 and was later appointed Director of the Central Bureau of Health Intelligence.

appraise the situation and suggest how it might be rectified. The team's operations were planned and organized by Dr Jacobus Keja, the adviser on smallpox eradication in WHO's South-East Asia Region, and by Dr Singh. In India, an assessment such as this, in which WHO staff travelled to the field, was an uncommon event at that time. Most WHO advisers remained in New Delhi or occasionally visited the more populous state capitals, in which hotels were plentiful. When preparations were being made for the trip, it was discovered that the regional office had in its stores none of the commonly used Indian bedrolls that were needed when travellers stopped at government rest-houses.

The assessment team, comprising 8 senior national health officers and 8 WHO staff and consultants, spent 6 weeks in the field, from 8 October to 19 November. They visited Maharashtra and Uttar Pradesh, two states experiencing epidemic smallpox in 1967, as well as Punjab in the north-west, a state with moderate incidence, and the southern state of Tamil Nadu. The last of these states was of particular interest because of the very few cases reported (263 in 1967) among its population of nearly 40 million.

The observations made by the team are telling, as they provide an overview of the status of smallpox and of the programme in 1967. The team concluded that the programme "is still far from achieving its objective of smallpox eradication in most areas and ... in fact, a very considerable epidemic potential exists in India at the present time." The conclusions of its report are paraphrased below:

Supervision and direction

● The functions and responsibilities of the National Smallpox Eradication Programme from the central level to the periphery are fragmented among a variety of independent and semi-independent organizations. There is lack of clarity and definition of responsibilities and objectives at all administrative levels.

● The *central directorate* is inadequately staffed and has no effective mechanism for exercising clear guidance and direction of the programmes at state and local level. Its functions are limited to the collection from the states of inadequate data regarding smallpox incidence and the number of vaccinations performed, the distribution of imported freeze-dried vaccine, the occasional organization of meetings of state and local programme directors, the distribution of some health education material and liaison with international organizations.

● The *states* exhibit a great variation in organizational structure. In many, responsibility for the programme is given to a senior officer burdened with many additional responsibilities. With few exceptions, the state directorates act merely as channels for funding, the transmission of instructions and the receipt of periodic reports from the districts.

● In the *districts*, the district health officer has overall responsibility for the programme as one of many responsibilities. Although as many as 3 paramedical personnel act as assistants, field visits are infrequent, supervision is poor, morale is low, interest in the programme is fading and vaccine is improperly handled and stored. Vaccinators are superintended partly by local administrative bodies and municipal boards and partly by the district staff.

Programme execution

● *Legislation* regarding compulsory vaccination varies widely. In some states both primary vaccination and revaccination are required, while in others vaccination is not compulsory. The laws governing enforcement involve cumbersome procedures, and fines are minimal and rarely imposed.

● The *plan* calls for the vaccination of all newborn infants and other individuals not

Table 15.5. India: vaccinator productivity and salary costs per vaccination performed, 1967

	Number of blocks studied	Number of vaccinations performed per vaccinator per day (range)	Cost per vaccination[a] in rupees (range)
State:			
Maharashtra	10	6.3 (0.5–11.3)	2.42 (13.9–0.48)
Punjab	8	5.7 (0.1–12.7)	3.17 (13.2–0.42)
Tamil Nadu	11	24.5 (6.4–51.6)	0.49 (1.04–0.16)
Uttar Pradesh	19	11.4 (3.1–37.2)	0.94 (8.71–0.20)
Municipality:			
Bombay		14.3	0.47
Madras		8.5	..[b]

[a] Salary costs only—i.e., not including costs of vaccine, supervision, supplies or transport. (In 1967, 1 rupee was equivalent to US$0.13.)
[b] .. = data not available.

previously vaccinated and the revaccination of everyone every 3 years; it also requires an assessment of "takes" among all primary vaccinees and 50% of revaccinees, as well as entry in the family registers of actions taken. The team concludes that none of the targets is being reached and that records are being falsified in most areas visited.

- The number of *vaccinators* is high (ranging from 1 for every 26 000 persons in Maharashtra to 1 for every 31 000 in Uttar Pradesh) but productivity is low [Table 15.5]. The mean number of vaccinations performed per day ranges from 5.7 in Punjab to 24.5 in Tamil Nadu, but in some blocks the average is less than 1 vaccination per day. Vaccinator salary costs alone average 0.47 rupee (US$0.06) per vaccination, but in 3 blocks they exceed 7.5 rupees (US$0.98) per vaccination.
- *Supervision*, except in Tamil Nadu, consists primarily in determining whether or not the vaccinator reports for work.
- *Vaccine* is improperly stored, inventories are inaccurate and refrigerators are frequently lacking or not in working order.
- The number of *reported cases* is estimated to be no more than 10% of the actual number and notification is considerably delayed except in Tamil Nadu, in which reporting appears to be reasonably complete. Many cases which are officially notified to state authorities are not subsequently reported to the national authorities. This deficiency in notification is illustrated by the situation in Punjab, in which state records to date in 1967 showed 1370 cases, of which only 273 had been notified at the national level.
- *Containment* measures are insufficient. For example, in a village in Uttar Pradesh, with a population of 250, 20 cases occurred; after containment, it was found that 20% of the unaffected children remained unvaccinated.
- Contrary to the findings of other reports, *vaccination acceptance* is good and the number of refusals for religious reasons is negligible. For the most part refusals stem from the unwillingness of people to be vaccinated at a time when a serious reaction might interfere with occupational responsibilities. Contributory factors are the tactlessness of some vaccinators, a crude vaccination technique and failure to inform people of the importance of vaccination. The rotary lancets waste vaccine (15 vaccinations are obtained from a vial of 0.25 ml compared with the 25–50 vaccinations obtained when the scratch technique is used); the lancets are difficult and time-consuming to sterilize and produce unusually severe local reactions.
- *Vaccination take rates* are said to be 100%, but assessment from records was possible only in Bombay. The records there show a take rate of 99.7%, but, in fact, failures were being recorded only after 3 unsuccessful attempts. The records show a maximum take rate of 77% after a single vaccination but it is probable that the actual take rate is considerably lower.
- The *family registers* everywhere are incomplete and contain numerous errors. They have been abandoned in Uttar Pradesh; in the Punjab and Maharashtra, in which a serious effort is being made to use them, vaccinators spend more than half their time on keeping them up to date.

Levels of achievement

- Smallpox incidence, the ultimate yardstick for measuring success, is noted to be rising. The total number of cases by the end of 1967 will represent the greatest incidence to be recorded in a decade. Even so, this total will represent 10% or less of the actual incidence.
- Cases are occurring in all age groups, although two-thirds or more in the states assessed are found in individuals under 15 years of age [Table 15.6].
- The proportion of the population reported to be receiving primary vaccination each year is less than 4% in all 4 states. With an estimated birth rate of 4% and many children born in previous years remaining unvaccinated, it is apparent that the number of susceptible subjects is accumulating.
- Sample surveys conducted among individuals under 15 years of age in randomly selected districts of the 4 states and wards of the cities of Madras (Tamil Nadu) and Bombay (Maharashtra) reveal widely different levels of performance [Table 15.7]. Uttar Pradesh has a higher proportion of unvaccinated children than was found in a survey conducted 10 years ago. In contrast, 90% of those in Tamil Nadu and 87% of those in the Punjab have vaccination scars. Vaccination levels in Madras and Bombay are substantially better than in the non-urban areas, a result attributed, in part, to the vaccination of children at birth (nearly 80% of them are born in hospital).

The team offered a detailed series of recommendations prefaced by the statement: "The Central Government should develop a new and long-term strategy to meet the

Table 15.6. India: age distribution of cases of smallpox in 4 states, 1967

problem." In brief, it recommended that greater emphasis should be given to case detection and the containment of outbreaks, especially during the summer months, when the incidence was lowest; and that primary vaccination, including the vaccination of newborn infants, should be given priority. An increase in the personnel complement of the national directorate from 1 to 5 professionals and a concomitant extension of their scope of responsibility were also recommended, along with the strengthening of supervision at all other administrative levels. It was suggested that vaccine production should be centralized and financed under national rather than state authority, that the use of liquid vaccine should cease throughout India, that the bifurcated needle should replace the rotary lancet, and that the family registers should be abolished.

Progress Achieved in the Programme, 1968–1970

The recommendations of the joint assessment team were basically sound but smallpox eradication was not high among the government's priorities. Nevertheless, over the succeeding 3 years, the production of freeze-dried vaccine increased and its quality was improved, many laboratories producing liquid vaccine were closed, the bifurcated needle was introduced, the number of primary vaccinations increased, the vaccination of newborn infants was initiated in several areas, and in some states effective surveillance–containment programmes were conducted.

Vaccine and the vaccination programme

On the basis of WHO recommendations, Dr Singh stressed in a number of directives the importance of primary vaccination, and, as from 1968, the proportion of the population reported to have been given primary vaccination increased significantly (see Table 15.4). However, even with the increase, this proportion barely exceeded the birth rate. At the same time, the total number of reported vaccinations declined steadily.

The vaccination of infants at birth was recommended as a national policy. Traditionally, primary vaccination in India had been deferred until children reached at least 3 months of age. Studies begun in 1959 by Dr A. R. Rao in Madras showed that the vaccination of neonates was safe and that systemic symptoms were minimal (Rao & Balakrishnan, 1963). With the liquid vaccine then in use, 80% were successfully vaccinated but, when freeze-dried vaccine and the bifurcated needle became available, this rate rose to more than 95%. It was clear that if vaccinators could vaccinate all children whom they encountered, overall vaccinial immunity would be enhanced. Equally important, higher levels of vaccinial immunity could be achieved in large urban areas, where 75–80% of women were delivered in a hospital or nursing home. Because the high concentration of people in urban areas played an important role in sustaining smallpox transmission, it was hoped that routine vaccination of newborn children in cities might have a significant impact in diminishing incidence throughout the country.

The routine vaccination of neonates began in Madras and Bombay in 1967 and in several other cities of Tamil Nadu in 1968. However, the practice was not enthusiastically pursued in most areas, partly because of the lack of interest shown by the autonomous municipal health officers and partly because mothers were reluctant to let their babies be vaccinated. They had observed in other children

the severe lesions induced by the rotary lancet and had had no opportunity to see the results of vaccination with the bifurcated needle.

From 1968 to 1970, efforts were made to increase the volume and quality of vaccine produced in India and to improve the distribution system and storage of the product. In 1969 the government appointed a central director for vaccine production and distribution, Dr S. N. Ray, and the following year, the 4 vaccine production centres were placed under central government authority and financed by central government funds rather than state funds. This simplified distribution, because vaccine produced in any one of the institutes could then be sent to any state of India without special payments being required. Previously, vaccine produced in each of the state laboratories had been used mainly in that state, while vaccine donated to India, primarily by the USSR, was sent to other states.

Vaccine production in India gradually increased in volume but less rapidly than had been expected. Not until 1974, in fact, did the country become completely self-sufficient (Table 15.8). In part, the delays could be attributed to preoccupation on the part of the director of the Patwadangar laboratory, the principal production laboratory, with the introduction of comparatively new, more elaborate machines for freeze-drying—the so-called shelf-driers. Relatively simple centrifugal freeze-driers were then in use in many countries and when installed in competent laboratories, as in Indonesia and Kenya for example (see Chapter 11), could be used at full capacity within a year. The director justified the need for the shelf-driers on the grounds that extremely large quantities of vaccine would be required, estimating the need for far greater amounts than had been used during the 1962–1966 mass vaccination campaign. Moreover, he argued that the bifurcated needles, although they used less vaccine and had been adopted in most other countries, would never be acceptable in India. WHO smallpox eradication programme staff, however, foresaw the need for smaller quantities of vaccine, especially if the bifurcated needles could be used, and argued for the purchase of the less complex centrifugal driers. After an impasse lasting almost a year, a staff member of the WHO regional office, who was responsible for providing advice to laboratories, gave approval for the purchase of the shelf-driers, although he himself was not competent in vaccine production. With the promise of purchase of the shelf-driers, the laboratory director gave approval for studies of the bifurcated needle to be undertaken in India (see below). As had been feared, the shelf-driers proved difficult to operate and production increased only slowly but, because of the introduction of the bifurcated needle and the continued provision of vaccine by the USSR, vaccine shortages did not occur.

With an assured supply of freeze-dried vaccine available throughout India, it became possible for the government to insist on the cessation of production of the thermolabile

[a] With the rotary lancet, the contents of 1 ampoule were required to vaccinate 12–15 persons. When the bifurcated needle was used, the same quantity of vaccine sufficed to vaccinate as many as 100.

[b] The USSR donated from 5 to 6 million ampoules of vaccine annually beginning in 1962, but data regarding the distribution of this vaccine are not available before 1970–1971.

liquid vaccine. However, closure of the 14 state institutes which produced it proved to be difficult. The central government lacked the necessary authority; one by one, each state and centre had to be visited by officials of the central government and persuaded to cease production. This was finally accomplished in 1970, the last centres being in Calcutta and the eastern states. Even after closure of the production centres, however, problems remained. In several states, the stocks of liquid vaccine occupied all the available refrigerated storage space and, without the sanction of the finance department to destroy the vaccine, programme officers could take no action. Accordingly, in several areas, including Bihar State, in which smallpox was eventually to prove a major problem, stocks of freeze-dried vaccine continued to be stored at room temperature while the obsolete liquid vaccine was kept under refrigeration.

The provision of satisfactory refrigerated storage for vaccine was a continuing problem in other areas as well. The freeze-dried vaccine was supposed to be kept at ambient temperature for not more than 30 days but could be stored almost indefinitely at temperatures of 4 °C or less. Because, for reasons of logistics, most vaccinators could obtain vaccine supplies only once a month, it was important to ensure that vaccine stored in district offices, as well as in the state and national depots, was kept under refrigeration. Satisfactory storage at state and national distribution centres was gradually achieved through the provision of refrigerators by UNICEF and WHO and through the use of other facilities such as cold-rooms normally used for the storage of fruit and vegetables. In the districts, however, satisfactory storage was uncommon. Although virtually all district offices were provided with refrigerators for the storage of drugs and vaccines for a variety of programmes, few were maintained in working order. For example, as late as 1975, 85% of the refrigerators in district offices in Uttar Pradesh were found to be inoperative. Fortunately, as tests of vaccine showed, much of the vaccine produced in the USSR and India maintained levels of potency adequate for primary vaccination even after 3–4 months at high ambient temperatures (Sehgal, 1974; Sehgal & Ray, 1974).

The assessment team had also recommended that at least one-third of all batches of vaccine produced and tested in the separate laboratories should be independently tested by a national vaccine control laboratory and that the results should be confirmed by a WHO smallpox vaccine reference centre (National Institute of Public Health, Bilthoven, Netherlands). In 1969, an Indian central control laboratory was established at the National Institute of Communicable Diseases, New Delhi, although it was not until 1972 that the laboratory actually monitored the recommended number of batches. In 1969, some batches of vaccine also began to be sent to the WHO reference centre for testing. During the period 1969–1976, of the 241 batches tested by WHO only 9 (3.7%) were found to be substandard (Basu et al., 1979). Although these data would suggest a consistently high level of satisfactory production, it must be noted that all batches dispatched to WHO had been determined, first by the production laboratory and then by the central control laboratory to be completely satisfactory. The producers and the central testing laboratory found a much higher proportion of batches of vaccine to be of inferior potency or stability or unacceptably contaminated with bacteria. Some such batches were destroyed but, in the first few years, most were distributed anyway because vaccine was in short supply. Properly, it was considered preferable to use substandard freeze-dried vaccine than to use liquid vaccine or to have no vaccine at all. No compilation of data on vaccine quality is available, but it was known that the Hyderabad and Guindy laboratories both had persistent difficulties in producing satisfactory vaccine. However, together they accounted for less than one-fifth of all vaccine distributed in India and most of the vaccine they produced was distributed to states in southern India in which health services were generally better and smallpox incidence was lower.

The improved quality of vaccine and a better storage system undoubtedly resulted in a higher proportion of successful vaccinations in the field, although no data are available to substantiate this.

Introduction of the bifurcated needle

The bifurcated needle had been tested by WHO in late 1967 and early 1968 and was rapidly made available throughout most countries by the middle of 1968. In India, however, the traditional rotary lancet had

been in use since before the turn of the century and a number of prominent senior health authorities as well as the director of the vaccine production laboratory in Patwadangar resisted the introduction of the new instrument. They argued that it would produce fewer successful vaccinations, that vaccinators would find it too difficult to use, and that the population would resist vaccination with an unfamiliar device. Finally, it was agreed that comparative studies of the two instruments would be undertaken by the National Institute of Communicable Diseases and the Central Health Education Bureau (WHO/SE/70.16).

In 1969, the National Institute assessed the efficacy of the two techniques (Pattanayak et al., 1970). In one study, previously vaccinated children were vaccinated on one arm with the rotary lancet and on the other arm with the bifurcated needle. Vaccines of three different levels of potency were employed. The results showed that the bifurcated needle had a clear-cut advantage over the rotary lancet (Table 15.9).

Comparative data derived from a study of a small number of children given primary vaccination showed similar results. It was found that vaccinators readily learned the new technique and used it successfully.

During the same period, the Central Health Education Bureau investigators assessed the acceptability of the new technique, with surprising results. Persons in 5 villages were vaccinated with the bifurcated needle, but they were given no explanation about the new device. One week later, the vaccinees were examined to determine the proportion with successful vaccinations and were interviewed about the new technique. All those given primary vaccination, and 79% of those who had been revaccinated, had successful takes. As the investigators noted, "surprisingly, few realized that the technique applied was different from the customary rotary lancet method" (WHO/SE/70.16). With these results, the needle was accepted by the national health authorities for use in India.

Needles were provided by WHO in large numbers and, by late 1969, they were in wide use in many states. However, the adoption of the new technique required that a decision should be taken separately by each state and municipality, and some were not persuaded. Not until 1971, for example, were the needles used in the states of Uttar Pradesh and Bihar. In many municipalities, vaccinators continued to use the rotary lancet until late 1973, when municipal smallpox eradication staff were brought under state jurisdiction.

The use of the bifurcated needle, however, brought a curious and unforeseen administrative problem. Auditors in India continually scrutinized the number of vaccinations performed in an area and compared it with the number of vaccinations reported in order to detect wastage. The vials of vaccine containing 0.2 ml allowed for only 15 vaccinations if the rotary lancet was used. With the bifurcated needle as many as 100 vaccinations could be performed with the contents of one vial, but in practice, an average of only 40–50 vaccinations was achieved because whatever reconstituted vaccine remained at the end of the day was supposed to be discarded. Although, in fact, more vaccinations were performed per vial supplied, the auditors calculated that each vial should now yield 100 doses of vaccine. Their assertions that vaccine was being wasted were to plague smallpox eradication staff throughout the rest of the programme.

Sample surveys to determine vaccination status

In 1969, the technique for vaccination scar surveys which had been developed in Afghanistan (see Chapter 14) was introduced into India. Through such surveys it was hoped that responsible officials would identify for themselves deficiencies in their vaccination programmes and correct them.

Table 15.9. India: results of simultaneous revaccination of children with the rotary lancet and the bifurcated needle

Vaccine potency (pock-forming units/ml)	Number of children	Rotary lancet	Bifurcated needle
		Number (%) with satisfactory response	Number (%) with satisfactory response
1×10^8	84	22 (26)	47 (56)
5×10^7	82	10 (12)	29 (35)
1×10^7	81	10 (12)	26 (32)

The simplified methodology for scar surveys, using a cluster sample technique, was enthusiastically received in many states and numerous surveys were undertaken, some of which were state-wide. Not all the surveys were well designed, but the results consistently revealed a remarkably high proportion of vaccinated persons. The surveys showed that vaccination scars were borne by 92–99% of individuals in the age group 5 years and above; by 78–92% of those aged 1–4 years; and by 10–60% of infants under 1 year. Although the results were dutifully compiled and reported, few used the data constructively to identify populations or areas in which vaccinial immunity was low and to improve performance in such areas. The idea of assessing vaccination status in this way was reasonable but, in retrospect, the approach was probably counter-productive in that it served to reinforce the notion that mass vaccination was the principal foundation of the programme, rather than surveillance–containment measures.

The decline in smallpox incidence

Between 1967 and 1970, the reported number of smallpox cases fell dramatically—from 84 902 to 12 773, the lowest total ever recorded in India. Both government and WHO staff recognized that this reflected, at least in part, the normal periodic fluctuations of smallpox. Peaks in smallpox incidence in India normally occurred every 4 7 years, a periodicity extending back many decades. The peak in 1967 occurred just 4 years after the peak in 1963, which had been preceded, 5 years before, by the peak in 1958. This pattern was said to occur as a result of the gradual increase in the number of susceptible persons because of the waning of immunity in the population at large and the addition of susceptible newborn children. It was believed that when a sufficient number of susceptible persons had accumulated, an epidemic would ensue which would diminish this pool of susceptible individuals and thus the ease with which smallpox could spread. Following the epidemic, smallpox incidence would again decline. The decrease in the number of reported cases between 1967 and 1970 was thus not unexpected, but because the incidence had fallen to such low levels, some government and WHO staff were both optimistic and, to a certain extent, unduly satisfied with progress in the redirection of the programme. The archaic notification system, with its delays in reporting, only served to reinforce this optimism. By mid-January 1971, for example, only 8026 (63%) of the 12 773 cases eventually recorded for 1970 had been reported to the Central Bureau for Health Intelligence.

Southern India, 1967–1970

The decline in smallpox incidence between 1967 and 1970 was especially notable in the 6 states and 5 union territories which formed the entire southern part of India. This area had a population in 1967 of 196 million (38% of the national total). The number of cases fell from 42 633 in 1967 to only 795 in 1970. Many districts reported no cases in that year (Fig. 15.5) and none was detected in the entire state of Tamil Nadu (population, 41 million) (Table 15.10).

In part, this decline was attributable to a generally more developed health service structure, especially in the states of Kerala and Tamil Nadu and, in consequence, a better execution of the mass vaccination campaign. It was also associated with the development of an effective surveillance–containment programme—first in Tamil Nadu and later in parts of Andhra Pradesh.

To evaluate the applicability of surveillance–containment in India, it was decided in 1968 to investigate and contain all outbreaks in Madras, the capital of Tamil Nadu, and subsequently in the state itself, employing a surveillance team directed by Dr A. R. Rao, then Health Officer of the Madras Municipal Corporation. Support for this operation was provided by the Indian Council for Medical Research and WHO (WHO/SE/68.6 and WHO/SE/68.7, A. R. Rao). Dr Rao, for many years the Director of the Madras Infectious Diseases Hospital, had conducted extensive investigations into the clinical and epidemiological behaviour of smallpox (Rao, 1972). He was an ideal person for the task and interested in taking up the challenge.

Smallpox incidence in Tamil Nadu had declined sharply, from 8901 cases in 1963 to only 263 cases in 1967, of which 38 cases had been reported by the Madras Municipal Corporation. The joint India–WHO assessment team (1967) believed that reporting was better in Tamil Nadu than elsewhere in India and, if indeed there were as few cases as notifications suggested, it should be possible to stop transmission with a comparatively

modest outbreak containment programme. If successful, it would serve as an example for other states in India.

Between January and June 1968, the season of highest smallpox transmission, Dr Rao investigated 13 outbreaks in Madras, which were detected when patients were brought to the hospital or when fatal cases were registered at the burial grounds. The source of 7 outbreaks could be traced, 6 of them coming from adjoining states. Eight of the index cases were hospitalized within 10 days of onset and none of them spread the disease. Five of the infected persons were hidden at home and, before discovery, 8 second generation and 4 third generation cases occurred. However, the total number of cases was small and, as Dr Rao emphasized, smallpox did not spread rapidly in this population despite its high density and the season of the year. In mid-

[a] No cases were recorded during this period in the union territories of Andaman and Nicobar Islands, Lakshadweep and Pondicherry.
[b] Became the state of Karnataka late in 1973.

June, the team began to extend its activities beyond the boundaries of the city. The investigation of a case brought to the hospital from a village 24 kilometres away revealed an outbreak of 44 cases in 5 villages. The outbreak had begun in January, when migrant workers returned from the neighbouring state of Andhra Pradesh. As in the city, smallpox had spread surprisingly slowly, suggesting again that outbreaks might be readily controlled. Between July 1968 and June 1969 only 2 additional outbreaks were found in all of Tamil Nadu: one comprised 6 cases imported from Madhya Pradesh State, and the other involved a single patient who had been infected in Gujarat State (WHO/SE/70.19, A. R. Rao). Transmission in Tamil Nadu had been interrupted less than 6 months after a single surveillance team had begun its work; after May 1968 the state remained smallpox-free except for importations.

The Madras team had little to do and so, in October 1969, with the agreement of the authorities in the neighbouring state of Andhra Pradesh (population, 43 million), Dr Rao investigated outbreaks in coastal villages 160 kilometres north of Madras. In all, he documented more than 200 cases in the poorly vaccinated population of a group of fishing villages (WHO/SE/70.17, A. R. Rao et al.). This, in turn, stimulated surveillance activity on the part of the state authorities of Andhra Pradesh. The number of cases in Andhra Pradesh diminished from 7951 in 1968 to 1893 in 1969 and to 358 in 1970. However, transmission persisted, primarily among the fishermen and their families, who migrated seasonally from this area northwards to Orissa State.

The success of surveillance and containment measures in both Andhra Pradesh and Tamil Nadu was dramatic, but, despite Dr Rao's presentations at subsequent national and international meetings, little notice was taken of the achievement. The state smallpox eradication programme officer who accompanied Dr Rao to the meetings rightly noted that the vaccination campaign in Tamil Nadu had been exceptionally well executed, but he argued that it was for this reason, and not because of the surveillance–containment activities, that transmission had been interrupted there. Authorities in other states dismissed the attainment as not surprising in the generally more prosperous southern states and of no applicability to most of the rest of India.

Western India, 1967–1970

Although progress in southern India gave cause for optimism, the number of reported cases of smallpox doubled in the western state of Gujarat (population, 27 million), increasing from 3403 cases in 1967 to 7654 in 1968. The epidemic continued into 1969, when 6284 cases were recorded—i.e., one-third of all cases reported in India (Table 15.11) and, in fact, almost one-fifth of all cases reported throughout the world.

WHO proposed to the government of India that a team should visit Gujarat to assess the situation. The government agreed, albeit reluctantly, to a 1-week field trip. Since the 1967 India–WHO assessment of the programme, field visits by WHO Regional Office staff, although resident in New Delhi, had been discouraged. It was the government's view that WHO staff could

Table 15.11. Western India: number of reported cases of smallpox, 1967–1970

Grand total	84 902	35 179	19 281	12 773

contribute little to a programme that was directed by a national staff who had been engaged in eradication since 1962. Field visits by national staff were likewise uncommon, Dr Singh rarely being able to leave New Delhi because of his innumerable responsibilities. Moreover, his authority was circumscribed because the responsibility for programme execution rested primarily with the states.

In April 1970, a 3-man team, comprising Dr Andrzej Oles, from the WHO Regional Office for South-East Asia, Dr Singh and Henderson, visited Gujarat State and its capital, Ahmedabad (population, 1.7 million). The epidemic in Ahmedabad was considered by local staff to have begun in November 1969 and, to combat it, 150 temporary vaccinators had been hired to supplement a staff consisting of 1 supervisor (medical officer), 39 vaccinators and a 6-man "flying squad". This provided 1 vaccinator for approximately every 9000 persons. The hiring of large numbers of temporary vaccinators without additional supervisors was a common response throughout India to epidemic smallpox. Between January and March 1970, more than 360 000 people had been vaccinated but the number of reported cases continued to increase. The Deputy Director of Health and Medical Services, Dr G. J. Ambwani, had done a commendable job in improving the facilities for vaccine storage and distribution and in introducing the bifurcated needle. Vaccinial immunity was found to be high in all areas which the team visited. The containment of outbreaks was prompt but poorly executed. The team found many additional unreported cases and in none of the outbreaks had an effort been made to identify the source of infection and, thereby, additional outbreaks. Although local civil authorities were responsible for case reporting, almost all the cases were reported by vaccinators.

More disturbing was the discovery that the large numbers of cases reported were not reflected in reports to the national authorities. It was found that the Central Bureau for Health Intelligence had recently informed state statistical sections that it wanted a final report from all districts within 3 weeks of the notification of an outbreak. In Gujarat, this was interpreted to mean that any additional cases that were found after this period or any cases that had experienced the onset of illness more than 3 weeks previously should not be reported to the Central Bureau. The cases were, however, recorded by the state's smallpox eradication programme office. Not only was the epidemic in Gujarat of a far greater magnitude than had been suspected, but the discovery that this new policy had been adopted led to the suspicion that India's remarkable decline in incidence might possibly be an artefact caused by a reporting system distorted by misguided or misunderstood directives.

The team concluded that cases were occurring predominantly among a small, unvaccinated segment of the population, amounting to not more than 5–10% of the total, primarily in slum areas and among migrant labourers.

After just 5 days' work in the field, Dr Ambwani realized that he had not previously understood the surveillance–containment strategy and promised to implement such a programme forthwith. Working with the state smallpox eradication programme officer, Dr S. D. Verma, he was remarkably successful. The numbers of cases declined rapidly and in June 1971, only 14 months after the team's visit, transmission ceased.

Plate 15.3. Members of an Indian/WHO team to assess the smallpox epidemic in Gujarat State in April 1970. *Left to right*: Andrzej J. Oles (b. 1923), an epidemiologist with the WHO Regional Office for South-East Asia; Mahendra K. Singh; and G. J. Ambwani, Deputy Director of Health and Medical Services of Gujarat State.

Other cases occurred later but they were traced to importations from other states. The success in Gujarat suggested to both senior Indian and WHO staff that if states were given modest assistance to foster surveillance–containment programmes, these results might be replicated elsewhere. Unfortunately, Gujarat, like Tamil Nadu, was to prove an exception.

The team returned to New Delhi encouraged by Dr Ambwani's interest in and responsiveness to the surveillance–containment strategy but now less confident that the remarkable decline in the number of reported cases was real. A recommendation was made that the reporting system should be changed but this was vigorously resisted by the director of the Central Bureau for Health Intelligence. Thus, the programme continued, its personnel less certain of the true incidence of smallpox but now placing increased reliance on data provided by state eradication programme officers rather than on official government statistical reports. However, because the quality of the programme officers varied greatly from state to state and because the Central Bureau's directives were variously interpreted by officials at different levels, it was difficult to known what the different sets of numbers really meant without field visits to every state—and no staff were available to undertake such visits.

Yet another disturbing observation was made in the western states in the spring of 1970. It began to appear that smallpox might be moving as an epidemic wave in a clockwise direction around India. In 1967, immediately before the 1968–1969 Gujarat epidemic, Maharashtra, the state immediately to the south, had reported especially severe epidemics. That year, it had recorded 27 961 cases, one-third of all cases reported from India. The number dropped to 3173 in 1968 and to 1411 in 1969. In the spring of 1970, the states of Rajasthan and Haryana, immediately to the north of Gujarat, began to experience major epidemics.

This had not been expected. Since the 19th century, major epidemics in the Indian subcontinent had been observed to occur every 4–7 years, but the periodic fluctuations had been thought to take place more or less simultaneously throughout the country. The wider availability of vaccine had not altered this pattern. That the periodicity had persisted until 1962 was understandable because intensive and widespread vaccination had been conducted during and immediately after epidemics, but as smallpox waned so did interest in vaccination. However, it was quite unexpected that the intensive ongoing national vaccination campaign begun in 1962 had not prevented the 1967 epidemic. To explain this recurrence, it was suggested that many states had not conducted effective

campaigns, and because much of the vaccine used had lacked potency, the large pool of susceptible persons had not significantly diminished. Between 1967 and 1970, however, most of the vaccine reaching recipients was believed to be fully potent and because the number of primary vaccinations had substantially increased, the opinion was held that India should not again experience a major epidemic year. Thus, the recurrence of epidemic smallpox, apparently moving in a clockwise direction around India, was totally unexpected but a critical factor in the formulation of subsequent strategy.

In 1970, senior national government staff began to take a greater interest in the smallpox eradication programme. Epidemic areas in Haryana and Rajasthan abutted on New Delhi, the national capital. Reports of the outbreaks appeared in increasing numbers in New Delhi newspapers, and members of Parliament expressed concern through "call-attention" motions, obliging the government to give an account of what was being done.

The Gujarat team had concluded in its recommendations to the government: "... of greatest importance ... is the need to augment the staff at state level to provide leadership to the programme and to develop and coordinate, by active field work, the very critical surveillance–containment activities." WHO proposed to the government that 4 WHO epidemiologists should be recruited to work as advisers with state programme officers. One would be assigned to Rajasthan, in which smallpox incidence was rapidly rising; one each would be allocated to Uttar Pradesh and Bihar, the two densely populated states comprising most of the northern Ganges river plain, and, if assumptions regarding the clockwise movement of epidemic smallpox were correct, the next to experience major epidemics; the fourth epidemiologist would be assigned to work with state programme officers throughout the southern states in an effort to interrupt transmission in this vast area. Dr Singh, meanwhile, would plan to work with programme officers in the small neighbouring states of Haryana, Punjab and Himachal Pradesh as well as the Delhi Municipal Corporation.

The Director-General of Health Services and the Secretary of Health were initially of the opinion that 2 advisers would suffice but ultimately agreed to 4. On 9 September 1970, an agreement was signed by the government and WHO which committed WHO to provide: (1) 4 epidemiologists and 3 short-term consultants for 3 months each in 1970 and 1971, plus the costs of their travel; (2) vehicles and other supplies; and (3) funds to pay salaries, travel and per diem "for additional personnel employed full-time in smallpox units at the national and state levels up to the limit of Rs. 1 125 000 each year" (US$146 250). In 1970, WHO support to the programme for the first time exceeded US$100 000. During the succeeding 7 years, more than US$11 million would eventually be provided, most of which represented contributions from the government of Sweden (Table 15.12). Additional funds were allocated to the WHO Regional Office for South-East Asia, which as the Indonesian programme concluded, began to devote more time to the programme in India.

The Foundations are Laid for the Intensified National Campaign, 1971–1973

From 1971 until the summer of 1973 the programme gradually evolved and, in doing

[a] Expenditures by the central government (1965–1969) and state governments (1965–1972) are estimates. Of funds expended by WHO between 1974 and 1977, US$0.1 million were provided by the Swedish International Development Authority.

[b] Excludes the estimated value of vaccine provided between 1965 and 1974, which amounted to 701 million doses from the USSR and 5 million doses from WHO.

[c] Value of contributions in cash and in kind from Tata Industries (US$600 000), USA (US$402 000), UNICEF (US$380 000), and OXFAM (US$100 000).

Plate 15.4. **A**: Alberto M. Monnier (1914–1979), an epidemiologist, served as the WHO smallpox officer in Rajasthan State from 1971 to 1976. **B**: Viatcheslav A. Moukhopad fulfilled the same role in Uttar Pradesh State from 1971 to 1976.

so, laid the foundations for the intensified national campaign, termed "Smallpox Zero", which began in the autumn of 1973. A closer working relationship was established between the government of India and WHO; the bifurcated needle replaced the rotary lancet in all but a few municipal corporations; the use of liquid vaccine ceased completely; larger quantities of good-quality freeze-dried vaccine produced in India became available; the reporting system was changed; and a procedure for the detection of cases was elaborated.

WHO recruited 2 new regional smallpox advisers, for what was then called the Regional Epidemiological Surveillance Team, as well as 4 epidemiologists for assignment to India. Dr Nicole Grasset, a French virologist and epidemiologist, became the regional adviser in 1971, replacing Dr Keja, who had been transferred to Indonesia. She had worked previously in smallpox and measles control activities in eastern Nigeria and had proved to be a charismatic leader. She was joined in the regional office in 1972 by Ježek as the second regional adviser. Although they were responsible for smallpox eradication activities throughout the South-East Asia Region, much of their work was to be devoted to the programmes in India and Nepal. The 4 epidemiologists for the programme in India were assigned to the states. Dr Alberto Monnier, a Mexican epidemiologist who had been with the Indonesian smallpox eradication programme, began work in Rajasthan in January 1971 and Dr V. A. Moukhopad, a Soviet epidemiologist, arrived a month later to begin work in Uttar Pradesh. That summer, a Czech epidemiologist, Dr Vladimir Zikmund, began work in the southern states. Another epidemiologist reported for duty in Bihar during the summer but stayed only 6 months before resigning. At that time, the post in Bihar was felt to be the least critical, since the available data for 1971 showed smallpox was then concentrated in the north-western part of the country (Fig. 15.6), geographically distant from Bihar. A principal problem in Bihar, as well as in the other states, was the stipulation that each state should provide a vehicle for each adviser and cover the costs of its operation. Rarely before had WHO staff been assigned to work at state level in India and, with vehicles in the states in short supply and poorly maintained, the provision of transport for the advisers was a problem. In Bihar, none was made available and, in general, state officials showed little interest and offered the minimum of cooperation in helping to solve difficulties of this kind. Not until 2 years later were the inadequacies of the Bihar health structure fully appreciated. Conceivably, more energetic measures in Bihar at that time might have averted the catastrophe that lay ahead.

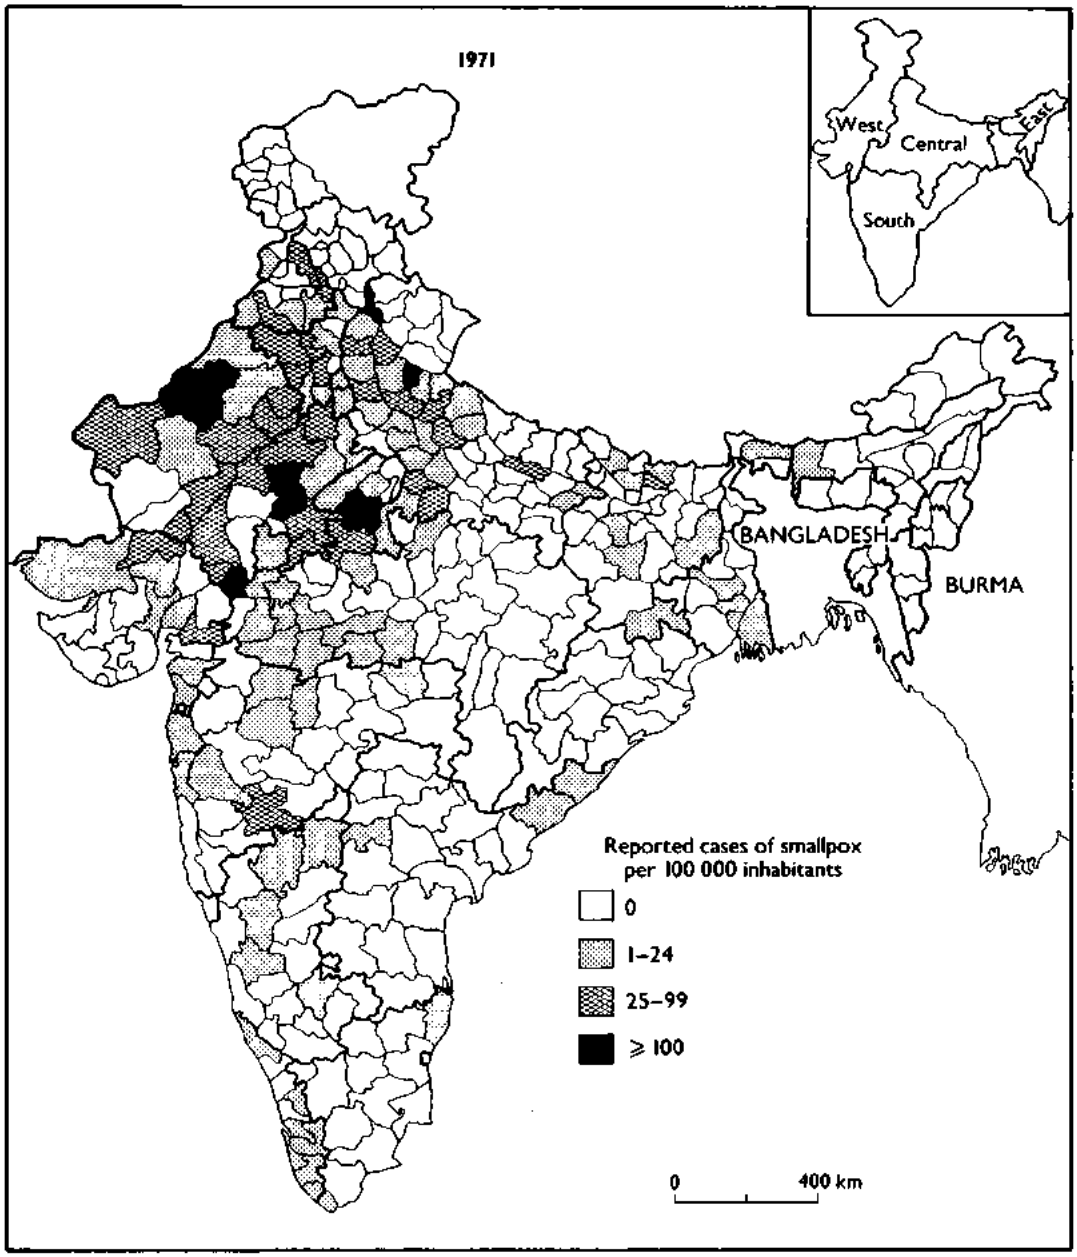

Fig. 15.6. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1971.

Smallpox eradication activities continued in all states throughout 1971–1973, with varying levels of success. During this period there were developments of particular note in the western states and in Uttar Pradesh, as well as in certain of the areas of low incidence in the south, and an unanticipated setback originating in a Bangladeshi refugee camp in West Bengal. These are described below.

Western India, 1971–1973

It had been hoped that the dramatic success of the surveillance–containment programme in Gujarat might be repeated in the other western states and in Uttar Pradesh, in which epidemics were then beginning. Dr Monnier, assigned to Jaipur, the capital of Rajasthan, and Dr Moukhopad, assigned to Lucknow,

the capital of Uttar Pradesh, provided needed support. Full-time assignments were deemed advisable: in Rajasthan because health and other services were less well developed in this conglomerate of former princely states than in most of India; and in Uttar Pradesh because of its vast population (91 million) and its dismal performance during the mass vaccination campaign.

Rajasthan, besides having a less adequate structure of health services and a less literate population than much of India, was geographically a problem, nearly two-thirds of its area being desert and semi-desert. Roads were few and working conditions demanding. The population of 26.5 million was principally settled in 151 towns and 33 305 villages, but there were nomads as well. Three state teams were created which were directed, respectively, by the Deputy Director for Communicable Diseases, Dr M. L. Aggarwal; his deputy, Dr D. K. Jagdev; and Dr Monnier. Each was assigned a paramedical assistant. Vehicles were made available sporadically for the state officials but Dr Monnier used his private car for almost a year until it was agreed that WHO would provide him with a vehicle. In addition to training district and local staff in reporting and containment measures during their extensive travels and in specially convened meetings, the teams undertook to detect and contain outbreaks.

As in other countries, the discovery of suspected cases was usually accomplished by questioning village leaders, schoolteachers and their pupils, and people attending weekly markets. In Rajasthan and in many other parts of India, there were two additional methods, unique to India, by which cases could be detected. One consisted in questioning visitors to the Sītalā mata temples. Many villagers came to give thanks to the goddess for recovery from smallpox or to offer homage in the hope that they and their families would be spared a visitation by the goddess. Cases could also be detected in villages when, as was customary in many areas, branches from the neem tree were hung over the front door of a house in which a patient lived. The leaves of the neem were considered to have special cooling properties when applied to the skin of the patient and other, less tangible, properties when hung above the doorway.

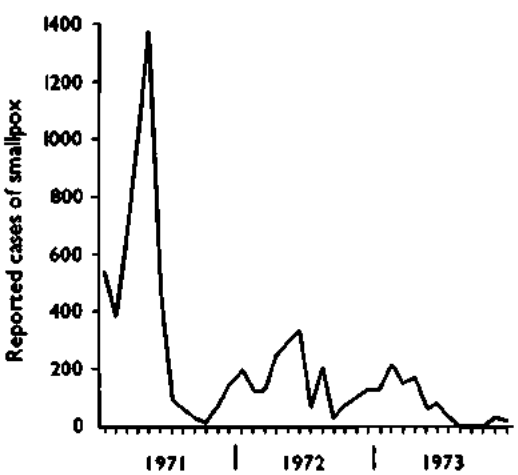

Fig. 15.7. Rajasthan State: number of reported cases of smallpox, by month, 1971–1973.

The programme in Rajasthan made commendable progress. At the beginning of the summer of 1971, the number of reported cases declined steeply, and the incidence remained comparatively low during the spring smallpox season of 1972 (Fig. 15.7). In October, in order to strengthen the programme, other health workers, such as the family planning and malaria eradication programme staff, were directed to report any smallpox cases found during the course of their work. A further decline in incidence occurred in 1973 (Table 15.13), and from August to October 1973 no cases whatsoever were detected. Cases occurred subsequently in Rajasthan, but they originated from importations. The results were impressive and what had been hoped for, although the programme was undoubtedly assisted, as in Gujarat, by a decline in incidence associated with the longer-term fluctuations of smallpox. Nevertheless, little more than 2 years had elapsed between the time the surveillance teams

had begun work and the unprecedented occurrence of 3 months without detectable smallpox.

Dr Singh, through such visits as he could make to the western states near New Delhi, was no less successful in stimulating effective surveillance–containment programmes. The number of cases in the contiguous states of Haryana, Himachal Pradesh and Punjab and in Delhi Municipal Corporation (total population, 32 million) fell somewhat less steeply than in Rajasthan, but by the winter of 1972–1973 fewer than 100 cases were being detected monthly, many of which resulted from importations from the neighbouring state of Uttar Pradesh. By September 1973, transmission had been interrupted throughout this entire area, the only reported cases resulting from importations into New Delhi.

Meanwhile, the programme in Gujarat had progressed so satisfactorily that only 44 outbreaks were detected during the first 6 months of 1971, and none whatsoever from July to the end of October. It seemed impossible that transmission could have been stopped in a state so heavily infected as recently as 1970. Accordingly, Arita was asked to direct a special assessment of the state in November 1971. During a 3-week period, he led a 6-member team which visited 90 towns and villages in high-risk areas of 11 districts. No evidence of smallpox since June of that year could be found. The success reflected, in part, improved case detection and containment of outbreaks, but intensive vaccination undoubtedly also played a role. District surveys in September 1971 revealed that vaccination scars were present in 98–99% of those aged 5–14 years, in 96–99% of those aged 1–4 years and in 66–88% of those aged less than 1 year.

The smallpox eradication programme throughout the western states was progressing everywhere as had been hoped (Fig. 15.8) with a single exception—the northern state of Jammu and Kashmir (population, 4.8 million), which had once been free of smallpox. In the autumn of 1972, the state began reporting increasing numbers of cases. Until October, Jammu and Kashmir had experienced only occasional importations which, according to state reports, had been quickly contained. It had been hoped that by preventing smallpox from becoming re-established in Himachal Pradesh, a geo-

graphical barrier to the northward spread of the epidemic would be created, preventing the disease from reaching Jammu and Kashmir. Dr Singh, working with effective state programme staff, proved successful in maintaining the non-endemic status of Himachal Pradesh. Unfortunately, many travellers to Jammu and Kashmir imported smallpox from infected areas more than 50 kilometres away. Because of the paucity of senior smallpox advisers, assistance had not been provided to state staff in Jammu and Kashmir and the health services had been unable to cope. The failure to strengthen activities in this state was an omission for which the programme would subsequently pay dearly in additional effort.

Uttar Pradesh, 1971–1973

The development of surveillance–containment programmes in the western states proved to be comparatively straightforward, but in the adjacent state of Uttar Pradesh, the experience was entirely different. Uttar Pradesh was India's most populous state (population, 91 million) with a density of 300 persons per square kilometre. Most of the state comprises the Ganges river plain, where population densities were among the highest in India and where transport and communication services were quite well developed. There was an extensive, well-established infrastructure of health services and a large, reasonably well trained health staff. In retrospect, unexpected problems might perhaps have been foreseen because of Uttar Pradesh's poor performance in the mass vaccination campaign, and because it was the last state in India to replace the rotary lancet with the bifurcated needle (1971).

During 1971, Dr Moukhopad and the state programme officer travelled extensively to conduct regional training programmes for all district health officers and their programme staff. However, almost as soon as they were trained in reporting and in surveillance–containment procedures, they were transferred to other districts or assumed other duties. Many who reported substantial numbers of cases of smallpox from their districts were disciplined by the state Director of Health Services by being transferred to hardship posts on the grounds that the presence of cases was tacit evidence that they had not conducted an effective vaccination campaign. Although other states followed this practice, none did so as frequently as Uttar Pradesh and neighbouring states in northern India. Continuing efforts were made by national staff and WHO advisers to persuade state officials that their actions were counter-productive, but with only partial success.

Progress in the programme in Uttar Pradesh was difficult to assess, in part because of the suppression of reports by district officers and in part because of the archaic state and national reporting system. During 1971, the number of cases reported from Uttar Pradesh to the Central Bureau for Health Intelligence never reached 500 per month, and indeed between July and September of that year fewer than 100 cases were notified each month for the entire state. The relevant data, reported to the Central Bureau and to WHO up to 26 October 1971, are shown in Table 15.14 (*Wkly epidem. Rec.*, 1971b). Even if one were to assume that there were 10 times as many cases as had been reported, not only Uttar Pradesh but India as a whole appeared to have very few chains of smallpox infection. On the basis of a growing experience with surveillance–containment programmes, it seemed reasonable to expect that transmission could be interrupted comparatively easily and rapidly. The greatest impediment in assessing the true situation and in deciding how best to deploy resources to achieve this goal was the reporting system.

In November 1971, the government and a new acting director of the Central Bureau for Health Intelligence agreed to modernize the reporting system so that its procedures would resemble those used in other countries. Each primary health centre was directed to notify to the district on Saturday of each week the total number of cases detected that week irrespective of the date of onset. If no cases were reported, a "nil" report was to be submitted. The submission of a nil report was a most important feature. Previously, the absence of a report had been assumed to mean an absence of cases when, in fact, the responsible medical officer may have been negligent in reporting or had decided not to report because there were a great many cases. Officials who had been accustomed to suppressing information through the simple expedient of not submitting a report found it difficult to indulge in deliberate falsification. The districts were asked to ensure that reports from all primary health centres were

submitted and to compile all reports then available on the following Tuesday and to send them to the state smallpox eradication programme office. The state, in turn, was made responsible for ensuring that all districts reported and, on each Thursday, for telegraphing a report to the Central Bureau for Health Intelligence and the National Smallpox Eradication Programme office. Many months, and in some states several years, of work were required before the reporting system functioned well but a major obstacle to the achievement of eradication in India had at last been removed.

In November 1971, Uttar Pradesh was the first state to implement the new reporting scheme. By February 1972, the number of districts which had not reported for 3 weeks or more had fallen from 17 to only 5, and by summer, 48 of the 55 districts were submitting reports promptly each week. Whether because of improved reporting or because of an actual increase in incidence, the number of recorded cases rose during the winter of 1971–1972 to between 1200 and 1600 each month (Fig. 15.9)—but still, in a population of 91 million, this was not a great number. Senior staff continued to believe that with sustained support to the surveillance–containment effort, Uttar Pradesh would repeat the experience of the western states. It was not to be. Smallpox eradication staff were diverted to perform cholera vaccinations between September and December 1972, at a time when the containment of smallpox outbreaks was most crucial. Although cholera vaccine had been shown to be of little value, this was the usual and politically acceptable response of the health services when cholera occurred. Explosive outbreaks of smallpox spread across the state; the number of cases increased rapidly during the early months of 1973, reaching a peak in May, when 5000 cases were reported.

Particularly discouraging was the continuing antipathy of state officials to the surveillance–containment strategy. An episode in early April 1973 in the district of Muzaffarnagar vividly illustrated the prevailing attitude. This district, located less than 100 kilometres north of New Delhi, began experiencing outbreaks of smallpox in the autumn of 1972 and, in January, reported 440 cases. This greatly exceeded the number reported that month by any other district of India except 2 districts in West Bengal associated with the Salt Lake Refugee Camp disaster (see later in this chapter). In February 1973, Arita joined Dr Moukhopad in a special investigation of the problem. Active searches at schools and markets soon revealed that although the reported smallpox incidence was high, there were many other undetected and uncontrolled outbreaks occurring throughout the district. With the cooperation of a responsible, energetic district health officer, they decided to mobilize all health staff throughout the district by closing the health centres and training the staff to undertake a 2-week systematic village-by-village search for cases. The health staff responded with enthusiasm and efficiency and soon discovered that cases were occurring in more than half the villages. In all, 641 cases were discovered in February and 1219 in March. Containment measures had scarcely begun, however, when the state Director of Health Services ordered the cessation of all surveillance–containment operations and the immediate vaccination of the entire population of the district. He then warned that when this had been completed the report of any further cases would result in the transfer of the district health officer to the most unpleasant post in the state. It was clear that considerable persuasion of state officials and heroic efforts in the field would be required if Uttar Pradesh was to become free of smallpox. However, the demonstration that it was possible to mobilize effectively the poorly supervised army of health staff offered hope for the future.

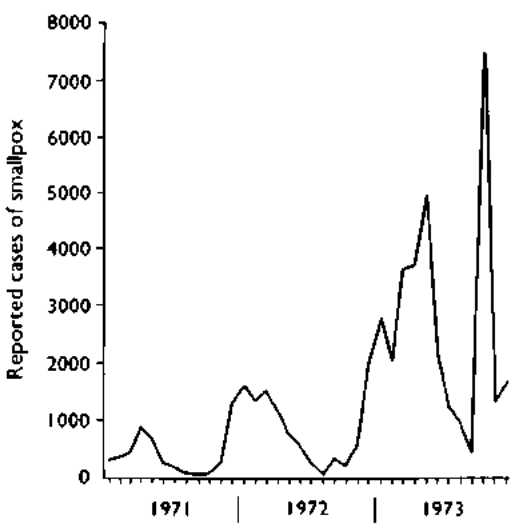

Fig. 15.9. Uttar Pradesh State: number of reported cases of smallpox, by month, 1971–1973.

The southern states, 1971–1973

In the southern states, it had been hoped that the WHO adviser, Dr Zikmund, working with state programme officers might succeed reasonably quickly in developing surveillance–containment activities to the point of interrupting transmission throughout the entire area. Tamil Nadu continued its successful programme and from the beginning of 1971 to the end of 1973 only 11 cases were recorded (Table 15.15), all following well-documented importations. Mysore (renamed Karnataka in 1973) and Andhra Pradesh, the contiguous states to the north, were targets of high priority. Virtually all cases in Andhra Pradesh occurred during the first half of 1971 among generally uncooperative, poorly vaccinated fishermen who migrated seasonally between Andhra Pradesh and Orissa. District health officials, considering them to be temporary residents, had ignored them. Once vaccination and outbreak containment began, transmission quickly stopped. In Mysore, 185 of the 223 cases reported during 1971 were from a single district and these outbreaks were contained by midsummer. Maharashtra was also successful in stopping transmission. In the entire southern area, between October 1971 and January 1972, only 45 cases were detected, all of them occurring in 3 districts. Considering that the southern states accounted for 38% of India's total population, there was reason for optimism about the prospects for the eradication of smallpox in India.

Uncertainty persisted, however, about the situation in the state of Kerala. There, smallpox transmission appeared to have been interrupted in 1967, only 42 cases, presumably importations, having been detected between 1968 and 1970. However, between January and May 1971, 105 cases were

reported, with 1 additional case in September and 2 in November. Kerala's health services, among the best in India, reported that the cases had not occurred in outbreaks as one would expect, but rather were scattered across 7 of its 10 districts. Because the epidemiological pattern of the cases was difficult to explain, Arita joined state officials in a special study in February 1972. Of the reported cases, 70% were found to be in persons over 15 years of age, and of the patients whose vaccination status was known, 102 had previously been vaccinated. Arita and his collaborators examined 35 patients who had recovered, but none had the residual pockmarks typical of smallpox. As it turned out, the state in late 1970 had requested health staff to begin to collect specimens from patients with chickenpox as well as from those with suspected smallpox to confirm with greater certainty that the state was smallpox-free. A state laboratory with little experience in the identification of variola virus had examined the specimens using the gel-precipitation technique and reported that 104 out of 386 tested were either "positive" or "doubtful" for variola virus. Although there was little doubt on the part of physicians about the clinical diagnosis, the virological reports were accepted and the cases duly notified. The team eventually concluded that none of the reported cases was smallpox and the reports were retracted. Except for 4 imported cases in 1974, Kerala was to remain smallpox-free.

The findings in Kerala provided further encouragement but, in February 1972, it suddenly became apparent that there were serious, hitherto unrecognized, problems in Mysore. The discovery of smallpox in Mysore was made by surveillance teams in the neighbouring state of Andhra Pradesh, whose programme was directed by Dr M. C. Appa Rao. There, case detection had improved significantly when, at the end of 1971, a sum of 10 rupees (US$1.33) was awarded by the government for the discovery of a case—the first time in India that such a reward had been offered. The teams detected outbreaks in Hyderabad whose source of infection was a village in Gulbarga District, one of 19 districts of Mysore State. The outbreak was unknown to the Mysore state programme officer. The district (population, 1.7 million) had an extensive network of health facilities, including a large general hospital, 71 health centres and dispensaries, a medical college, and special programmes for the control of malaria, filariasis and tuberculosis and for family planning. It was assumed that if smallpox cases had been present, they would have been quickly detected. State officials, in collaboration with Dr Zikmund, began an immediate investigation. It soon became apparent that not one but numerous outbreaks had occurred, beginning almost 15 months earlier, in December 1970. By the end of March, the investigators had discovered 81 outbreaks and 730 cases. They found that even the staff members of primary health centres who lived in villages with major outbreaks had not reported them; many directors of primary health centres who were notified of cases dismissed them as chickenpox; and, indeed, the District Director of Health and Family Planning, who had been officially informed of smallpox cases as early as September 1971, had suppressed the reports. It was concluded that radical measures would be required to stop the epidemic.

Able leadership was provided by a newly appointed District Medical Officer of Health, Dr Rama Rao; health staff were transferred from other districts; and all health and family planning staff in Gulbarga District were mobilized to undertake repeated house-to-house searches for cases throughout the district. When outbreaks were discovered, they were promptly contained. New outbreaks rapidly decreased in number, from 34 in April to 12 in May and 4 in June. To counter the tendency to conceal cases, a reward of 25 rupees (US$3.33) was offered to anyone who reported a case of smallpox.

Table 15.15. Southern India: number of reported cases of smallpox, 1971–1973[a]

State or union territory	1971	1972	1973

Grand total	16 190	27 407	88 114

[a] No cases were reported during this period from the union territories of the Andaman and Nicobar Islands, Goa, Daman and Diu, Lakshadweep, and Pondicherry.
[b] Became the state of Karnataka late in 1973.

Chickenpox—a Problem in Surveillance in Kerala

Cases of and deaths from severe chickenpox proved the most difficult in differential diagnosis. The most problematic cases were those in adults. Among residents of the southern state of Kerala (population, 24 million), as well as among migrants from that state, cases of chickenpox in adults occurred with unusual frequency, and this resulted in a number of erroneous reports and special investigations. In the process of confirming that transmission had been interrupted in India, a special study was conducted in Kerala to ascertain that the deaths attributed to chickenpox had been correctly diagnosed (White, 1978).

Age Distribution of Deaths Due to Chickenpox, January 1975–March 1976

Age group (years)	*Males*	*Females*	*Total*	*Prevalence per 100 000 of cases of chickenpox*[a]
0–4	6	3	9	64
5–9	2	1	3	102
10–19	4	3	7	87
20–29	1	3	4	59
30–39	14	3	17	56
40–49	34	1	35	69
50–59	34	5	39	48
60–69	31	14	45	31
⩾70	74	27	101	36
Total	200	60	260	71

[a] Based on a special search in April 1976 in 11 primary health centres.

Of 260 persons who died of chickenpox over a 15-month period, 241 were 20 years of age and older. For many, the immediate cause of death was attributed to "old age" or a chronic or unrelated acute illness, although chickenpox may have been cited as a contributory factor.

It was suggested that the frequency of adult cases related to the dispersed population in Kerala and, until recently, the difficulty of travelling from one village to another. Thus, it was reasoned, many were not exposed to chickenpox until they were adults. The hypothesis was attractive, but other factors must have been involved because adult chickenpox was not such a problem in other, even more isolated, areas of Africa and Asia.

However, cases spread from Gulbarga to 5 other districts in Mysore, to 2 districts in Andhra Pradesh and to at least 1 district in Maharashtra. More than 1400 cases in all were traced to this single district. Although the outbreaks were largely contained in a period of 2 months, fully 6 months elapsed before transmission finally ceased. Most surprising to senior Indian and WHO staff alike were the numbers of health staff who could be mobilized, the rapidity with which a search programme could be organized, and the responsiveness of staff in executing a well-conceived plan. This experience was subsequently replicated in Muzaffarnagar District, Uttar Pradesh (see previous section) and, in May 1973, throughout Orissa State. It ultimately led to the plan to undertake nation-wide searches for smallpox cases—the essential strategic component of the campaign beginning in the autumn of 1973.

Although transmission was successfully interrupted in Mysore by September 1972, Hyderabad, the capital of Andhra Pradesh, had by then been reinfected; from there the disease spread to 8 other districts. Dr Appa Rao, who was responsible for other programmes in addition to smallpox eradication, was unable to devote sufficient time to the programme and smallpox continued to spread, albeit slowly. Smallpox was reasonably well contained, with the help of Dr Zikmund, until January 1973, when he was forced to leave for Orissa because of outbreaks there

resulting from importations from the Salt Lake Refugee Camp. Smallpox continued to spread in Andhra Pradesh. Between January and June 1973, 924 cases occurred. In view of the size of the population (47 million), the number of cases was not large but, clearly, transmission in Andhra Pradesh and the southern states was not being interrupted as quickly or as easily as had been hoped. The potential for epidemic spread remained, as the Gulbarga experience had shown. The movement of smallpox was too rapid and effective to be contained by the few epidemiologists available.

West Bengal and the Salt Lake Refugee Camp, 1971

The densely populated state of West Bengal (population, 46 million), with its crowded capital city of Calcutta (population, 7 million), was a demographic centre of vital importance to smallpox eradication in the eastern states of India. In West Bengal, progress in the control of smallpox appeared to be satisfactory—until December 1971. The number of recorded cases had diminished to only 374 in 1970 and to 217 in 1971, the lowest totals ever reported. The Eastern Province of Pakistan (later Bangladesh) on its eastern border, predominantly Muslim but also Bengali-speaking, had detected its last case in August 1970 (see Chapter 16). Thus, importations of smallpox by travellers who frequently crossed the border were not a threat. However, civil war began in March 1971 in East Pakistan, and during that year an estimated 10 million refugees fled across the border into India. Numerous refugee camps were set up, primarily in West Bengal, Madhya Pradesh and Assam. It was feared that if smallpox were introduced into the camps, devastating epidemics would rapidly develop. On the orders of the National Smallpox Eradication Programme staff, all refugees entering the camps were examined for the presence of smallpox, but no cases were found. As a preventive measure, state officials were requested to ensure that all persons entering the camps were vaccinated. Indian national staff and WHO advisers visited and confirmed that this procedure had been followed in a number of camps, but not in West Bengal, where the state authorities refused to permit national intervention. The largest refugee camp, the Salt Lake Camp near Calcutta, sheltered an estimated 200 000–300 000 persons, and there an international private voluntary organization had been given responsibility for providing health services. For reasons unknown, no vaccination campaign was conducted.

Smallpox was probably introduced into the Salt Lake Camp in November. Many cases were hospitalized within the camp but were diagnosed as chickenpox. The diagnosis of probable smallpox was finally made on 19 January 1972 by an epidemiologist in the USA while viewing a television news documentary made in the camp. The report was relayed rapidly from Atlanta to Geneva to New Delhi. The Director of Health Services of West Bengal categorically denied there were cases, but Dr S. N. Ray, from the National Programme office, flew to Calcutta and, on visiting the camp, found an extensive outbreak. A vaccination programme was begun, but it was too late. On 16 December 1971, one month earlier, the independence of Bangladesh had been proclaimed. By 20 January 1972, an estimated 50 000 refugees had already departed for Bangladesh. The epidemic spread from the camp through West Bengal and from there to the neighbouring states of Orissa and Bihar. West Bengal, which had detected only 217 cases in 1971, reported 4753 in 1972; Bihar reported 1307 cases in 1971 and 4153 in 1972.

The number of cases that occurred in the camp can never be known, but as from 22 January, infected persons among the refugees remaining in the camp were admitted to the Calcutta Infectious Diseases Hospital; admissions continued until the end of February. During this period, the hospital admitted 764 patients, of whom 48% died (Guha Mazumder & Chakraborty, 1973).

West Bengal, which had been comparatively free of smallpox in 1971, became a major epidemic focus in 1972 (Fig. 15.10) and Bangladesh was again reinfected (see Chapter 16).

The beginning of the "final phase" of the Intensified Smallpox Eradication Programme, November 1972

By the autumn of 1972, global progress in the Intensified Programme was most encouraging. Only 3 endemic countries remained in the whole of Africa—Ethiopia, Botswana and the Sudan—and in the latter two interruption of transmission appeared imminent. Both South America and Indonesia were smallpox-

free and Afghanistan was almost so. Bangladesh had been reinfected but it had re-established its national programme and Pakistan's programme had been extended to the entire country. India was reporting increasing numbers of cases as epidemic smallpox began moving across the Ganges plain from the west and from Calcutta in the east. However, the extent of the infected areas in India, as well as in other Asian countries, had diminished significantly (Fig. 15.11).

With endemic smallpox so limited geographically and some form of surveillance operating in all areas, it seemed to WHO propitious to encourage a more concentrated effort in the remaining infected areas: the "final phase" of the Intensified Programme. The proposed target was ambitious—to interrupt smallpox transmission during the following 2 smallpox seasons, a period of about 18 months. To encourage the renewed effort, special seminars were convened in

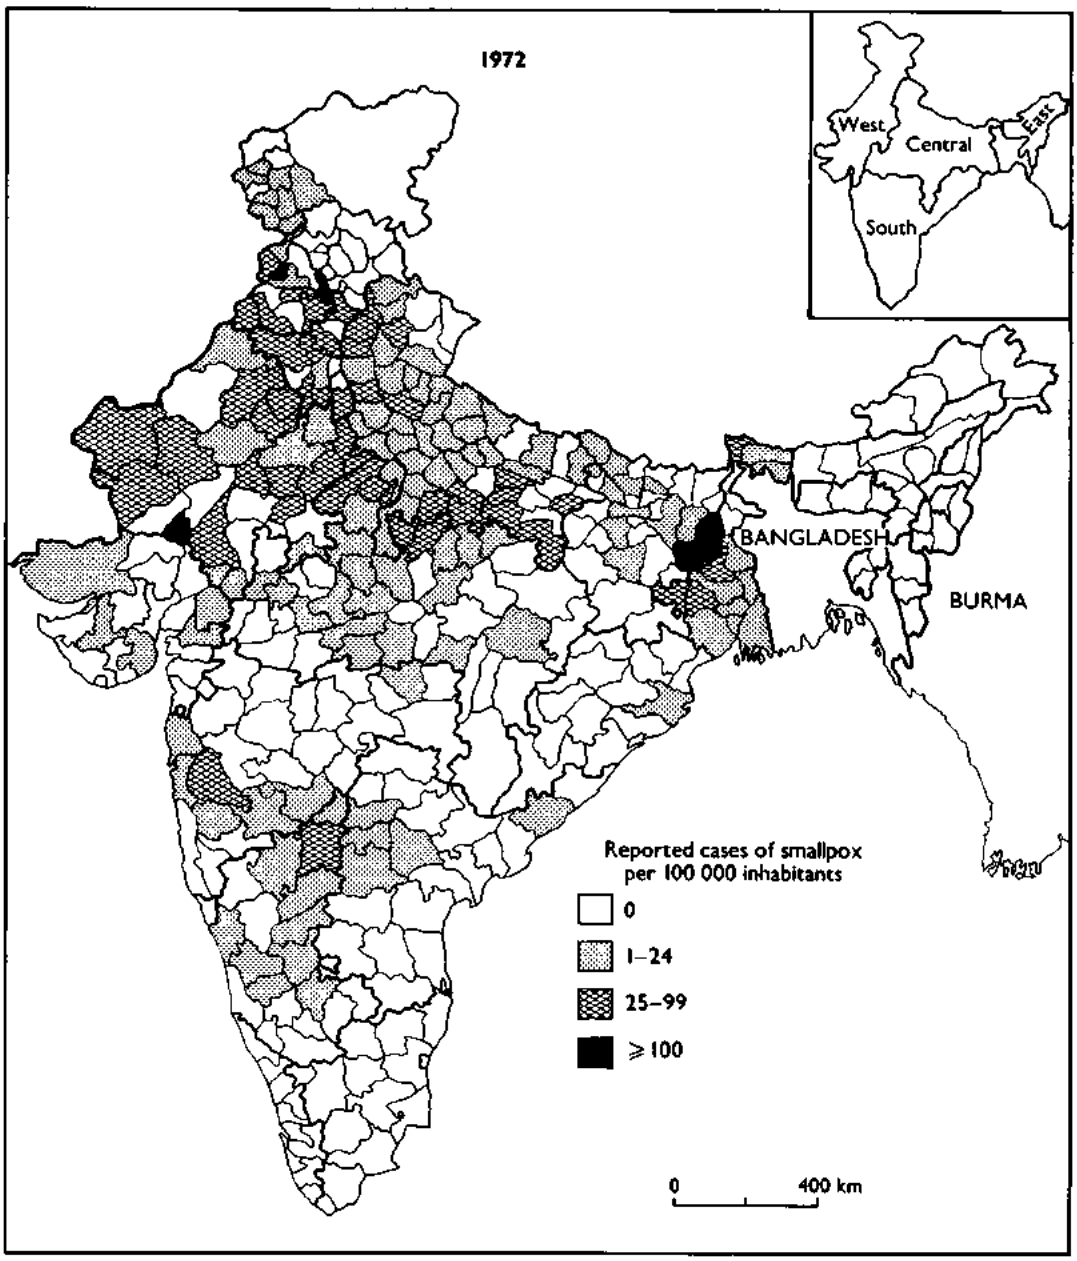

Fig. 15.10. India: number of reported cases of smallpox per 100 000 inhabitants, by district, 1972.

September–November in Addis Abeba (mainly for staff in Ethiopia and the Sudan); in Karachi (principally for staff in Afghanistan and Pakistan); and in New Delhi (for staff in Bangladesh, Bhutan, India and Nepal).

In India, despite the success of surveillance–containment measures in southern and western states, many state health officials still persisted in their belief that 100% vaccination was the only way to achieve eradication. With officials from all over India attending the seminar, attention was focused explicitly on the surveillance–containment strategy. The success in Indonesia was a helpful stimulus in encouraging a change in direction, as is illustrated in the following extract from Henderson's opening address:

"Two years ago, in December 1970, a seminar on smallpox eradication was held in this very room. I said at that time that the question was repeatedly asked as to how such major changes [in the smallpox eradication programme] could occur so rapidly when, for years, many endemic countries had been conducting mass vaccination programmes with only limited success. The principal difference between present and past efforts is one component—surveillance. In every country where a concerted effort has been made to investigate promptly and to contain *every* outbreak, smallpox transmission has been interrupted within two years or less. Many of you will recall that at that Seminar the director of the Indonesian programme presented a provocative paper which stated 'a proper surveillance–containment action brought smallpox under control in a short period,

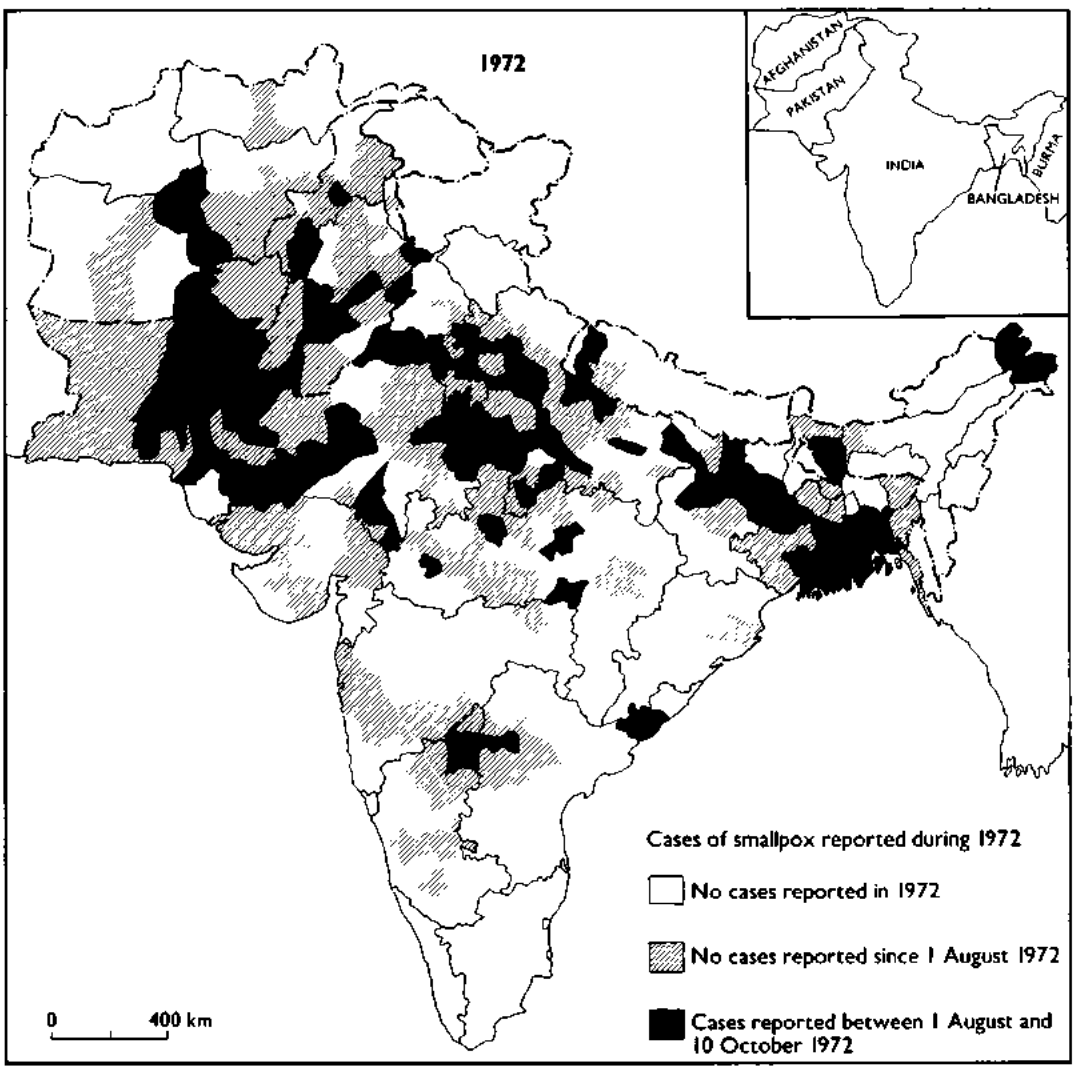

Fig. 15.11. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1972 (as of 10 October).

while on the contrary, routine vaccination and mass vaccination campaigns had little effect in interrupting smallpox transmission'. That year, Indonesia reported 10 000 cases of smallpox, only 20% fewer cases than in India. Many at that Seminar took violent exception to the Indonesian director's contention that all available resources should be diverted to surveillance even at the expense of a vaccination campaign. Who was right? I would ask you to note that the number of cases in Indonesia decreased from 10 000 in 1970 to 2000 in 1971 and to 34 this year. Despite a continuing active search for cases, none have been found in all of Indonesia for over eight months."

State health authorities in India had argued that there were not enough health staff. However, it was noted that, even in countries

Plate 15.5. Refugees from East Pakistan, many infected with smallpox, leave the Salt Lake Camp near Calcutta in December 1971 to return to their newly independent country, Bangladesh.

with less well developed health infrastructures, such as Ethiopia, only 80 workers were employed (1 for every 300 000 persons) and in Afghanistan the corresponding ratio was 1 for every 100 000 persons. In India, 1 smallpox vaccinator was available for every 8000–20 000 persons.

The need for surveillance was echoed in the address by the Indian Minister for Health and Family Planning and by Dr P. Diesh, the Additional Director-General of Health Services, who concluded the seminar with the statement: "History tells us that whoever rules the Indo-Gangetic plain rules the country. The battle of smallpox will be fought in the Indo-Gangetic plain, where 70% of the cases are reported now." And this indeed was where the major battle was fought over the following 3 years.

The seminar report concluded with a number of recommendations which stressed surveillance:

1. It is essential to delineate smallpox endemic and non-endemic areas within a state or country. The endemic areas should receive highest priority and the major part of the resources at present available. In the non-endemic areas, an active search for cases should be planned and implemented to ensure their smallpox-free status. Any suspected cases should be dealt with as a national public health emergency.

2. In states where surveillance teams are not yet in existence, state teams should be created by 1 December 1972.

3. The investigation of all outbreaks by the state programme officer or at least by state surveillance teams is essential.

Other recommendations emphasized the importance of containment and the need to trace the source of outbreaks. It was also noted that "the newly introduced reporting system in India should be improved as rapidly as possible". The new system was that previously described, in which primary health centres, districts and states reported weekly all cases of smallpox detected during a given week or reported "nil" if no cases were found.

The central programme office was further strengthened in the autumn of 1972, with the appointment of a senior public health officer to head the programme, Dr R. N. Basu, Assistant Director-General of Health Services (Smallpox), who continued in this position until the conclusion of operations. Dr Basu, who held a more senior rank than Dr Singh, carried greater weight with national and state officials. Dr Diesh, who was effectively second in command to the Director-General of Health Services in the Ministry, also took a special interest in the programme and made a number of visits to the state capitals to meet health ministers and directors of health services in order to encourage greater activity. Visits by an official of this rank were uncommon and implicitly indicated that the government accorded high priority to the smallpox eradication programme. Meanwhile, working relationships between WHO staff and Indian national and state staff had gradually become less formal. Arrangements for WHO staff from the regional office to travel to the field and for state-assigned staff to travel from state to state had become a simple matter of discussion and verbal agreement. This was in marked contrast to the earlier formal relationships which required that, before each trip, a written request should be submitted by the WHO Regional Director to the Ministry of Health and that this request should be considered within the Ministry and eventually a formal reply prepared—a process that often took weeks. With each adviser in possession of a vehicle purchased by WHO and an agreement by WHO to defray all travel costs, a further obstacle to the execution of the programme was removed.

1974

Plate 15.6. Rabinder Nath Basu (b. 1928), Assistant Director-General of Health Services, was appointed to direct the National Smallpox Eradication Programme in the autumn of 1972 and continued in this capacity until after the certification of eradication in 1977. He subsequently directed the development of India's Expanded Programme on Immunization and later became the Director of the National Institute of Communicable Diseases.

7 JEZEK

Plate 15.7. Outbreaks of smallpox occurred among poorly vaccinated pavement dwellers in crowded urban areas. The discovery and containment of such outbreaks were a continuing problem throughout the course of the Intensified Programme.

At the November seminar, goals were fixed in terms of geographical areas within which it was hoped endemic smallpox could be contained by the end of March 1973. For India, it was agreed that by that date the objective would be to eliminate endemic smallpox from all areas except the state of Bihar and 49 districts comprising parts of Uttar Pradesh, Madhya Pradesh and West Bengal.

As early as the end of December 1972, it was evident that the problems once again were greater than had been anticipated. As has been mentioned earlier, major epidemics were discovered in the previously smallpox-free state of Jammu and Kashmir. In Bihar State, health workers went on strike, bringing all work to a standstill. In Uttar Pradesh, then the principal focus of smallpox, eradication staff had been diverted to a cholera vaccination campaign. The new reporting system was an improvement over the old one but, even so, half or more of the states and union territories were consistently up to 5 weeks late in reporting cases.

During 1972, 27 407 cases of smallpox were reported from India, an increase of 69% over the 16 190 cases reported the year before. More complete notification undoubtedly accounted for some of the increase but there was no way of measuring the magnitude. In January 1973, predictions as to the expected incidence of smallpox in 1973 were made by WHO Headquarters staff, in consultation with national staff, on the premise that such predictions served to gauge familiarity with the problems in each area, the rate of progress being made or anticipated and the understanding of the epidemiological situation. It was forecast that 30 700 cases would occur throughout the world, of which 17 000 would be in India. It soon became evident that neither WHO nor Indian staff had comprehended the magnitude of India's smallpox problem.

By the end of March 1973, India had recorded 14 376 cases, of which 29% were outside the established target area. Not only were serious problems present in Bihar, Uttar Pradesh, and Jammu and Kashmir, but it had also become apparent that West Bengal had not done well in controlling the epidemic which had spread from the Salt Lake Camp area. By the end of February, 19 cases imported from Calcutta were detected in Orissa and 30 in Bihar. The estimate of the total number of cases in India projected for 1973 was revised upwards from 17 000 to 35 000

and then to 60 000, a figure which would represent the highest number of cases since 1967. Although reporting had undoubtedly improved, smallpox was far more extensive than had been expected; many still did not subscribe to the new strategy of surveillance and containment. During the spring of 1973, smallpox incidence continued to rise and by the end of June, 49 478 cases had been reported, of which 45 697 (92%) were from the 4 contiguous states in or immediately adjacent to the Gangetic plain—Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. The total number of cases was almost 3 times greater than the number recorded during the same period in 1972. Comparisons with trends in Pakistan and Bangladesh (*Wkly epidem. rec.*, 1973b) portrayed the unfavourable situation in India (Fig. 15.12).

India was then one of only 4 countries in the world with endemic smallpox, and it accounted for nearly 60% of the world's cases. Politicians and senior health officials alike had become increasingly concerned and had taken a greater interest in the programme. The Twenty-sixth World Health Assembly in May 1973 provided an added stimulus.

During discussions in the Health Assembly regarding the smallpox eradication programme, the delegate from Malaysia bluntly assessed the situation. His observations were summarized as follows (World Health Organization, 1973b):

"... an alarming development in recent months had been that serious smallpox epidemics were raging in two of the endemic countries, despite the fact that WHO was now entering the seventh year of its intensified smallpox eradication programme. Among the reasons for the setback, as given in the *Weekly Epidemiological Record* ... were: lack of staff; inadequately developed surveillance programmes; periodic diversion of smallpox staff to other programmes; delayed and incomplete reporting; and inadequate containment measures. Lack of staff should not be an insurmountable problem; it could be overcome by improved deployment of staff and crash recruitment and training programmes. Nor should it be too difficult to organize and develop surveillance programmes. In view of the vital importance of smallpox eradication, any diverting of staff to other programmes would be premature and ill-advised, and inadequate reporting and containment measures indicated a lack of appreciation of the urgency of the problem. He did not wish to criticize any individual country, but he hoped that the points he had raised would be taken in a constructive spirit.

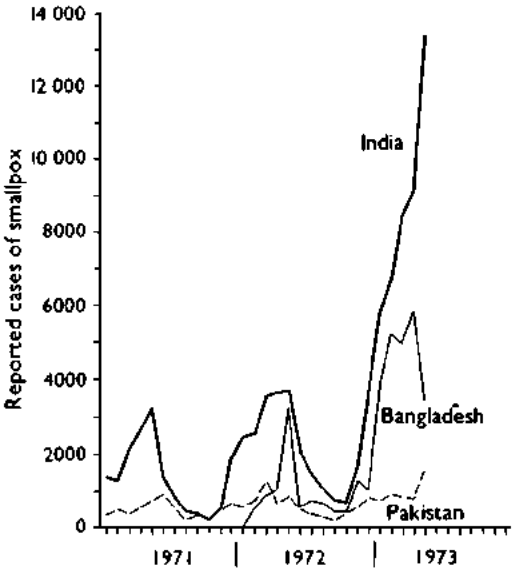

Fig. 15.12. Bangladesh, India and Pakistan: number of reported cases of smallpox, by month, 1971–1973 (as of 19 June 1973).

"WHO had declared that it was willing to send emergency aid on request ... to any country facing problems in smallpox eradication. He wondered whether the countries now suffering from outbreaks had taken full advantage of that offer ..."

In the World Health Assembly, criticism such as this of another country's health programme was unusual; to India's Director-General of Health Services, it was acutely embarrassing. He returned to India determined to strengthen the programme.

Endemic smallpox in India remained comparatively limited geographically (Fig. 15.13) although the number of cases was large, and it appeared that an intensified programme would require a special mobilization of resources in only a few states of India. With the season of diminished transmission immediately ahead, it was decided to initiate an "epidemic of activity" preceding the usual season of epidemic smallpox.

The Intensified Programme in India, June–December 1973

At the end of June 1973, WHO staff from Headquarters and the Regional Office for South-East Asia held meetings with Indian national and state health personnel to devise a new campaign plan whose strategy would be to detect and contain the comparatively

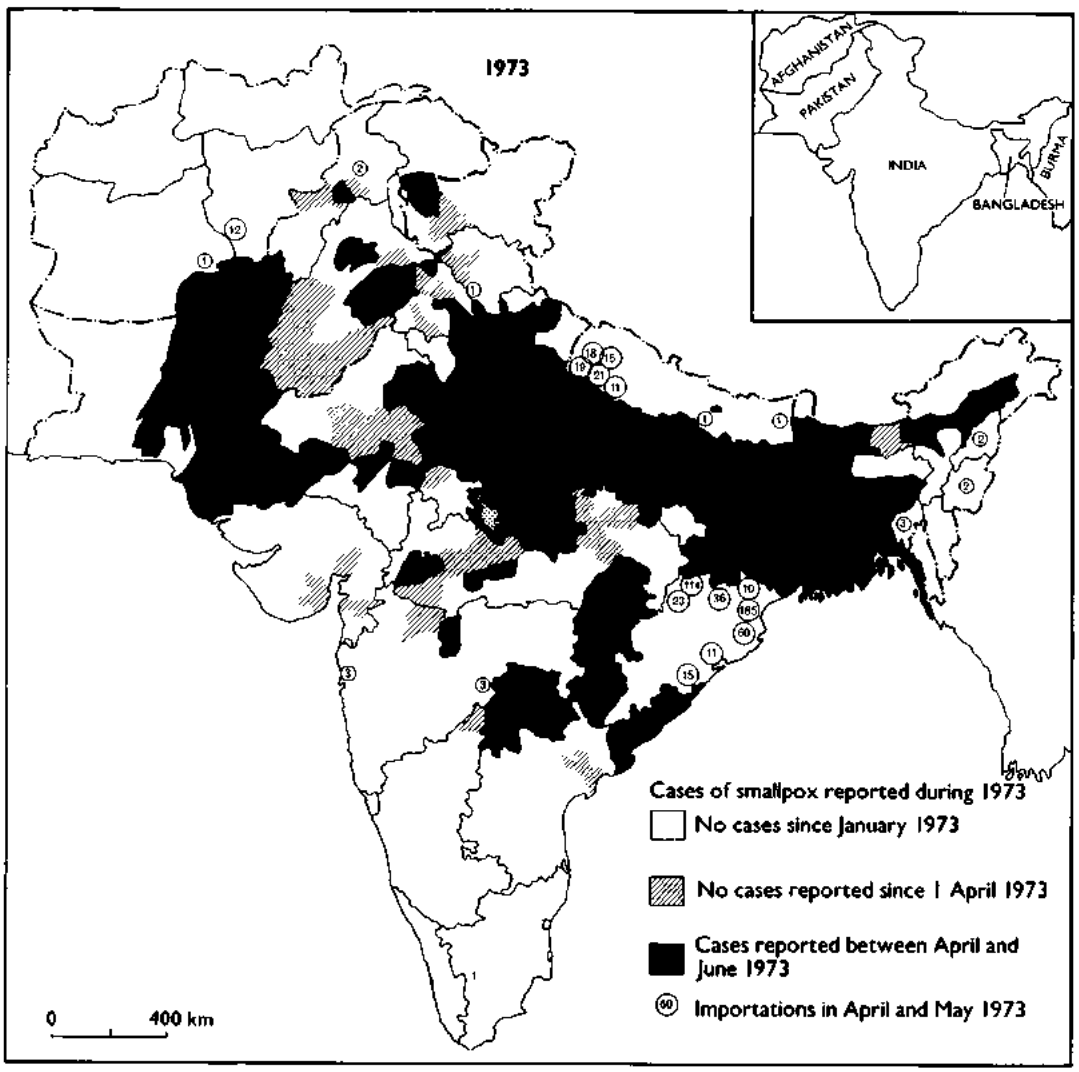

Fig. 15.13. Indian subcontinent and adjacent countries: areas reporting cases of smallpox during 1973 (as of 19 June).

few outbreaks expected to occur during the autumn months of seasonally low incidence. If most of these could be contained by December, it was expected that the remaining foci could also be contained by state and district surveillance teams during the January–June period.

The most highly infected states were Bihar, Uttar Pradesh and West Bengal. There, the deployment of an epidemiologist-adviser and a few surveillance teams for motivating local staff to report cases and to contain outbreaks had clearly failed. A different approach was required. The early detection of cases was of the greatest importance. Once cases were found, a comparatively small number of containment teams could deal with the outbreaks. Everyone had been impressed by the experiences in Gulbarga District (Mysore) and Muzaffarnagar District (Uttar Pradesh), in which it had proved quite simple to plan and execute a village-by-village programme of case detection which could reach all parts of a district within 1–2 weeks. It was reasoned that if a systematic search of this type could be conducted throughout entire states, in combination with an effective containment programme, it should be possible to contain smallpox quickly. To execute such a search in a state, in a group of states or in the whole of India posed problems of organization and motivation of an entirely

different magnitude from those involved in carrying out the operation in a single district. However, it was apparent that throughout the length and breadth of India a large complement of generally well-trained health staff existed—albeit often poorly supervised and supported. It seemed plausible that an increased number of senior smallpox eradication programme supervisors, following a carefully designed plan, could harness this considerable resource for a concerted effort over a period of a few months. This was the basic strategy decided on, and thus began what was to become one of the most ambitious and intensive national health programmes yet undertaken. Eventually, it would involve more than 130 000 staff who, within a 2-week period, could visit more than 90% of the 120 million households in India.

The principal problem area comprised the states of Bihar, Madhya Pradesh, Uttar Pradesh and West Bengal. Their combined population amounted to 249 million, or about 42% of the entire population of India. It was planned to assign a senior Indian epidemiologist and a counterpart WHO epidemiologist-adviser to assist each state smallpox eradication programme officer in these 4 states. An additional WHO epidemiologist would continue to work in the neighbouring state of Rajasthan, in which transmission appeared to have been interrupted but which was experiencing many importations. A sixth WHO epidemiologist would be based in Orissa State to assist in the development of search programmes and the investigation of outbreaks in the low-incidence states and union territories geographically close to the 4 highly infected states. He would also assist with any problems in a third group of states which were thought to have interrupted transmission or were expected to do so by September—the smallpox-free group (Fig. 15.14). Additional transport, supplies and equipment were made available by WHO to supplement the already considerable resources deployed by India.

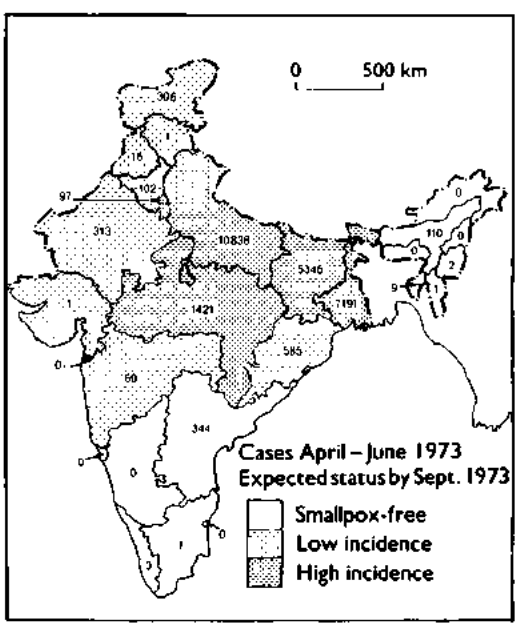

Fig. 15.14. India: autumn campaign of 1973. Number of reported cases of smallpox by April – June 1973 and the expected status of smallpox incidence, by state, in September 1973.

For the 4 highly endemic states, a 3-phase programme was formulated. Phase One, planned for the late summer of 1973, would consist of an active search for outbreaks in municipal areas. It was hoped by this search to find and eliminate urban foci, which often served to sustain smallpox transmission through the summer monsoon season. Because there was insufficient time for preparation, the first phase achieved little except to bring the smallpox eradication activities of most of the autonomous municipal corporations under the supervision of the state smallpox eradication programme office. Phase Two of the programme, from September to December 1973, would consist of statewide, week-long, village-by-village searches on 3 separate occasions approximately a month apart. Two searches would be conducted in the states with a low incidence, and at least 1 search in the states believed to be smallpox-free. Other health personnel and family-planning workers would be utilized to supplement the work of the smallpox eradication staff. The nature of Phase Three, commencing in January 1974, would depend on the status of smallpox at that time; it was expected that it would consist primarily of a search for cases by surveillance teams and the containment of a few remaining outbreaks.

The government of India and WHO agreed to increase the number of senior supervisory staff for this effort. The government provided an additional senior Indian epidemiologist for each of the 4 priority states. It assigned to the programme Dr M. I. D. Sharma, then the Director of the National Institute of Communicable Diseases; two of his epidemiologists, Dr C. K. Rao and Dr R. R. Arora; and the Assistant

Plate 15.8. State review meeting in Lucknow, Uttar Pradesh, in 1975. *Seated, left to right*: M. C. Chaturvedi, Additional Director of Medical and Health Services of Uttar Pradesh; C. K. Rao, member of the Central Appraisal Team; J. M. McGinnis, WHO consultant from the USA; M. I. D. Sharma, Commissioner of Rural Health for India; and N. C. Grasset, smallpox adviser from the WHO Regional Office for South-East Asia. *Standing*: M. Dutta, member of the Central Appraisal Team.

Director-General for Cholera, Dr Mahendra Dutta. With Dr Basu and Dr Singh of the National Smallpox Eradication Programme, and Dr S. N. Ray, who was responsible for vaccine production, they constituted the Indian component of a group officially termed the "Central Appraisal Team". The WHO component consisted of the intercountry team (formally, the Smallpox Eradication and Epidemiological Advisory Team), Dr Grasset and Ježek, who were joined that summer by Dr William Foege, who had formerly worked in Nigeria and then at the Communicable Disease Center (later called the Centers for Disease Control) in Atlanta, GA, USA, in directing the smallpox eradication effort in western Africa. In January 1974, Dr Lawrence Brilliant, a new member of the WHO smallpox eradication programme staff, became part of the team.

Beginning in June 1973, the group held frequent meetings, preparing, reviewing, and revising drafts of a "Model Operational Guide for Endemic States" and a "Model Operational Guide for Non-endemic States". To implement the programme in the field, 26 special teams were created. Half the teams were headed by Indian epidemiologists recruited by the government from Indian institutes and universities or brought back from retirement. The other half were headed by epidemiologists of other nationalities recruited by WHO. Twenty-two teams were assigned to the high-incidence states (10 to Uttar Pradesh, 2 to West Bengal, 5 to Bihar and 5 to Madhya Pradesh); 2 teams worked in the eastern states; and the remaining 2 in the smallpox-free and low-incidence states in the south.

Eventually, a total of 230 epidemiologists from 31 countries and a comparable number

of Indian epidemiologists would head such teams for periods of 3–24 months each. As many as 90 epidemiologists would be participating at any one time. Each epidemiologist was given 5 days' training before going to the field. Particularly useful for this purpose was a series of slides prepared by WHO illustrating clinical smallpox and 2 case-history studies, one of which dealt with the day-by-day management and investigation of a smallpox outbreak and the other with the management of a district smallpox eradication programme. (The latter eventually found its way into the syllabus of the Harvard School of Business Administration.)

As the autumn campaign began, there were only 26 epidemiologists in the field (Table 15.16). Each epidemiologist in the high-incidence states worked in a zone covering an average of 5–6 districts (approximately 10 million people) and had as his counterpart the division and/or district health officer responsible for the area. The special teams conducted training sessions for district and local staff to explain and organize the searches. In addition, they supervised the implementation and evaluation of surveillance activities and verified the diagnosis when cases were reported. When smallpox was detected, they organized outbreak containment and identified the source of infection.

Additional vehicles were essential and these were quickly obtained through the purchase by WHO of Jeeps manufactured in India. For WHO, this was a departure from a long-standing policy that the country itself should purchase locally produced equipment and supplies. Prompt delivery of the vehicles would have been impossible if traditional procedures had been followed—i.e., the purchase of Indian-made Jeeps by the government or the purchase of foreign-made vehicles by WHO. To have manoeuvred such a purchase through the complex Indian bureaucracy, even with the highest level of government support, would have taken anything up to a year; the delivery of vehicles from foreign sources was even more protracted at that time. The Indian-made Jeeps, although more susceptible to mechanical failure, were simpler in design and easier to repair. A most important consideration was that spare parts were widely available and there were many mechanics who were familiar with the vehicle. On balance, the Indian Jeeps proved more utilitarian than did imported vehicles.

Each of the epidemiologists was assigned a driver and a paramedical assistant and given a monetary advance (an imprest account) to be used, as necessary, for petrol and vehicle repair, travel allowances and supplies. The funds were accounted for at regular intervals before further advances were made. The disbursement of funds for the discretionary use of the field epidemiologists was also a departure from customary administrative practice, but it was one of the most important steps in facilitating the execution of the programme.

The strategy of the search programme and of the surveillance-containment activities was explained in detail at state-level meetings presided over by state officials and attended by senior officials of the national government and WHO, as well as by state and divisional and/or district health officers. These discussions were followed by similar meetings at the divisional level (for states with a divisional structure) convened by the commissioners of the divisions and attended by chief medical officers of health from the districts and municipal corporations. Meetings were then held at the district level, attended by the district health officers and primary health centre medical officers. Lastly, searchers and

Plate 15.9. Project vehicles in Patna, Bihar State, at the beginning of the programme.

supervisors at each primary health centre were instructed in the specific techniques of search, outbreak containment and reporting. Such meetings at different administrative levels were subsequently conducted before each new search; the experiences of the previous search were evaluated and additional or revised procedures implemented.

To organize the numerous meetings and to develop strategy over the extensive area involved required an extraordinarily intensive effort on the part of the Central Appraisal Team. As an illustration of this endeavour, one may cite the experience of a member of the team who travelled more than 1800 kilometres by car in 5 days, during which he participated in 7 district and regional meetings. To do so necessitated driving all day and through the night; the team member and his driver shared this task, alternately driving and sleeping in the cramped Jeep.

The organizational plan called for one search worker to visit one village or section of a city each day. The hundred or more villages in each primary health centre area were divided up among the staff of 15–20 health workers. To facilitate supervision, a search schedule determined which worker would be in which village on which date. Each search was planned to be completed within 7–10 days. A supervisor oversaw the work of 4 or 5 workers and was assigned villages to be checked at random.

The searchers were instructed to show the WHO smallpox recognition card (see Chapter 10, Plate 10.11) and to inquire about any suspected cases that had occurred during the preceding 2 months. All village leaders and watchmen were to be contacted, as well as schoolteachers and their pupils, and persons congregating in tea-shops and market areas. Two or 3 houses in each of 4 parts of a village and the section of a village or town in which the poorest families lived were also to be visited. When the teams travelled from village to village, they were instructed to stop at brick kilns, bus stands, migrant camps and festivals to solicit reports of possible cases of smallpox.

Suspected cases were to be notified immediately to the primary health centre physicians, who were asked to verify the diag-

nosis. In addition to the assessment of work by the supervisors, each primary health centre medical officer was expected independently to assess one village or urban area assigned to each supervisor; each district-level supervisor was expected to visit one village, one school and one market in each primary health centre area; and each state surveillance team was expected to check 100 villages, 10 markets and 30 schools after each search. Areas selected for assessment were the least accessible villages and those most distant from the primary health centre. It was assumed that if the work was well done in the more distant and difficult areas, it was likely to be satisfactory in the areas easy of access. Radio, press, and other media were utilized to inform the public where to report cases of smallpox.

The first searches in the highly endemic states began in September. With such large populations and with so many health staff involved, the logistic requirements were formidable, as will be appreciated from the following inventory of material supplied to West Bengal for its first search: 100 copies of the Operational Guide; 10 000 small smallpox recognition cards and 3000 large recognition cards; 100 copies of each district map to be used to plan search workers' schedules; 3000 copies of the searchers' village-by-village schedules; 16 000 copies of forms for recording the results of the village visit; 400 copies of forms for listing outbreaks; and 3000 copies of the weekly reporting form to be dispatched from the primary health centres to the district. For a country-wide search, it was calculated that 8 tonnes of forms would be necessary.

Because of floods, only 9 out of 16 districts in West Bengal could be reached during the September search; but only 75 cases of smallpox were detected. It was uncertain whether the search had been good and the few cases that existed had been found, or whether it had been poor and many cases had been missed. However, a more extensive search conducted throughout the state in early October identified only 143 infected villages among West Bengal's 38 000 villages and 137 towns. Moreover, Calcutta, which many had feared might harbour extensive foci, had far fewer cases than had been expected.

The encouraging reports from West Bengal were quickly followed by alarming—almost unbelievable—reports from Uttar Pradesh and Bihar. During the week preceding the search, only 354 cases in 21 districts had been reported in Uttar Pradesh and only 134 cases in 8 districts in Bihar. However, the 1-week October search revealed 1525 outbreaks with 5989 cases in Uttar Pradesh and 614 outbreaks with 3826 cases in Bihar (Fig. 15.15; Table 15.17). It should be noted, however, that outbreaks occurred in only

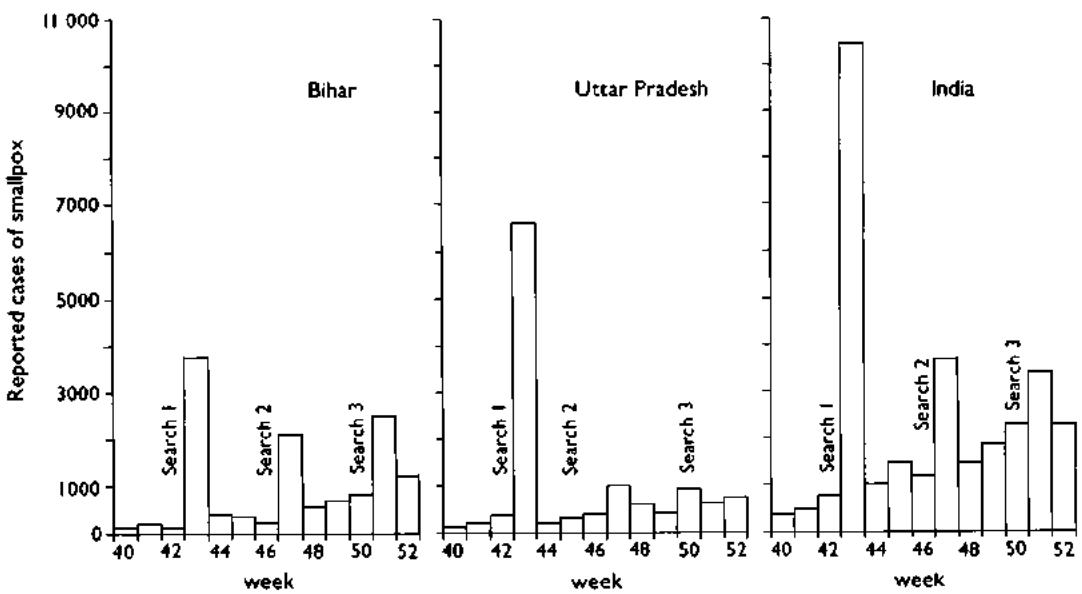

Fig. 15.15. Bihar State, Uttar Pradesh State, and India as a whole: number of reported cases of smallpox, by week, showing results of special searches, October–December 1973.

Table 15.17. Bihar, Uttar Pradesh and Madhya Pradesh: results of the 1973 search for outbreaks of smallpox

State	Month of search	Number of towns and villages	Number of villages with new outbreaks (% of total)	Number of municipalities with new outbreaks	Total number of new outbreaks found	Number of new cases found
Bihar	Oct.	67 727	601 (0.9)	13	614	3 826
	Nov.		484 (0.7)	21	505	2 459
	Dec.		385 (0.6)	20	405	2 619
Uttar Pradesh	Oct.	112 854	1 483 (1.3)	42	1 525	5 989
	Nov.		390 (0.3)	24	414	1 711
	Dec.		309 (0.3)	22	331	1 148
Madhya Pradesh	Nov.	71 116	164 (0.2)	6	170	1 216
	Dec.		51 (0.1)	2	53	215

1.3% of all villages in Uttar Pradesh and in only 0.9% in Bihar. However, smallpox was found in 42 out of the 293 municipalities in Uttar Pradesh, in 13 out of 161 in Bihar, and in almost all districts of both states.

The staff had cause for alarm because, in October, smallpox incidence was at a seasonal low. Moreover, the percentage of villages then infected was equivalent to the percentage infected *at any time* during the course of an entire year in the studies by Dr D. B. Thomas and his colleagues in Sheikhupura District in Pakistan (Thomas et al., 1972; see Chapter 14). Until this time, Sheikhupura District had been considered to be the prototype of a district with an unusually high incidence of smallpox in the generally well-vaccinated Indian subcontinent.

Despite the extensive planning and training, assessment revealed that many villages, indeed entire areas, had not been searched, and thus even the high figures recorded understated the problem. With smallpox present throughout both states and in many urban areas, it was apparent that when transmission rates increased, a major epidemic would be possible. In neither state were the health services functioning well and a 3-month period of intensive training and supervision provided little time in which to improve the performance.

The November and December searches were more thorough than the October search. Nevertheless, the number of infected villages which were discovered decreased in both states—more sharply in Uttar Pradesh, suggesting that the new strategy was having an impact. In Madhya Pradesh, geographically India's largest state, the first search was delayed until November because of floods. The results there were highly encouraging. Only 170 outbreaks were found in November and only 53 in December.

Searches in 8 "low-incidence" states revealed only 4 with outbreaks and, during 2 separate searches, fewer than 200 cases were discovered in each (Table 15.18).

Of 10 states which had been expected to be free of smallpox by September, only Andhra Pradesh was found to have had outbreaks, and, in all, only 197 cases were discovered (Table 15.19).

As 1973 ended, it was apparent that large areas of India had remained free of smallpox (Fig. 15.16), and the search programme had confirmed this. In December only 6 states recorded 100 or more cases, and 2 of them—Bihar and Uttar Pradesh—accounted for 84% of the total (Table 15.20; Fig. 15.17). Although the total number of cases recorded in India was 88 114, the highest since 1958, reporting was far more complete than it had ever been.

The autumn campaign had shown that it was possible to mobilize health resources effectively throughout entire states to search for cases and to contain outbreaks. However, with smallpox still widely prevalent in the 4 central states and the period of high transmission again beginning, it was clear that Phase Two of the campaign had to be extended into 1974.

In early January 1974, Henderson had meetings in New Delhi with Indian and WHO staff to assess possible strategies and needs for the coming months. The situation was critical. If the intensified search campaign was to continue, a commitment of additional funds was urgent. Funds earmarked for India in the WHO regular budget were sufficient to cover the campaign activities for 2–3 more months at most. To obtain additional money from WHO was a problem. WHO's budget for smallpox eradication had remained at a constant level since 1967. The funds had been proportionately

Table 15.18. India: searches for outbreaks of smallpox in low-incidence states and union territories, 1973

Low-incidence state or union territory	Number of searches	Average number of villages searched	Personnel complement	Number of outbreaks revealed	Number of cases revealed

allocated to each of WHO's regional offices in 1967 and the proportions had not changed thereafter. With the certification of eradication in the Americas in 1972, it had been requested that the 1973 allocation for that region should be transferred to the South-East Asia Region. However, the proposal was turned down. Within the South-East Asia Region, some diversion of funds from Indonesia, now free of smallpox, was possible but the amount was not great. Meanwhile, repeated appeals to governments for support had brought generous donations of vaccine but little cash. A further emergency appeal was considered but thought to be futile because governments could seldom respond to such requests in less than several months to a year. Although the programme in India had achieved a momentum which offered hope of success, little could be done without additional resources and there appeared to be no solution forthcoming. Henderson returned to Geneva to consult the newly elected Director-General, Dr Halfdan Mahler. Later that week the WHO Executive Board was to meet. On the agenda was the question of how to use US$900 000 allocated to China, a new Member State of WHO, which had declined to accept WHO funds provisionally allotted for the support of its health programmes. The Director-General agreed immediately that a cable could be sent to India indicating that these funds would be used for its smallpox eradication programme, a decision later endorsed by the Executive Board. Another emergency in an apparently never-ending series of financial crises in the programme had been averted.

The Darkest Months of the Programme, January–June 1974

In January 1974 optimism prevailed. Funds were available to continue the programme, case notification was far more complete than ever before, and the search programmes were showing steady improvement in all states. In Bihar, in which the greatest numbers of cases were being recorded and the health services were the least adequate, the programme office reported that 50% more villages had been visited during the third search, in December 1973, than during the first in October. Despite a more extensive search and despite seasonally higher transmission rates, fewer villages with new outbreaks had been found.

The results in Uttar Pradesh had been even better, with the number of newly found outbreaks declining from 1525 in October to 331 in December. Progress in West Bengal was no less encouraging. There, Arita had introduced a new system to document progress in the programme. From October

Plate 15.10. Implementing the search programme required extensive field work by national and international staff. **A**: Ram Rakha Arora (b. 1925), an Indian member of the Central Appraisal Team in West Bengal. **B**: *Left*: Lawrence Brent Brilliant (b. 1944), an epidemiologist from the WHO Regional Office for South-East Asia; *right*: Anatolij N. Slepushkin (b. 1929), an epidemiologist from the Smallpox Eradication unit at WHO Headquarters.

1973, each newly discovered outbreak was added to a master list as an "active outbreak" and not removed from the list until 4 weeks had elapsed since the last case. At the end of December, there were only 124 active outbreaks in the whole of that populous state. In Madhya Pradesh, the last of the 4 key central states, a search conducted during 7–12 January 1974 revealed only 49 new outbreaks, two-thirds of which consisted of 3 cases or less. Of 5000 outbreaks discovered in these 4 states between October and December, it was estimated that not more than 1700 were still active. In the other states, the number of reported cases—many of them resulting from importations—remained low. Meanwhile, Bangladesh reported that only 172 of its villages were infected; in Nepal, virtually all outbreaks were said to have resulted from importations.

The Dedication of the Smallpox Programme Staff

The commitment and determination of staff who worked in the programme were extraordinary and indeed might well be the subject of a separate book. The meeting in New Delhi on 1 January 1974 of the Indian and WHO Central Appraisal Team and Henderson provides an illustration. All members of the team had been working a 7-day-week for nearly 4 months, travelling to some of the country's most remote and inhospitable areas in a frantic effort to motivate the army of health workers to contain the vastly larger number of outbreaks than anyone had foreseen. All had lost weight and were exhausted, one person had incapacitating renal colic, a second a painful facial herpes zoster infection, a third a serious fungus infection of the foot (which eventually required surgery) and a fourth atypical pneumonia with high fever and pleuritic pain. The only question asked at the meeting was how to find additional resources to sustain the momentum. When Henderson expressed scepticism of their own ability to work, let alone to continue the schedule proposed even if given the needed resources, the reply was simply: "We've considered the question and have decided that things can't get worse; therefore they must get better".

Exemplifying this determination in the field was a 50-year-old Indian professor of social and preventive medicine, Dr T. P. Jain, who was assigned as an epidemiologist in a flood-stricken area of Assam. Investigation and containment of many of the outbreaks required wading from house to house in areas in which leeches were legion and snakes a problem. A devout member of the Jain religion, he had requested a week's leave to attend ceremonies in another state commemorating the 2500th birthday of Mahavira, founder of the religion, a long-anticipated and sacred event. Another epidemiologist, arriving in the area to check the existing outbreaks in Jain's absence, found him waist-deep in water trudging from house to house, unwilling to leave for even a day so long as smallpox persisted in his area.

The commitment of the government to the programme was demonstrated early in 1974, when Dr Sharma was promoted to the position of Commissioner of Rural Health while retaining responsibility for smallpox eradication. Dr Sharma was widely known and respected among professional health staff and politicians alike for his expertise in the field of communicable diseases and for his executive ability. He had the full support of the Minister of Health and Family Planning, Dr Karan Singh. His commitment to the surveillance–containment strategy was total, and this he communicated to national and state officials on frequent visits to the field. It was important that he did so because the Director-General of Health Services, to whom he was subordinate, adhered to the traditional view that only a thorough mass vaccination campaign could succeed in eradicating smallpox, a view he expressed on frequent occasions. In part because of this contradictory advice, state officials in Bihar and occasionally in Uttar Pradesh were to call periodically for the suspension of search and containment activities in favour of total mobilization for a mass campaign to vaccinate everyone in the state. The mass vaccination approach was more easily understood and although it had been demonstrably unsuccessful in the past, there was the belief that if the health personnel were *really* properly organized and motivated the objective of 100% vaccination could be achieved. Dr Sharma's appointment ensured that the basic surveillance–containment strategy would be sustained.

A summary statement appearing in a WHO South-East Asia Regional Smallpox Surveillance Report (4 February 1974, unpublished) is indicative of the optimism prevailing at the beginning of 1974:

> "The tremendous increase in smallpox activities in the region since October 1973 has had its impact. Smallpox is diminishing in many areas at a time when it traditionally increases ... proving that smallpox transmission can be interrupted even at the height of the smallpox season. Within a few weeks a decrease in the transmission of smallpox can be expected ... If programme activities can be maintained or increased, most areas in India and Bangladesh could interrupt transmission before the monsoons."

BY COURTESY OF R S AGARWALA, 1974

Plate 15.11. Mudi Inder Dev Sharma (b. 1919), the Commissioner of Rural Health for India, vigorously and enthusiastically supported the programme from early in 1974 through extensive travel and personal inspiration. He is using the WHO smallpox recognition card to ask villagers in Uttar Pradesh State about possible cases of smallpox.

It was to be the last optimistic statement for many months.

In February 1974, the fourth search was conducted in Bihar. It revealed 1170 new outbreaks in villages and 18 in urban areas, almost 3 times the number (405) found in December, and more than twice as many cases as in January—10 697 as against 4816 (Table 15.21). The most seriously affected areas were the eastern districts. From here, smallpox began to spread to West Bengal (65 importations by mid-February) and to Nepal (11 importations).

Additional Indian and WHO epidemiologists were hurriedly recruited and assigned to Bihar. The fifth search (11–16 March) revealed 2374 new outbreaks, double the number found in February: more than 7000 cases were recorded during the search period (Fig. 15.18). By the end of the fifth search, there were 3682 active outbreaks in the state. Containment policies at this time called for the vaccination of residents only in the 20–30 houses adjacent to infected households. Even so, there were too few surveillance and containment teams to be able to visit more than a small proportion of the outbreaks, which were detected in many areas, and even the minimal containment measures were poorly executed. Desperate for additional help to supervise the search and containment programme, senior programme staff decided to recruit recent medical school graduates and, after a special training programme in New Delhi, 40 "junior doctors" were assigned to field work in Bihar. Eventually 140 were to participate (Jha & Achari, 1975).

Epidemic smallpox in Bihar was a problem of formidable proportions, and the occurrence of one natural or man-made calamity

[a] Population estimates by states are based on United Nations (1985) data for all of India proportionately allocated by state on the basis of the 1971 census.

[b] No cases were reported during this period in the union territories of Andaman and Nicobar Islands, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, and Pondicherry.

after another further hampered the eradication effort. Indian Airlines workers went on an extended strike, making it difficult to ship vaccine and for senior personnel to travel. The railways began to be extensively used until railway workers likewise went on strike. Meanwhile, the international oil crisis had developed and, in April, petrol costs in India doubled and shortages occurred. Drought in southern Bihar, sufficiently severe to require international assistance, resulted in the migration of large populations of refugees seeking food and spreading smallpox. This was soon followed by the most severe floods in a decade in northern Bihar and even more refugees fleeing in search of food and refuge. Civil disorder and political disturbances began to occur throughout Bihar and, over large areas, government authorities were totally occupied with maintaining law and order. Throughout this period, heroic efforts were made to ensure an adequate flow of supplies and to stockpile materials such as vaccine and reporting forms in anticipation of expected shortages; however, most supplies were barely adequate to meet the current needs.

That the programme in Bihar functioned at all was remarkable and for this due credit must go to its Smallpox Programme Director, Dr A. G. Achari, a conscientious and tireless worker who, with the officers of the Central Appraisal Team, Dr Foege and Dr Dutta, sought valiantly to mobilize a lethargic health staff and to sustain morale among the Indian and WHO epidemiologists, who were overwhelmed by the explosive spread of smallpox.

When it seemed that little else could possibly go wrong, the health workers in Bihar threatened to go on strike. Dr Achari, Dr Dutta and Dr Foege sought desperately to develop a contingency plan but with little support. The observation of one district health officer was characteristic of the attitude of some supervisory health staff: "If we

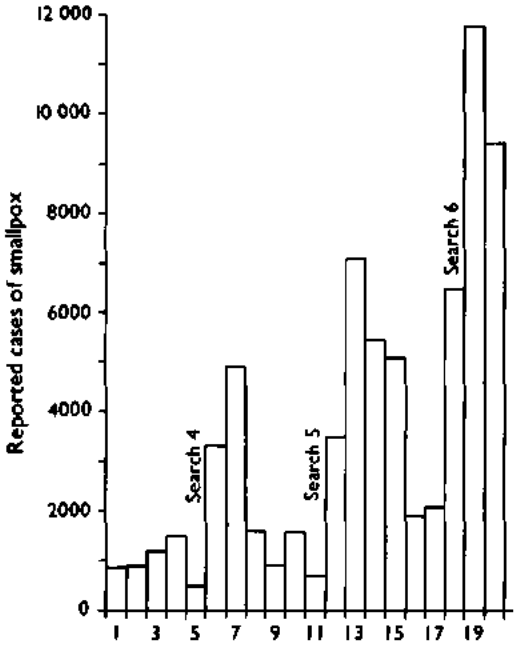

Fig. 15.18. Bihar State: number of reported cases of smallpox, by week, showing results of special searches, January–May 1974.

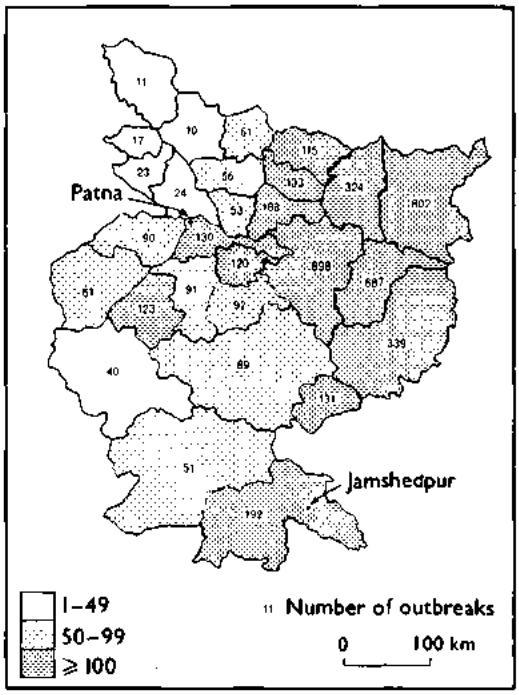

Fig. 15.19. Bihar State: number of active outbreaks of smallpox, by district, as of 5 May 1974.

don't have a strike, we don't need a contingency plan; if we do have a strike, it is no longer my responsibility."

The sixth search in Bihar (29 April–4 May) recorded 2658 additional outbreaks—the number of active outbreaks increasing to 4921. More than 7% of all villages and municipal areas in the state were infected, the most heavily afflicted being in the north-east (Fig. 15.19), where, in 3 districts, 25% of all villages were infected.

India's Director-General of Health Services, still an advocate of mass vaccination, became increasingly alarmed and advised Bihar's Minister of Health to withdraw staff from the infected areas and to begin mass vaccination campaigns in the areas still free of smallpox to prevent them from becoming infected. Dr Sharma, learning of this only after the minister in Bihar had begun to take action, protested direct to India's Minister of Health and Family Planning, Dr Karan Singh, and together they flew to Bihar to intercede. The Bihar minister rescinded his order. In an epidemic as extensive as that occurring in Bihar, some of the Indian and WHO programme epidemiologists began to speculate that Bihar might represent a special case in which the now well-tested surveillance and containment strategy might not be applicable.

Throughout May and into early June, the epidemic continued to intensify. With daytime temperatures normally exceeding 40 °C, field work became ever more difficult, morale began to deteriorate and, again, the question of a return to state-wide mass vaccination arose. The minister was more resolved than before and, in the June meeting of state and district programme officers, strongly advocated this approach. Senior programme staff argued in vain, until an Indian physician, working in one of the districts, pointed out in a deferential manner that he had grown up in a village and there, when a house was on fire, they put water on that house and not on all houses in the village. The minister reluctantly agreed to defer a mass vaccination campaign for one more month but only on the understanding that if no apparent progress had been made by then, mass vaccination would be initiated. Senior staff hoped that, even if containment were less than optimum, the seasonal decrease in transmission would partially stem the epidemic and so preserve what they believed to be the only possible effective strategy—surveillance and containment.

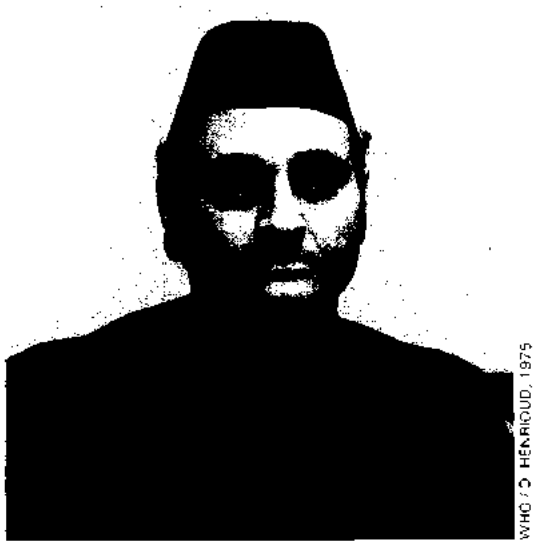

Plate 15.12. Karan Singh, Minister of Health and Family Planning of India from 1973 to 1977, provided strong political support for the programme and for the surveillance–containment strategy.

In the other states of India, the situation was better than in Bihar but not so good as had been expected in February. Uttar Pradesh was the next most heavily infected state. The numbers of reported cases and outbreaks had risen steadily since January, although less precipitously than in Bihar. A peak of 1905 active outbreaks was reached in May, with 8337 cases reported that month. Outbreaks were reported from 442 (51%) of the state's 875 primary health centres and in 47 of its 55 districts (Srivastava & Agarwala, 1975). However, 82% of the outbreaks occurred in only 15 districts, primarily in eastern Uttar Pradesh, where their large number precluded the taking of effective containment measures. Elsewhere in the state, with the support of the Director of Medical and Health Services and Family Planning, Dr G. P. Srivastava, the health staff had begun to function well.

In West Bengal, the number of active outbreaks increased steadily, from 124 in December to 556 following the seventh search in mid-April. However, more than 75% of the outbreaks took place in only 5 of the state's 16 districts, and here village volunteers began to be recruited and trained for containment operations, an effective practice later adopted in other states. The increase in the number of outbreaks in West Bengal was largely accounted for by importations, mostly from Bihar. Between January and May, programme staff documented 386 imported outbreaks, and others occurred as a result of spread from these importations.

Importations, principally from Bihar, Uttar Pradesh and West Bengal, accounted for an increase in the number of cases in Madhya Pradesh, Maharashtra and Orissa. Each state worked diligently and effectively to discover and contain the outbreaks as rapidly as possible, but by May, both the smallpox eradication staff and the general health service personnel were reaching a critical point of fatigue and frustration. Meanwhile, the eastern states, hitherto all but free of smallpox, experienced a sharp increase in the number of cases, resulting from importations from Bangladesh, Bihar and Uttar Pradesh. This was cause for additional alarm because, in the eastern states, health services were generally less extensive and not much better organized than those in Bihar. Although they were not populous states, road and rail services were poor and both search and containment activities were difficult to organize and to execute.

The unexpected and explosive epidemic of smallpox in Bihar and its spread to other states had required the mobilization of far more Indian and WHO epidemiologists (see Table 15.16) than had been foreseen and had necessitated the emergency purchase of more vehicles and supplies of all types than had been planned. By April, funds to support the smallpox programme were again at a low level. Requests were made to numerous governments for additional finances; few showed any interest and no country indicated it was in a position to act quickly in answering an appeal. Privately, many expressed scepticism about the programme's prospects of success. The reaction was not surprising in view of the fact that the number of cases of smallpox recorded in India in the spring of 1974 was the largest for nearly two decades. WHO's frequent appeals in the past for funds to bolster its malaria eradication campaign, and the continuing setbacks in that programme despite infusions of ever larger sums of money, were well remembered. Once again, the programme approached a critical point, but, unexpectedly, substantial help materialized from a new source, the Swedish International Development Authority (SIDA). In a casual conversation with the Personnel Officer of the WHO Regional Office for South East Asia—an official of Swedish nationality—Dr Grasset learned

Plate 15.13. Jarl E. Tranaeus (b. 1923), Head of the Development Co-operation Office of the Swedish Embassy in New Delhi from 1973 to 1978, persuaded Swedish authorities and the Indian government's Planning Commission of the need for substantial additional assistance to the smallpox eradication programme at a crucial moment.

that SIDA planned to examine alternative uses for Swedish funds which had become available because of the cancellation of another project in India. Discussions promptly followed with Mr J. Tranaeus, at the Swedish Embassy in New Delhi. Convinced, as few others were, that an effective and well-directed campaign was in progress whatever the smallpox incidence might suggest, he persuaded the Planning Commission of the government of India, as well as his superiors in Stockholm, of the merits of the programme. Within a few weeks, a memorandum of agreement had been signed on behalf of the governments of India and Sweden which made available to WHO US$2.8 million in support of the smallpox programme. With Mr Tranaeus's continuing enthusiastic interest, SIDA was eventually to provide US$10 million to the programme. The government of India also increased its own central allocation of funds. For 1974, a sum of US$13 million was made available for field operations.

Time was required to effect the necessary transfer of funds, but the Division of Budget and Finance in WHO Headquarters readily agreed to permit funds to be obligated even though they were not yet in hand. Meanwhile, the administrative staff in the WHO regional office were experiencing difficulties, because of the substantial expansion in the number of personnel in the programme receiving a stipend from WHO, the larger numbers of imprest accounts to be handled and the need to procure a greater volume of supplies (Table 15.22). It was essential that additional personnel should be recruited and that budget and finance operations should be established for the programme. The Center for Disease Control (formerly the Communicable Disease Center) in Atlanta, which was already providing many field epidemiologists, responded to this need by sending its most capable senior administrative staff to help to bring some order into an increasingly chaotic administrative situation. Beginning with the Center's Deputy Director, Mr William Watson, an exceptionally imaginative group of administrators worked tirelessly with the group of no less talented WHO administrative staff to provide essential services in support of the field staff.

Although the smallpox epidemic was featured more often and with greater prominence in Indian newspapers, little was known of the problem outside the country. However, in May 1974, the epidemic became international news. On 18 May 1974, India tested its first atomic device in an underground explosion in Rajasthan. At that time, the smallpox epidemic was at its height, more than 11 000 cases being reported in a single

[a] Between 1972 and 1976, it is estimated that WHO, in addition, arranged to print and distribute the following material: approximately 31 million forms for use in reporting and in search and containment operations; 500 000 booklets for use in outbreaks and in market searches; 400 000 posters; 1 million smallpox recognition cards; and 500 000 other guides and miscellaneous publications.

week. International news reporters who had flown to India to cover the atomic test arrived just as the smallpox epidemic hit the headlines in the local press; international media coverage of both events was extensive. Programme staff repeatedly explained that more complete reporting accounted in major part for what appeared to be the largest epidemic for many years, but scepticism was prevalent and understandable.

Although the problem in Bihar was serious, the eradication programme throughout India was steadily improving and gaining momentum. Week-long village-by-village searches were being performed each month throughout the high-incidence states and less frequently in the others (Table 15.23). The number of those engaged in the searches was increasing (Table 15.24).

As serious and frustrating as the situation appeared, yet another disaster aggravated it—the Jamshedpur epidemic in Bihar State. Its discovery resulted from investigations in Madhya Pradesh. Special efforts had been made to interrupt transmission in Madhya Pradesh. It was one of the 4 central states considered to be of highest priority, and was geographically the largest state in India, with a population of 46 million. Most of the outbreaks which had been discovered during the autumn searches were in the northern and eastern districts of the state, bordering on Bihar and Uttar Pradesh. The December 1973 search had revealed only 215 cases and 53 new outbreaks. By the beginning of March 1974, and after 5 monthly searches of its 10 million households, smallpox appeared to be present in only a single, geographically limited focus, in a tribal area and one of the least developed parts of the state.

Table 15.23. India: frequency of active searches for outbreaks of smallpox, 1973–1975

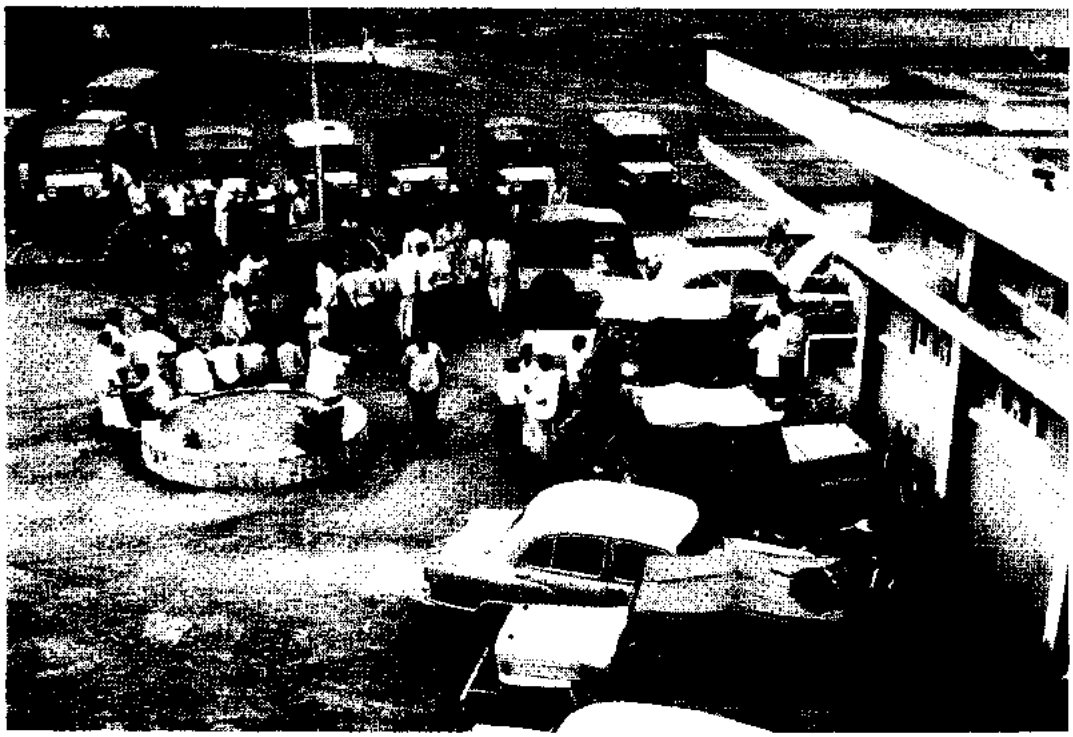
1976	134 412	43 688	54 261	36 463

In late March 1974, however, reports of smallpox outbreaks began to arrive from many areas of Madhya Pradesh which had been considered to be smallpox-free. Investigations revealed these to be the result of recent importations from the neighbouring state of Bihar. The source of infection of many was traced to an industrial complex in southern Bihar: Jamshedpur in Singhbhum District. *Adivassis* (tribal people) often travelled 300–800 kilometres to Jamshedpur from their homes in Madhya Pradesh in search of seasonal employment. If they became ill with fever, they returned to their native villages, where many subsequently developed rash and spread smallpox to others.

Dr Brilliant was dispatched to Jamshedpur in late April to assess the situation. He found a major problem of unexpected magnitude.

The epidemic in Jamshedpur, Singhbhum District, Bihar

The Jamshedpur industrial complex is one of India's most important steel-producing areas, its prosperity contrasting sharply with economically depressed neighbouring areas of southern Bihar, eastern Madhya Pradesh



BY COURTESY OF TATA INDUSTRIES

Plate 15.14. The office of Tata Industries, Jamshedpur, became the smallpox eradication headquarters for Chotanagpur Division, Bihar State.

and northern Orissa. As such, it attracted numerous seasonal workers, beggars and transients.

The special investigation began in early May. The District Medical Officer of Singhbhum disclosed that during the preceding 6 weeks, he had received 125 notifications of outbreaks in other districts of Bihar and in other states which were suspected of having originated in his district, and that 12–15 notifications were then being received daily. Little action had been taken, the government health structure in this district being poor. In addition to 27 primary health centres that reported to him, all of which were then known to have smallpox cases, there were 15 autonomous and separately administered health units in Jamshedpur (population, 800 000). The health units included small company towns, corporations, large colonies of railway employees and others. No one was charged with the task of reporting cases among the large migrant population, and the railways denied all responsibility for the reporting of cases from the areas they administered. Half the health units were found still to be using rotary lancets.

At the industrial complex, a group of heavy industries of the Tata group, officials professed ignorance of the problem but immediately agreed to provide help in a search of the city and of 1760 villages within a 45-kilometre radius. In a search that took place in mid-May, 50 physicians, 200 paramedical supervisors and 900 searchers discovered 1479 cases in the city and 726 cases in the 456 villages found to be infected (Basu et al., 1979). An intensive programme of containment and case detection was immediately undertaken. This involved, in addition to government and WHO health staff, personnel and transport provided by 7 of the Tata industries as well as voluntary organizations, including the Rotary Club, the Lions Club, the Bihar Flying Club, the local blood bank and the All-India Women's Council (Bharucha, 1975). All bridges and major roads were barricaded and no one was permitted to pass unless vaccinated. A special programme dealt with railway travellers, especially third-class passengers, of whom perhaps one-third travelled without tickets. Trains were diverted to special platforms, which permitted all passengers to be checked

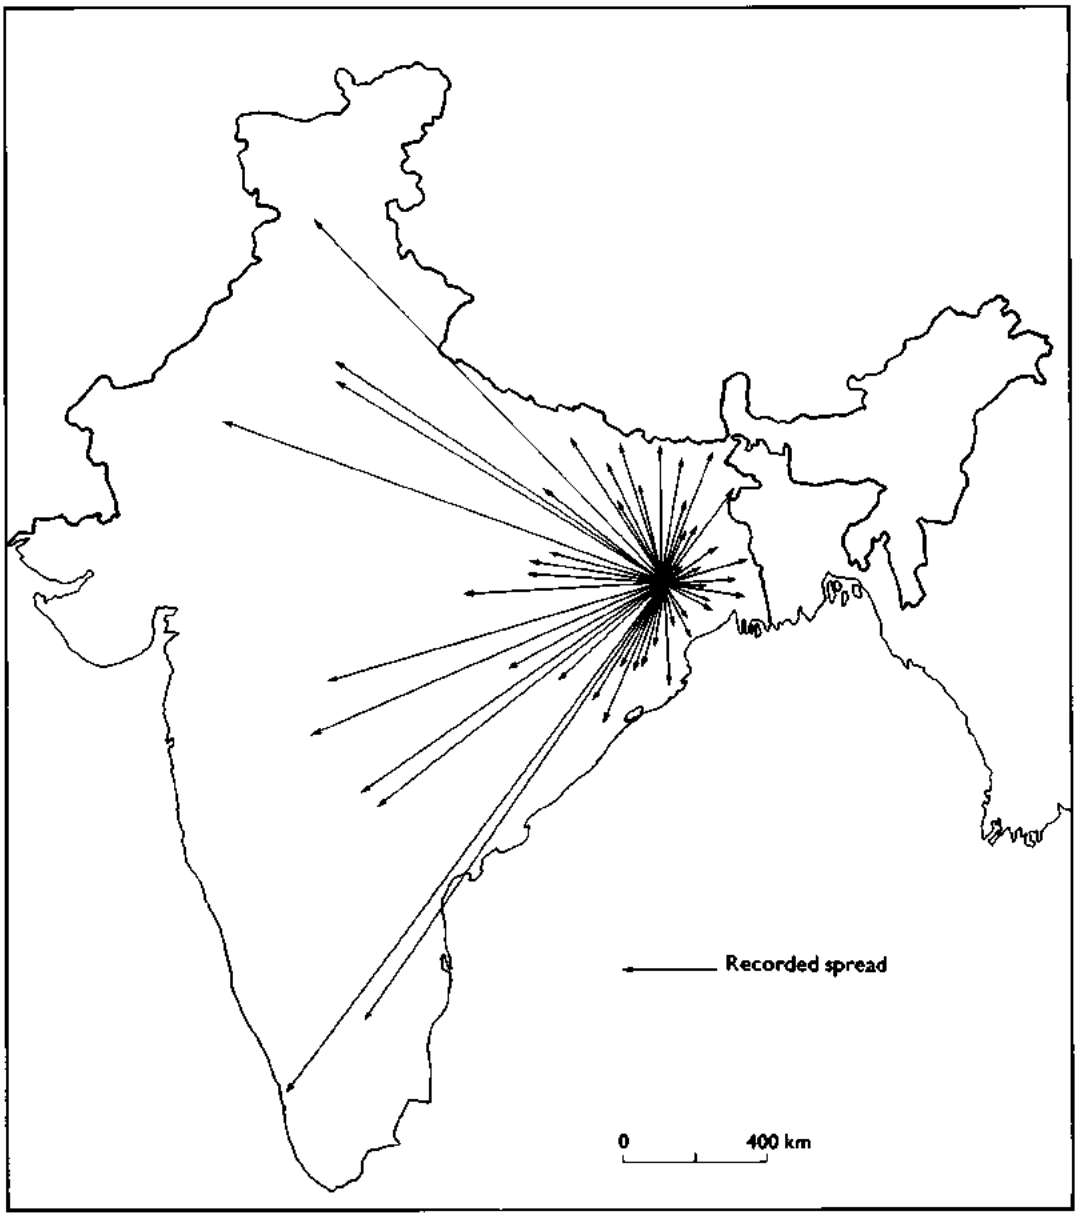


Fig. 15.20. Spread of smallpox from the Jamshedpur urban industrial complex to the rest of India, 1974.

when boarding or leaving a train. Checkpoints were established at bus stations, and employers ensured that workers and their families were vaccinated. Meanwhile, the containment of all known outbreaks began, an effort which in fact necessitated house-to-house vaccination of the entire urban complex and most of the surrounding villages.

Two months were required to bring the epidemic under control. Meanwhile, 300 outbreaks and at least 2000 cases occurred in 11 states of India and in Nepal as a result of travel from Jamshedpur (Fig. 15.20). The area most affected was Bilaspur District (Madhya Pradesh), with 484 cases in 72 villages.

A Redoubled Effort, June–December 1974

Early June 1974 was the psychological low point of the Indian smallpox eradication programme, if not of the global Intensified Programme itself. A 9-month intensive campaign had been conducted throughout India

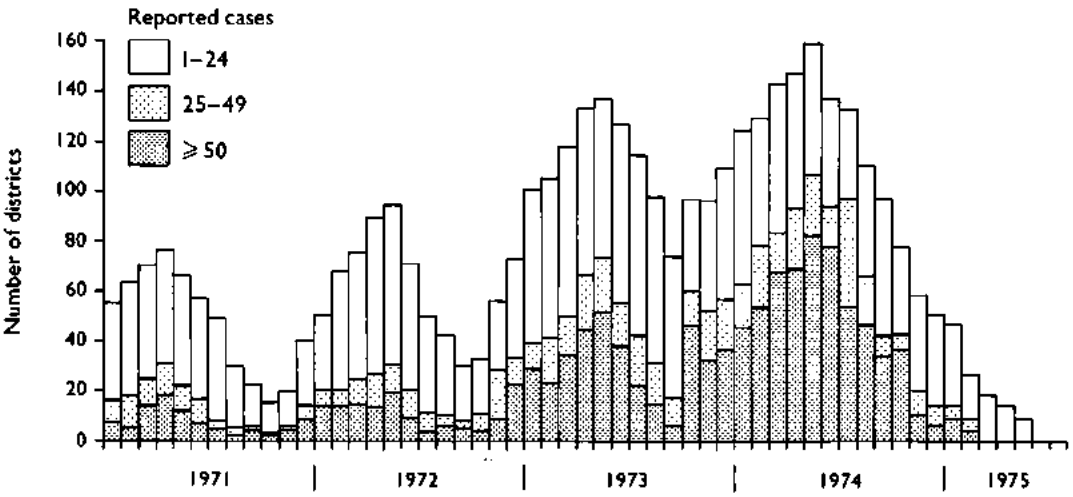

Fig. 15.21. India: number of districts reporting cases of smallpox, by month, 1971–1975.

with senior staff and numerous field staff working 7 days a week. Despite the large expenditure of money and effort to date, and despite what appeared to be an increasingly successful effort in surveillance and containment activities, there were 8664 known outbreaks. Moreover, up to the end of May, India had already recorded 116 188 cases, a number greater than that reported for the entire world during any of the preceding 6 years of the Intensified Programme. Cases were reported in May from nearly one-third of the districts in India, of which 80 reported 50 cases or more (Fig. 15.21). Many areas of India remained free of smallpox or had only a few outbreaks resulting from importations (Fig. 15.22), but the epidemic wave then surging through Bihar seemed to be moving both east and south. It was clear that the efforts made so far in Bihar had been inadequate to contain smallpox, and the states which appeared to be the next candidates for epidemic smallpox—Orissa to the south and the states to the east—had health services which were not much better in quality than those in Bihar.

During June, with the beginning of the monsoon period, smallpox transmission normally declined in India and the number of outbreaks diminished. However, with the disease so widely seeded throughout Bihar and adjacent areas, it was clear that unless a concerted effort were made to contain the outbreaks during the summer, smallpox would remain widely disseminated at the commencement of the next season and the experience of the spring of 1974 would be repeated. Activities of all types usually diminish in India during the summer months—the hottest, the most humid and the most difficult months of the year in which to work. A staff which had toiled to the point of exhaustion between September and May would have to mount one more effort.

On 17 June 1974, the Central Appraisal Team met the Secretary of Health and the Director-General of Health Services to discuss an emergency programme for the whole of India, but especially for Bihar. It was decided to increase the number of special epidemiologists from the 50 who were in the field at the time to more than 100. WHO would initially provide 12 additional international epidemiologists, and 6 non-medical surveillance officers; the government of India would attempt to recruit 40 epidemiologists. If that proved impossible, WHO would try to obtain the services of more international epidemiologists.

Six central-level surveillance teams would be established which would respond to emergency smallpox problems as they developed. State surveillance teams, hitherto restricted in travel to the state in which they were assigned, would be directed to cross state borders whenever necessary to seek the source of infection of outbreaks.

Three hundred additional containment teams would be recruited, each to be headed by recent Indian medical graduates. A further 375 Jeeps would be purchased or hired. To

fund these activities, SIDA offered additional financial assistance, which was rapidly made available.

It was recognized that special efforts would be required in Bihar. Following consultations between the staff of the WHO regional office, the Governor and the State Health Minister, the Chief Secretary of the State of Bihar sent a special letter to all district magistrates, informing them that as from the end of June they and the block development officers would assume responsibility for the conduct and organization of the campaign in their districts. Dr Achari would continue in his role as State Smallpox Eradication Programme officer but more effective senior administrative staff would replace the health service staff in bearing primary responsibility for the programme.

The president of Tata Industries was

The Situation in India as Seen in June 1974

Memorandum, dated 24 June 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The epidemics of smallpox now occurring in Bihar, eastern Uttar Pradesh and adjacent areas have been the subject of world-wide press interest during the past two weeks with many articles appearing in all major newspapers and news magazines. Providing perspective on the problem has not been easy. While there is no question but that Bihar and eastern Uttar Pradesh are heavily afflicted and represent now the "epicentre" of the global problem, the fact of a far more active programme and more complete reporting unquestionably magnifies the severity of the problem when comparing this year's and last year's data. Whatever the relative magnitude of the problem, it is clear that the most critical battle of the entire programme is now being fought on the Indo-Gangetic plain of Bihar, Uttar Pradesh and the adjacent states. Our success in these efforts over the coming months will be determining in regard to the goal of global eradication.

"The reporting of large numbers of cases as is now the case in Bihar, eastern Uttar Pradesh and adjoining areas, is of real concern but, at the same time, it may also be regarded as an encouraging sign. Unless outbreaks are found, they cannot be controlled. And one must recall the experience in Brazil when, in 1969, surveillance was first introduced into the programme. Smallpox incidence abruptly rose that year to reach the highest level in almost a decade, only to fall to '0' less than a year later. Can we do the same in these other problem areas? Unquestionably we can, provided there is full government support at all levels and that every effort continues to be made to find all cases and outbreaks and to contain them.

"While the epidemics in India have captured the headlines, equally newsworthy are the spectacular achievements in Pakistan. It is apparent that staff at all levels of the programme now realize that eradication is imminent and with this realization has come an even more energetic burst of activity."

approached for help in dealing with smallpox in the 6 southern districts of Bihar comprising Chotanagpur Division. He agreed to assist and the company's Board of Directors approved the expenditure of 7.2 million rupees (US$900 000) and the assignment of personnel and vehicles. An unusual semi-autonomous public and private sector programme was created in this division, involving personnel and equipment from WHO, Tata Industries, the government of India, the state of Bihar, and OXFAM, a private voluntary organization. The consortium participating in the Chotanagpur Division programme was to function capably and with remarkable cooperation over the following 12 months.

Deficiencies in the containment of outbreaks had proved to be a serious weakness of the programme in most states, particularly Bihar and Assam. Where smallpox outbreaks were few, state surveillance teams had usually assisted local staff in their investigation and in the vaccination of village residents. Where smallpox was widely prevalent, procedures called for the detection of all cases in the area and the vaccination of those in the 20–30 nearest households. The names of any absent household members were supposed to be recorded and the village visited on a later occasion to ensure that all were vaccinated. This directive was rarely followed, however. In many areas of the world, and indeed in many parts of India, simple containment measures had sufficed to stop transmission. In the more densely populated parts of India, however, they proved ineffective. Many persons left their homes during the day to go to the fields, to market or elsewhere; some who objected to or feared vaccination simply hid themselves and their children when the teams were in the villages; many visited relatives and friends, including those with smallpox, in other villages. The result was that even after intensive containment vaccination, numerous susceptible persons remained and smallpox transmission persisted.

It was therefore decided to systematize the containment activity in a manner that could be readily understood and widely applied and

Plate 15.15. One of the 56 surveillance teams in Chotanagpur Division, Bihar State, setting up camp in a tribal village. The programme in Chotanagpur, one of the most seriously affected areas, represented an unusual co-operative effort of groups from the public and private sectors.

that was subject to verification by a supervisor. "Containment books" were designed, printed and distributed in August 1974. One book was used for each outbreak. The name of each person in each of 500 houses surrounding an infected household in a rural area (1000 houses in an urban area) was to be listed in the book and repeat visits made to the village until all persons had been vaccinated and the fact duly registered in the book (Sharma & Grasset, 1975). In a separate section of the book, information regarding each case was recorded.

Three specific standards were also established at this time as indices of the effectiveness of, respectively, surveillance, containment, and outbreak investigation activities. The provision of standards by which a programme in any area could be measured was thought to be helpful in improving the quality of supervision. An indication of the degree of effectiveness of surveillance was the lapse of time between the onset of the first case and the detection of the outbreak. The detection of at least 75% of outbreaks within 14 days of the onset of the first case was felt to be attainable. If adequate containment were performed, all susceptible contacts would be vaccinated and none should develop smallpox once vaccinial immunity had developed say, after 7–12 days. Assuming that it would take several days to identify and vaccinate susceptible persons, it seemed reasonable to establish a second goal—namely, that no cases should develop more than 17 days after an outbreak was detected. The quality of the investigation of an outbreak was more difficult to measure, but such quantification was considered important because experience had shown that the least well performed part of an investigation was usually the identification of the source of infection. The concept that each individual with smallpox must have been in face-to-face contact with another individual with smallpox just 7–17 days before onset was a surprisingly difficult concept for many to grasp. On investigation forms, many simply listed "sporadic" as the source of infection. To identify the source, however, was vital because often other, as yet undiscovered, outbreaks were unearthed in this manner. Thus, the third goal called for the identification of the source of the outbreak in 90% of outbreaks, a level of success which had been achieved by competent epidemiologists in other areas.

The measurement of progress based on the number of the then existing infected villages and urban *mohallas* (sections of a city) had been initiated in October 1973 in West Bengal and had been introduced in some other states as well, particularly those with a low incidence of smallpox. In June 1974,

The Problem of Beggars

The containment of outbreaks among beggars proved to be an exceptionally difficult problem requiring imaginative and administratively unorthodox solutions. The isolation of beggars with smallpox in their homes was impossible because most were transients. In fact, isolation either in a house or in a hospital was refused because both the beggars and their families were dependent on begging for their livelihood. Even those actively ill with smallpox travelled from village to village shouting for alms, as was their custom. During 1973, a number of instances were documented in which infected beggars had transmitted smallpox to a dozen or more people and had been the source of many widely dispersed outbreaks.

In 1973 an epidemiologist wrote to propose that beggars with smallpox and their families should be given food and lodging until they recovered. The proposal was rejected by WHO regional office administrators and senior Indian staff, who foresaw this as a precedent to providing support to a legion of beggars. Undeterred, Dr Stephen Jones, a free-spirited American epidemiologist, used his imprest account funds to do just this and submitted a bill of 1800 rupees for the hiring of a house, the purchase of rice, a broom and various other supplies to house a family of beggars. Anticipating trouble in explaining the outlay to WHO's finance officer, Dr Grasset and Dr Foege decided to pay the relatively small bill themselves but argued more aggressively for a change in policy. Eventually, the practice was accepted. During succeeding months, hundreds of beggar families with smallpox were supported in this manner and effective containment of the outbreaks was achieved.

uniform definitions for this method of measurement were developed and it was formally adopted throughout India. Any village or *mohalla* in which a case had occurred within the preceding 4 weeks (subsequently extended to 6 weeks) was considered to be the site of a "pending outbreak". This concept recognized the potential for the spread of smallpox from the patient to susceptible contacts throughout the period concerned and the need to check the outbreak repeatedly to ensure that transmission did not continue. A list was kept in each primary health centre and each district (later, each state) showing the name of the infected village or *mohalla*, the date of onset of each case, the date of discovery, the date on which containment began, the source of infection, and the dates on which supervisory personnel had visited it. The outbreak was not removed from the list until the site was visited and searched again, not less than 4 weeks (later, 6 weeks) after the onset of the last case.

As at the end of June 1974, there were 6401 pending outbreaks in 17 states and Delhi Municipal Corporation (Table 15.25).

With additional resources and an increased complement of supervisory personnel, state-wide search and containment programmes continued throughout the summer. Most of the resources were assigned to Assam, Bihar, Uttar Pradesh and West Bengal, in which searches were conducted monthly. In Bihar alone, 35 national and international epidemiologists and more than 100 state epidemiologists and paramedical personnel assisted state, district and local health personnel (Jha & Achari, 1975); in Uttar Pradesh, there were 27 national and international epidemiologists and 19 state surveillance teams (Srivastava & Agarwala, 1975). Most other states conducted one search during this period, although some conducted two. The number of pending outbreaks began to decline sharply, and with fewer outbreaks surveillance teams were able to provide increasingly better supervision of search and containment activities. The quality of both procedures rapidly improved. In addition, the teams devoted more time to visiting markets and schools to inquire about rumours of possible cases. The number of pending outbreaks decreased to 4606 at the end of July and to 3267 at the end of August. The first hopeful note since February was sounded on 26 August in a WHO South-East Asia Smallpox Regional Surveillance Report: "The opportunities for interrupting smallpox transmission in India, Nepal and Bangladesh are better than at any time since the programme started."

By the end of September, there were only 2124 pending outbreaks, of which 1727

[a] No outbreaks were recorded in the union territories of Andaman and Nicobar Islands, Arunachal Pradesh, Chandigarh, Dadra and Nagar Haveli, Goa, Daman and Diu, Lakshadweep, Mizoram and Pondicherry.

(81%) were in Bihar (Table 15.25; Fig. 15.23). The north-eastern districts of Purnea and Katihar in Bihar had more than 600 pending outbreaks, but in only 8 other districts were there more than 50. Almost none were to be found in all of southern and western India. In September, 4674 cases were reported, one-tenth the number recorded in May.

The staff were optimistic but still concerned. The analysis of data from previous years indicated that some increase in transmission occurred at the beginning of October, coinciding with an increase in the numbers of persons travelling from place to place to attend festivals and marriages. Thus, there was a heightened concern about the spread of smallpox over greater distances. Moreover, active outbreaks persisted in 50 municipalities which were recognized to be important sites of dissemination to rural areas. Finally, in Assam, the number of pending outbreaks had actually increased from a low of 50 in August to 64 in September; in this state, field operations were greatly hampered by floods, a poor transportation network and a less than adequate health service. Its neighbour, Bangladesh, appeared to pose no threat, since there were only 163 infected villages in the country at the end of September, a competent programme was in place and the numbers of reported cases and outbreaks were declining as rapidly as in India. In Nepal, to the north, only 4 outbreaks were detected in September 1974.

Additional measures were implemented in October to strengthen surveillance and containment. In all urban areas with active outbreaks, a house-to-house search was conducted every 2 weeks. Additional personnel were assigned to work in Assam. Perhaps of greatest importance was the decision to offer throughout India a reward for the notification of a previously unreported outbreak of smallpox in which a case had occurred within the preceding 6 weeks. This, it was hoped, would permit earlier detection of cases and discourage the suppression of reports which, despite all efforts, remained a problem in some areas. In addition, smallpox cases were sometimes hidden by villagers who held

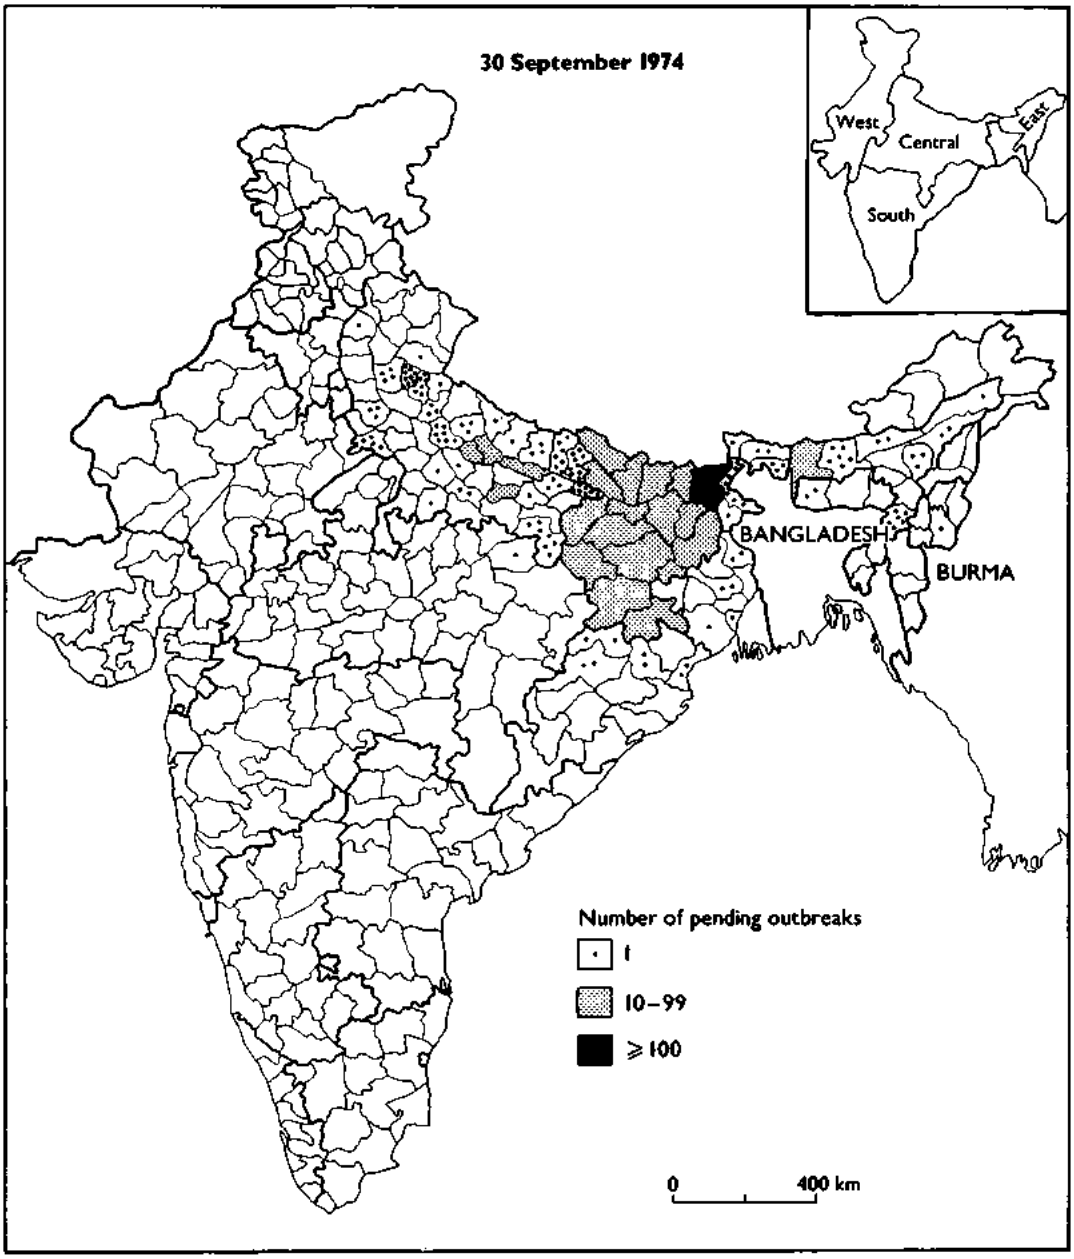

Fig. 15.23. India: number of pending outbreaks of smallpox, by district, as of 30 September 1974.

religious objections to vaccination or feared that patients might be removed to hospital. The offer of a reward had originally been proposed in 1972 in areas with a low incidence of smallpox, but many health officials had been reluctant to adopt the practice, fearing that it would create a precedent with regard to the reporting of cases of other diseases. However, as has previously been described, 5 of the southern states began offering rewards of 10–25 rupees, following the extensive suppression of reports which resulted in the Gulbarga (Mysore) outbreak in 1972. Early in 1974, some other states that had a low incidence or were thought to be smallpox-free also began to offer a reward, which was now increased to 50 rupees. The inducement had not been particularly effective, however, because information about the reward was not widely

Market Searches

Surveys in the traditional weekly markets, held throughout India, were especially useful in detecting cases of smallpox. It was found that 2 searchers could readily question 300–500 market visitors in the course of a working day (Basu & Khodakevich, 1978b) and obtain information about cases in villages 10–20 kilometres distant. It was a technique widely employed by surveillance teams.

Posters showing a smallpox patient and announcing the reward for reporting a case were posted at the entrance to the market and in tea-shops. At each entry point 2 workers were stationed, one of whom asked those entering the market if they knew of cases and which village they were from; the second worker recorded the information. Later, the searchers moved to the tea-shops to continue the questioning. The investigation of all reported or rumoured outbreaks was undertaken the following day.

To assess how effective the market search technique had been, a special study was conducted in a mountainous area of Assam (Khodakevich & Rao, 1978) in January 1976. In a district comprising 695 villages scattered over an area of roughly 15 by 55 kilometres, 7 markets were searched to determine whether outbreaks occurring over the preceding 3 years could be detected. The searchers were health workers who had not been associated with the programme and had no information about previous smallpox in the area. Visitors to the market reported 64 villages as having been infected with smallpox during the preceding 3 years. Investigation revealed that 18 of the villages were in another district, 2 had outbreaks in 1970, 2 had outbreaks of chickenpox, and in 8 others no evidence of outbreaks could be found. The remaining 34 villages in which smallpox was reported to have occurred included all 13 villages which had had outbreaks in 1975, 17 out of 32 of those with outbreaks in 1974 and 4 out of 13 of those with outbreaks in 1973. Although the market searches did not detect all outbreaks, they served to provide a great deal of information at a minimum cost in manpower.

disseminated by the health workers, who wanted to claim the money for themselves. To overcome this problem, it was decided to offer 50 rupees to the person first reporting a previously undiscovered outbreak and 50 rupees to the health worker who received the report.

Containment measures were also strengthened as some surveillance–containment teams, which now had fewer outbreaks to contend with, began to stay in infected villages overnight to ensure that all residents were vaccinated. One or two local inhabitants, termed "watchguards", were hired to stay at each infected house to prevent the patient from leaving and to vaccinate anyone who could not be dissuaded from visiting. Eventually, 4 watchguards were engaged to guard each house with a patient, 2 of them working during the day and 2 at night. This meant that if one watchguard had to absent himself, one would remain on duty. When it was found, in some areas, that visitors avoided the watchguard by entering through a back door, the back entrance was barricaded. Observing that new outbreaks were often found in villages adjacent to those infected, the teams began an increasingly intensive search in a 5-mile (8-kilometre) radius around each infected village.

Information on the means by which outbreaks were actually detected are available for 3798 outbreaks from mid 1973 to mid 1975. The data for the latter half of 1974 and for the first half of 1975 show that an increasing proportion of the outbreaks was being notified by the public and a lesser proportion was detected by periodic search (Table 15.26). In the non-endemic states, notification by the public played a more important role, the proportion of outbreaks so notified increasing from 15% in the first 6 months of 1974 to 29% in the second 6 months and to 36% in 1975.

The outbreaks were detected increasingly earlier after the onset of the first case (Table 15.27), although the standard which called for 75% to be detected within 14 days was never reached. The outbreaks persisted for a shorter time (Table 15.28) but in some of them cases continued to be found more than a month after detection. With earlier detection

and better containment, the outbreaks, as might be expected, were less extensive (Table 15.29).

Assessment of the ever-more-thorough searches was modified to determine the proportion of villagers who were aware of the reward for reporting cases. It was assumed that if the existence of the reward were generally known, cases would not be hidden for long. Personnel searching for cases were instructed to convey the fact of its existence to all the villagers. Radio, posters, leaflets, rickshaws with loudspeakers and announcements at weekly local markets were also used as a means of information.

During the autumn, the number of pending outbreaks fell steadily, from 2124 at the end of September to 980 at the end of October and to 343 at the end of November (Fig. 15.24), but then the rate of decline slowed considerably. Almost as many new outbreaks were being added to the list as were being removed. The winter season of more rapid transmission had begun. The numbers of outbreaks and cases were at a record low, but, if smallpox transmission was to be interrupted, even more rigorous methods of case detection and containment would be required.

Concern about the programme's progress suddenly turned to alarm in mid-December

Status of the Programme in Early December 1974

Memorandum, dated 9 December 1974, from the Chief of the WHO Smallpox Eradication unit to all smallpox eradication staff:

"The autumn saga of 1974 has been marked by weeks of unexpectedly rapid decreases in the number of pending outbreaks in Asia interspersed with weeks when there has been little or no decline. At present, we seem to be again in the latter phase. Does this signal the beginning of a phase where seasonally increased rates of transmission overbalance our capability to contain the outbreaks *or* does it represent but a pause in the countdown as we regroup to redeploy forces and to tighten up containment procedures and so recommence the countdown? Unquestionably, a greater effort is required during the winter months to ensure containment of each outbreak, but the task can be accomplished.

"With search activities now reasonably well developed in most districts and with market searches and the system of rewards serving to assure discovery of outbreaks missed in search, it seems to me that now is the time to deal far more rigorously with containment measures. In many areas ... staff have not dealt with containment as rigorously as is now required. This is not surprising. During the summer and early autumn months, further spread of smallpox occurred only infrequently even when containment measures were less than optimal. Inevitably, emphasis shifted to improving the search procedures, sometimes perhaps at the expense of the arduous and meticulous work required to assure 100% containment. With increased rates of transmission and more population movement, containment procedures which were effective in October are no longer so.

"At this stage, and with the comparatively few outbreaks we have, *every patient* must be subjected to 24-hour guard and, as required, food provided to the families to provide further incentive for them to stay put. If the guard is fully effective, every subsequent contact will be protected by vaccination. But *frequent* supervision by epidemiologists and senior staff is mandatory if the system is to work. Then begins the now necessary but arduous task of tracing all contacts of the patient from the time of onset of rash. This procedure is in effect in some areas but, as of the time of my visit two weeks ago, it was not in effect everywhere.

"Most important now is for each epidemiologist to consider each new outbreak as being indicative of a possible failure in the system. The question for each outbreak must be asked—'Why did this outbreak occur and what should be done to prevent a repetition of the episode?'"

1974 as major epidemics unexpectedly began in Bangladesh. Catastrophic floods, the worst in 20 years, had swept the northern districts of Bangladesh in August and September and, with the subsequent famine, tens of thousands of refugees migrated to other parts of the country. In December, smallpox began spreading rapidly and once again infected the major cities. The most heavily affected areas were along the northern Bangladeshi–Indian frontier and because of frequent travel across the border, numerous importations were to be anticipated. Of particular concern were the eastern states of India, in which the health services and the smallpox eradication programme itself were the least able to cope.

Realization that a difficult spring might lie ahead was soon followed by the ominous discovery of a cluster of outbreaks at a major pilgrimage site of the Jain religion about 85 kilometres from Patna, the capital of Bihar (Jha & Achari, 1975). The largest outbreak was detected in December 1974 at Puri village, in which the founder of the Jains had died 2500 years earlier. Forty households were infected at the height of the pilgrimage season. Complicating the problem was resistance to vaccination, common among Jains. A special appeal was made to the principal religious leader, who agreed, reluctantly, to recommend vaccination. The entire village was quarantined by the Bihar military police. Twenty-four-hour watchguards were posted at the houses of infected persons and at key areas in the village. A community kitchen was set up to feed patients so they would not have to leave their homes for food. Pilgrims were not allowed to enter sacred pilgrimage

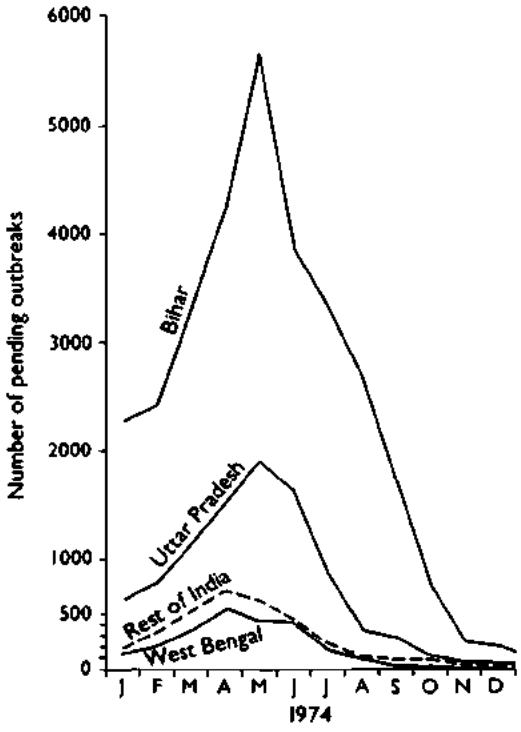

Fig. 15.24. Bihar State, Uttar Pradesh State, West Bengal State and the rest of India: number of pending outbreaks of smallpox at the end of each month, by month, 1974.

areas until they had been vaccinated. Although smallpox spread to 5 adjacent villages, the outbreak in Puri was finally controlled by the end of February 1975.

Elsewhere in the district, the number of outbreaks had increased from 16 to 75. Assessment revealed poorly conducted search operations and inadequate containment. Emergency measures were introduced. Whenever an outbreak was discovered, 20–25 vaccinators were dispatched to the infected village; containment vaccination was completed within 48 hours; 24-hour watchguards were posted at every infected household; and food was brought in to ensure household quarantine. Entire villages were cordoned off when necessary. Instead of a few vaccinators, dozens were assigned to each newly discovered infected village and camped there until no active case remained. In all, 102 new outbreaks were discovered in Bihar in January 1975.

"Operation—Smallpox Zero", January 1975

With smallpox present in only 285 of the more than 575 000 villages of India at the end

Problems in Containment: a Report by a Supervisor in Bihar, May 1975

"We have the misfortune to have to inform you of a new case of smallpox in the Painathi outbreak, a 4-month-old unvaccinated male with onset of rash on 30 April. The household is only 10 metres from a household where a severe case occurred on 13 April.

"The patient and his mother left Painathi on 29 March, 2 days before containment began. The mother was enumerated but the existence of a child was not made known. They returned on 14 April but their presence was concealed by the father. Searchers went daily to each house in the village to vaccinate and to inquire about fever and rash. Dr Khan and Dr Briedert personally visited this house to find out if all the vaccinations were successful and if this woman had returned. The father of the child, however, lied to them.

"The family had been resistant and uncooperative from the start. After enumeration, vaccination was possible only when we climbed over the compound walls and forcibly inoculated each family member. After a rumour reached Dr Khan, who had been staying in the village, he had to use a trick to gain entrance to the house. He asked for a glass of water and this was denied. He knew by custom that they had a case of smallpox inside the house because nothing can be given when a case of smallpox is in the house of a member of this religious sect.

"Dr Briedert is now staying *inside* the infected house. A room-by-room search has been done and will continue daily. All visitors have been traced—all had been previously vaccinated. The mother was vaccinated on 2 May. She has a primary scar and we can only hope that she will not develop into a case. We are nonetheless isolating her and keeping her under close observation for the next 14 days."

Plate 15.16. The search for smallpox cases intensified throughout 1975 as efforts were made to detect all cases of fever accompanied by rash. **A**: A village headman brings a child to smallpox eradication staff for confirmation of diagnosis. **B**: A search worker shows the WHO smallpox recognition card to children. **C**: Posters and writing on a wall advertise a reward of 100 rupees to anyone who detects a case of smallpox.

of December 1974 and with reasonable confidence that there were few undetected outbreaks, it appeared that the elimination of smallpox was at hand. However, from the experience of the past year in Bihar, it was clear that smallpox could spread rapidly in this densely populated area during the winter and early spring. Analysis of the experience in the autumn of 1974 showed that deficiencies in containment were primarily responsible for the failure to stop outbreaks. Vaccination of the population of affected villages was not as rapid as it might have been, visitors to the villages were often not vaccinated and some villages were declared free of smallpox without a thorough follow-up search. Although searches were conducted within a 5-mile (8-kilometre) radius of infected villages, some outbreaks traced to those villages were found to occur at distances of up to 16 kilometres.

At the end of December, new instructions were issued by the government entitled "Operation—Smallpox Zero". The following passages are extracts from the instructions:

"With the outbreaks so few in number, each outbreak must now be dealt with as an *absolute* emergency with maximum mobilization of staff and volunteers. As much concern should be directed to each outbreak as would be directed to control an outbreak in a non-endemic country such as in Europe. *Never* should a case occur more than 21 days after discovery of an outbreak.

"With the very small number of outbreaks present and with fully effective containment, smallpox transmission should be stopped in India in not more than 6–8 weeks. An all-India, all-out effort to achieve this objective will commence immediately and at all levels of the programme. These activities will be conducted under the code name 'Operation—Smallpox Zero' with the objective that no case of smallpox would occur after February.

"*PROCEDURES*

"1.0 A special Central command comprised of senior experienced Government and WHO staff will visit every new outbreak detected after 1 January and will revisit every outbreak in which a case is discovered more than 21 days after its discovery to ensure that every possible measure is being taken. These will supplement, not replace, other supervisory visits. To facilitate this, all new confirmed outbreaks must be reported immediately by cable to the State Programme Officer and to New Delhi. Any case occurring more than 21 days after discovery of an outbreak must similarly be reported by cable.

"2.0 Every outbreak must now be dealt with rapidly and with a massive containment effort. Instead of three or four workers, the containment teams should consist of *15 to 20 workers or more*, headed by the District Medical Officer of Health assisted by a national or WHO epidemiologist. In urban areas, this number may be several times greater. *Vaccination in an infected village/mohalla must be essentially completed within two or at most three days.* Three or four workers must camp in the village/mohalla until all scabs have separated from the last case. Two watchguard-vaccinators must be assigned to each infected house to maintain a 12-hour watch during the day while a second pair maintains a 12-hour watch at night. Watchguards will be responsible for (1) vaccinating all persons visiting the houses of smallpox patients; (2) identifying all household contacts who leave to go to other areas; (3) maintaining isolation of smallpox cases; and (4) maintaining an hour-by-hour log book record of activities and of movement of people in and out of the households. Food, necessary medicines and housing may be supplied to the family of an infected patient on a daily basis to ensure cooperation and isolation. Smallpox containment field books with complete enumeration of the village/mohalla must be completed on each outbreak.

A typical containment team might include:

1. 4 watchguard-vaccinators for each infected house
2. 8 vaccinators of which 4 should camp each night in the village
3. 2 motivation workers (village-level workers who know the village/mohalla and are respected by the villagers)
4. 1 supervisor and 2 vaccinators to trace household contacts who have gone to other areas
5. 3 supervisors
6. 1 containment team leader.

"3.0 House-to-house search will be made in a 10-mile [16-kilometre] radius around an outbreak as well as in high-risk areas which may be outside the 10-mile radius. In the urban areas the surrounding mohallas will be searched in a similar manner. This will be followed in two weeks by a second house-to-house search within a five-mile [8-kilometre] radius to find cases which might have been in the incubation period during the first search.

"4.0 In case of a death, the vaccinator will accompany the remains to be certain that the body is properly disposed of and that all garments are buried. All attending the funeral will be vaccinated, a register of participants and their addresses will be prepared and all villages from which they came placed under surveillance.

"5.0 After 1 January, a laboratory specimen from one or two cases in each new outbreak will be collected."

It was decided that the periodic routine search programmes would consist of house-

to-house visits, whereas previously searchers had checked only a sample of houses in each village. The reward for reporting a case was increased from 50 rupees to 100 rupees. Each suspected case—i.e., one with a rash and fever—was to be recorded in a "rumour register", which was established at every primary health centre. Each patient was to be visited immediately by the local health officer and the diagnosis confirmed by an epidemiologist. If the diagnosis was uncertain, it was to be considered smallpox and watchguards were to be posted. By experience, it was found that good performance on the part of watchguards could be ensured by the simple expedient of not paying them until they were relieved of duty. If, at any time, a watchguard was not found on duty, all 4 were dismissed without pay and new watchguards were recruited. Containment vaccination was to include all persons within a 1-mile (1.6-kilometre) radius of the outbreak. In all, this meant vaccinating some 4000–5000 people in rural areas and 80 000 in urban areas (Sharma & Grasset, 1975). Search throughout an area with a 10-mile (16-kilometre) radius, performed by locally recruited and trained staff, usually encompassed 300–600 villages. The costs of a typical containment operation in 1975 were estimated by Ježek to be about US$2700 (Table 15.30).

Investigations into the source of the outbreak were intensively pursued by national and international epidemiologists, but now, instead of notifying neighbouring states or districts of the existence of a suspected source, they themselves proceeded to the locality. This ensured that the sources would not be missed because of difficulties with telegraphic communication or confusion due to information being received from illiterate villagers and the consequent need to spell village names phonetically.

To guard against importations from Bangladesh, special surveillance teams were assigned and special searches conducted in Muslim Bengali areas and communities in India. Special attention was given to Calcutta, in which repeated night searches were made among the 48 000 street dwellers (Spring, 1975).

Table 15.30. India: estimated manpower employed and costs of a typical containment operation, 1975

		Rupees (Rs.)
1. Substantive staff		
Epidemiologist, 21 days at Rs. 100 per day		2 100
Junior medical officer, 42 days at Rs. 35–50 per day		1 764
Paramedical assistant, 42 days at Rs. 15–30 per day		924
Driver, 102 days at Rs. 10–15 per day		1 224
	Total:	6 012
2. Additional (temporary) staff		
Watchguards (assume 2 infected houses): 8 workers, 42 days at Rs. 5 per day		1 680
Search workers to search 10-mile radius (assume 500 villages), 300 search-days at Rs. 5 per day[a]		1 500
Search workers to do repeat search of 10-mile radius		1 500
Vaccinators to vaccinate the village population (assume 1000 population): 20 vaccinators, 5 days at Rs. 5 per day		500
Vaccinators to vaccinate population in a 1-mile radius: 20 vaccinators, 15 days at Rs. 5 per day		1 500
Supervision (at 1 supervisor to 5 worker–days)		
(a) for search of 10-mile radius, 60 supervisor–days at Rs. 10 per day		600
(b) for repeat search		600
(c) for watchguards, 1 supervisor, 42 days at Rs. 100 per day		420
(d) for vaccinators of village, 4 supervisors, 5 days at Rs. 40 per day		200
(e) for vaccination of population in a 1-mile radius, 4 supervisors, 15 days at Rs. 40 per day		600
	Total:	9 100
3. Petrol		
Usually, each new outbreak was attended by several teams of jeeps for various periods of time. The jeeps were used for supervision, search assessment and follow-up.		
Week 1: 4 jeeps or 28 jeep–days		
Weeks 2–3: 3 jeeps or 42 jeep–days		
Weeks 4–5: 2 jeeps or 28 jeep–days		
Week 6: 1 jeep or 7 jeep–days		
105 jeep–days	Total:	9 450
	Total cost:	24 562 (US$2 730)

[a] Based on petrol costs averaging Rs. 90 per day.

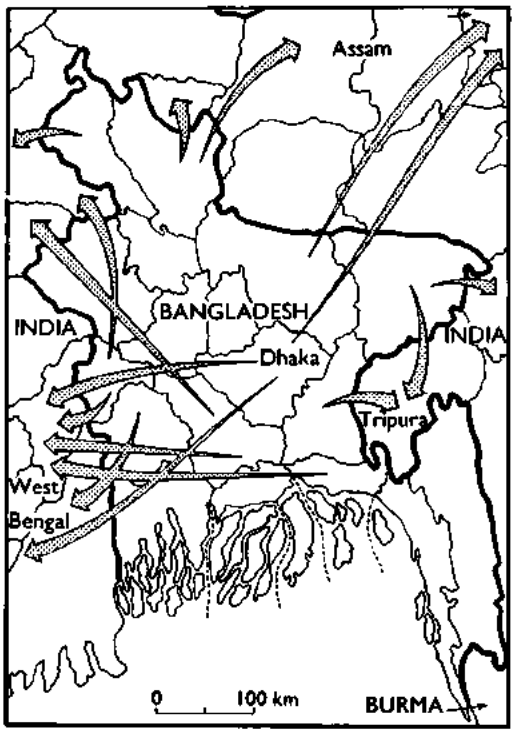

Fig. 15.25. Importations of smallpox from Bangladesh to India, 1975.

"Operation—Smallpox Zero", begun in January 1975, proved to be most successful. From November to December 1974, the number of pending outbreaks had decreased from 343 to 285 (17%); in January, to 194 (32%); and in February, to 113 (42%). As had been feared, cases were imported from Bangladesh, 30 importations being detected in West Bengal, Assam and Tripura (Fig. 15.25). Two-thirds were detected within 2 weeks of the onset of illness in the first case and only 8 additional outbreaks occurred as a result of further spread.

In all, only 308 outbreaks and 1436 cases were detected in India after 1 January 1975 (Tables 15.31 and 15.32). All were in the eastern part of India except for 10 in the far western Kutch desert of Gujarat, introduced by migrants probably infected in Bihar.

In April, 115 000 health workers undertook a week-long, house-to-house search throughout the whole of India. Independent assessment of some 5% of villages showed that 85%–96% of all villages in the various states had been searched. Among 574 517 persons interviewed, 61% knew about the reward for reporting a case and knew the amount of the reward. Only a few

[a] Outbreaks were reported immediately by telegraph or telephone; case reports (Table 15.31) were submitted through routine notification channels and were somewhat delayed in receipt.

outbreaks were found, all of which had resulted from importations. Smallpox had been virtually eliminated during the season of most rapid transmission. In May, the last cases and outbreaks in India were discovered.

The Last Case in India, May 1975

As in many other countries, so in India the last case presented some unusual features (Ježek et al., 1978a). Saiban Bibi, a 30-year-old homeless Bangladeshi beggar, developed a rash while living on the Karimganj railway station platform in Assam, where she was begging for food. She had contracted smallpox from a patient in Sylhet District, Bangladesh. On 26 May, she went to the Civil Hospital in Karimganj, which forthwith notified the District Health Officer. Accompanied by a WHO epidemiologist and the state surveillance team, he immediately went to investigate.

The situation was alarming. For the first 4 days of illness, the patient had lived on the platform of the railway station, the gateway to the states of Assam and Tripura and the union territory of Mizoram. Between 22 and 26 May, 9 trains had stopped at the station and 4535 railway tickets had been issued to 68 different towns and cities. A programme was immediately launched to search and vaccinate in the city wards in which the railway station and the Civil Hospital were situated. Later, containment activities extended to the whole town, as well as to all villages visited by the patient since 21 May. Railway authorities were instructed to intensify surveillance activities in and around the railway stations and railway colonies. All district health authorities in Assam and neighbouring states through which the railway passed were asked to initiate intensive searches during the subsequent 14 days. Special searches were conducted in all villages within 10 miles (16 kilometres) of the district border with Bangladesh.

The patient was isolated and 4 watchguards were stationed in the isolation ward for round-the-clock duty. All patients, visitors and hospital staff, together with their relatives, were enumerated and vaccinated. The hospital was closed to visitors and the discharge of patients was stopped. One watchguard was placed at the railway station to carry out surveillance and vaccination.

Three border checkposts were established and all incoming and outgoing travellers were checked and vaccinated. All border security forces and police outposts were alerted to look for possible cases.

Surprisingly, despite the time of year and the many persons who had been in contact with the patient, no further cases were found.

India Celebrates Independence Day and Freedom from Smallpox, August 1975

Six weeks passed after the onset of illness in the last patient and the last outbreak was deleted from the list of pending outbreaks. On 1 July, the reward for reporting a case was increased to 1000 rupees (US$125), the equivalent of 4 months' salary for an Indian labourer. This was done with some trepidation, since it was feared that unscrupulous persons might smuggle smallpox cases from Bangladesh to claim the reward. Indeed, on one occasion this did happen, but the ruse was readily detected. With a reward of this magnitude, thousands of patients with rash and fever were reported to the health authorities. Each was investigated; none proved to have smallpox.

On 15 August 1975—India's Independence Day—the government held a special celebration honouring India's freedom from smallpox, which was attended by the Director-General of WHO.

Less than 3 months had elapsed since the onset of the last case, and with smallpox still present in Bangladesh the staff were understandably apprehensive that at the last moment another focus might be found. The search continued, but an unexpected event of quite another type occurred. On the night of 15 August, the President of Bangladesh was assassinated. The government closed the airports and sealed the borders—to the extent that this was possible. It was feared that there might be yet another mass exodus of refugees.

An emergency surveillance programme was immediately put into operation, focusing on Bengali-speaking areas. Possible migration routes were identified, dozens of surveillance posts were set up at border crossings, special searches were conducted in designated high-risk areas and surveillance was intensified in Calcutta. Happily, the refugees were few and no further importations occurred.

On 16 October 1975, the last case of smallpox occurred in Bangladesh and the 2-year search began to confirm eradication throughout Asia.

Why the Smallpox Eradication Programme Succeeded

Two papers have been published by members of the smallpox eradication staff which comment on distinctive features of the smallpox eradication programme in India that were crucial to its success. Extracts are given below:

"The strategy used and the manpower and other resources provided ... greatly contributed to the rapid success of the programme; but without the passion given to the planning and implementation of the programme by the workers, achievement would not have been possible. Jawahar Lal Nehru once said 'Planning would be meaningless unless behind the plan there was a passion—passion with a tinge of anger at delays, anger at anybody not doing his part, anger at not achieving where achievement is possible'. The national and WHO staff have fought with passion the battle against smallpox... Hundreds of men and women—nationals and internationals—have worked up to 18 hours a day for seven days a week in the belief of an ideal which they have put above their personal happiness, their family life, their career and their health. The central level staff both of the WHO and the Government of India have spent on an average three weeks a month working in the field throughout the country to train, motivate, encourage the local staff. During the 1974 summer epidemic of smallpox in Bihar and [Uttar Pradesh], a number of WHO, central and state officers were publicly laughed at for having predicted that their states and the country would be free of smallpox in less than a year... Men and women from different states in India and from many countries of the world put aside their racial, national, religious or social prejudices and bore together all the difficulties and hazards. Many took risks in putting aside conservative regulations, red tape and antiquated technical methodologies, when these threatened to delay their task or obstruct the path to success. The toughest of men and women on many occasions were on the verge of discouragement—from physical tiredness and mental frustration, when having to cope with hundreds of infected villages in their area of responsibility. They persevered, waiting days, weeks, sometimes months, until it was possible to send them more men, better vehicles, funds for petrol, etc. In the smallpox offices in New Delhi and also in the state, district and block headquarters, medical officers, administrators and secretarial staff worked most of the days far into the night, over the weekends and public holidays so as to make sure that those in the field received the necessary support. However, even during the most difficult stages of the programme, men and women in the field and offices discovered like Rabindra Nath Tagore that they 'acted and behold duty was joy'." (Sharma & Grasset, 1975.)

"The decentralisation of authority to implement the strategy to the district health authorities and epidemiologists who were responsible for proper utilisation of available resources resulted in the early detection and effective containment of large numbers of disease foci in the shortest possible time and the consequent quick interruption of transmission. If one considers that ... India ... [was] spending over 40 million rupees a year for the past ten years on NSEP and [that an] additional amount of about Rs. 20 million each [year was being spent by WHO] during the campaign years 1973–74 and 1974–75... it becomes apparent that it has not been the quantum of money spent but the manner of doing it which made all the difference between success and failure. Relative freedom at district levels to take on-the-spot decisions to spend this additional amount... greatly contributed to the realisation of smallpox free status. Administrative and operational restraints in implementing the strategy were also minimal.

"All the national health programmes have built-in evaluation methods. The interval between occurrence of a defect/problem and its detection and the interval between the detection and correction has always been considerable... In this smallpox campaign the continuous monitoring of the smallpox status, feedback from the field staff and the authority for taking on-the-spot decisions regarding fiscal, administrative and technical matters have narrowed down the unknown and the unsolved problems to the minimum." (Dutta et al., 1975.)

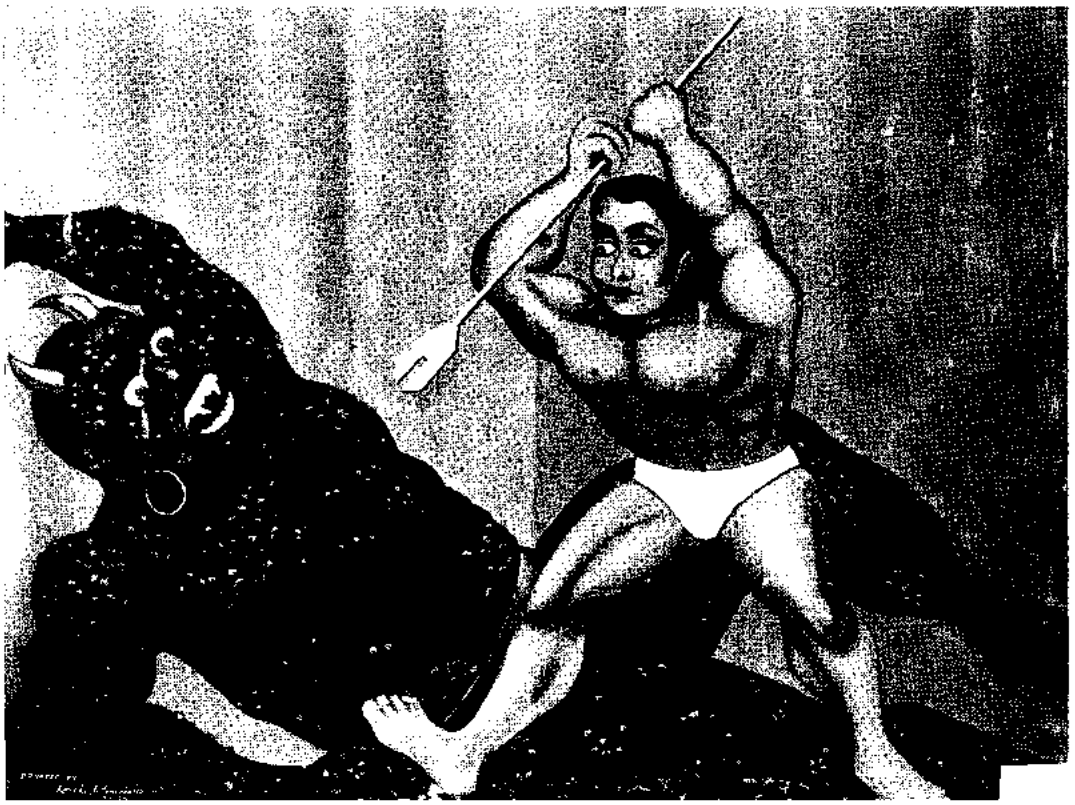

Plate 15.17. A wall-sized poster, in the style of a cinema advertisement, depicts a hero slaying the smallpox demon with a bifurcated needle. This poster, also used in smaller sizes, was displayed widely in India to promote the reward for reporting a case of smallpox.

Morbidity and Mortality Data

Information regarding the age, sex, vaccination status and survival or death of the patient was obtained for all cases in India. However, data were tabulated nationally for only a proportion of the total for the years 1974–1975 (Basu et al., 1979). These data were obtained from 4 high-incidence states and 13 low-incidence states and union territories, although most of the cases were from the former group. The age distribution of cases and case-fatality rates were similar to those observed elsewhere in the Asian subcontinent (Table 15.33).

Data are available for 23 546 of the 189 439 cases which occurred in 1974–1975. In all, 31% occurred in individuals less than 5 years of age, 40% in those aged 5–14 years, and 29% in those aged 15 years and over. The disease was equally prevalent among males and females.

A similar distribution of cases by age and sex was observed in all states with a high incidence. Imported cases in smallpox-free states, however, occurred predominantly in males (64.6%) in the older age groups, 18.7% being in men aged 50 years and over. This was attributed to the occurrence of many cases among migrant labourers and pilgrims, a much larger proportion of whom were adult males.

Data regarding the vaccination status of 14 463 cases from the same 17 states and union territories reveal that two-thirds of the persons concerned were unvaccinated (Table 15.34). Patients were classified as "unvaccinated" if they had no vaccination scar (regardless of whether they claimed to have been vaccinated) or if they had been vaccinated during the incubation period of the disease, too late to prevent infection.

The proportion of cases among individuals with an apparent vaccination scar was markedly higher than in other countries. This is explained by the frequent occurrence of vaccination-like scars associated with the use of rotary lancets in which secondary bacterial

infections occurred but vaccinia virus did not grow. Most of the cases among "vaccinated" children under 5 years of age occurred in Bihar and Madhya Pradesh, in which, as late as 1973, rotary lancets were still being used in some areas, especially the large municipalities. In Andhra Pradesh, in which the use of rotary lancets was abandoned in 1969, only 15.4% of cases occurred among those with what appeared to be a vaccination scar.

Case-fatality rates in India varied from 21% to 31% during 1950–1967 but for most years they were in the range of 25–30%. During the course of the eradication programme, the case-fatality rate dropped steadily, from 31.2% in 1967 to 16.6% in 1974 and to 12.3% in 1975 (Fig. 15.26). The decline is accounted for by an increasing completeness of the notification of cases. Initially, most cases and deaths were reported from infectious disease hospitals, to which the more seriously ill were taken and which recorded high case-fatality rates. As time progressed, differences between case-fatality rates in the various states narrowed considerably. Moreover, a much higher proportion of cases in otherwise smallpox-free areas was found among older children and adults, who experienced a lower case-fatality rate than did young children. Data for 23 546 cases that occurred in 1974–1975 show an overall case-fatality rate of 17.4%, but among infants under 1 year of age the rate was 43.5% whereas it was only 6.5% among the 15–19-year-olds. Although wide variations in case-fatality rates were observed in different epidemics, these variations were considered to be due to differences in the age distribution of the cases, the nutritional status of patients, and the history of previous vaccination.

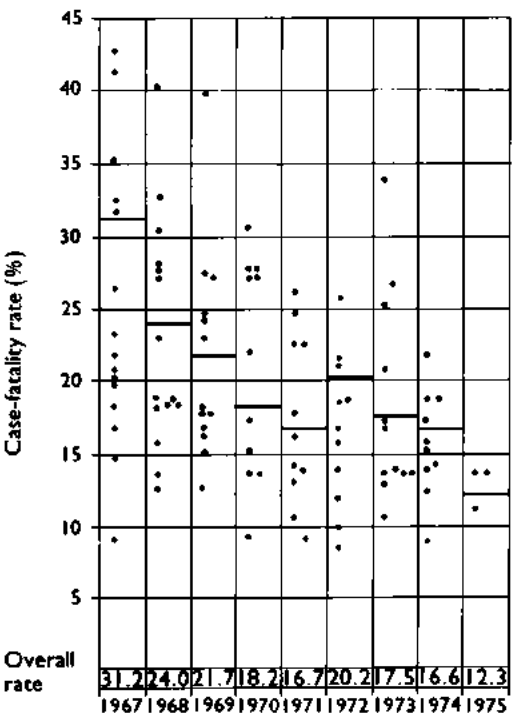

Fig. 15.26. Case-fatality rates for India and the states of Andhra Pradesh, Assam, Bihar, Gujarat, Haryana, Jammu and Kashmir, Karnataka, Madhya Pradesh, Maharashtra, Orissa, Punjab, Rajasthan, Tamil Nadu, Tripura, Uttar Pradesh and West Bengal, by year, 1967–1975. Each dot represents the case-fatality rate in a state in a year. For each year rates are plotted only for the states that recorded at least 100 cases that year. The bold lines denote the overall rate for India in the year shown.

NEPAL

Introduction

Epidemiologically, Nepal was a mountainous extension of the Indian states of Bihar and central and eastern Uttar Pradesh, but its programme differed significantly from that in India. Of the country's 10.8 million population (in 1967), 37% lived in the Terai, a northern strip of the broad Ganges river plain (see Fig. 15.1), which in Nepal was about 25–35 kilometres wide; another 53% lived in the adjacent Middle Hills area, which ranged from 30 to 50 kilometres in width. Most of Nepal's population thus lived within some 80 kilometres of the border with India and the majority were Hindu. Many had relatives in adjacent areas of India, and travellers and migrant labourers moved freely across the border. Roads were few, communications were difficult and the health services and other governmental structures were in an early phase of development.

In 1962, a WHO nurse working in Nepal assisted in the development of a pilot mass vaccination campaign in the Kathmandu valley, comprising 3 of Nepal's 75 districts with a population of 500 000. In 1968, the campaign was extended to other districts and by 1973 it included the entire country. Little was done to develop a reporting system until 1971. Data prior to this time represent only a partial enumeration of cases in the Kathmandu valley.

Strategically, the programme in Nepal was initially not of high priority in the global strategy because eradication there depended on the progress of the campaign in India, particularly in Bihar and Uttar Pradesh. Moreover, the mainly mountainous terrain, the predominantly rural population and the poor communications between villages in Nepal suggested that smallpox transmission could not be long sustained in most of the country. Since the population of the Terai was only about 4 million—the equivalent of 2 districts of India—it was expected that the interruption of transmission in that area and in the country as a whole would not constitute a major problem once smallpox had been controlled in India.

Because the health structure in Nepal was rudimentary and vaccine was available to only a small proportion of the population, additional WHO support was provided from 1968. The eradication programme was intended to make vaccination more widely available initially in the most populous areas along the border with India. Three years later, a plan was implemented to extend reporting and surveillance–containment measures progressively throughout the 75 districts. Progress in achieving these goals was remarkably rapid: by 1972 each outbreak was being investigated and contained and its source identified. Continuing transmission was, in fact, largely stopped in that year. Epidemic smallpox in the neighbouring Indian states of Bihar and Uttar Pradesh, however, resulted in an additional 239 outbreaks in 1972 and 1921 cases during the period 1973–1975. Most of these outbreaks could be traced directly or indirectly to importations and although they sometimes remained undetected for many weeks and were not always well contained, smallpox did not usually spread widely. On 6 April 1975, the last known case of smallpox occurred in Nepal as a consequence of an outbreak resulting from an importation from Bihar.

The Country: Geographical and Sociocultural Considerations

Until 1951 Nepal, ruled by hereditary prime ministers, had been closed to the outside world, and no organized health services or educational facilities existed. When a constitutional monarchy was instituted in 1951, Nepal began the arduous task of building a transport, communication, health and educational infrastructure. Because of the mountainous nature of the country and the dearth of human and natural resources, progress was slow. Throughout the 1970s, Nepal remained one of the world's least developed countries.

Administratively, the country was divided into 14 zones, which were subdivided into 75 districts; the population of a district ranged from 7000 to 350 000, a far smaller figure than that for a district in India. The smallest administrative unit was the panchayat, of which there were some 4000.

Until the 1960s smallpox had occurred widely throughout Nepal. According to a health survey conducted in 1965–1966, 24% of people over 30 years of age in the capital city of Kathmandu bore the facial pockmarks of smallpox, as did 13% of those aged 10–29 years and 6% of children under 10 (WHO/SE/78.107, Shrestha). Variolation

was known to have been widely practised until recent years and many older persons bore the resulting scars. However, unlike the situation in Afghanistan (see Chapter 14), the practice had died out in Nepal by the time the Intensified Smallpox Eradication Programme began. No cases attributable to variolation were discovered during the course of the programme.

As in India, smallpox epidemics were reported to have occurred approximately every 5 years, the last having happened in 1958 (WHO/SE/78.107, Shrestha). However, up to 1963, there was no reporting system; indeed, until 1971 few reports were received from anywhere except the small districts comprising the Kathmandu valley, the site of the capital city. Some Nepalese, especially those living in the Terai, had been vaccinated in India, as had some living near Kathmandu or in the vicinity of the few health units that had vaccine. Otherwise, vaccination was little practised in Nepal.

Socio-economic and demographic factors played unusually important roles in the development of the programme and in the pattern of occurrence of the disease. Geographically, the country consisted of three horizontal belts (Fig. 15.27) extending across the country: the flat Terai of the Ganges river plain, with a population density ranging from 750 per square kilometre in the east to fewer than 100 per square kilometre in the less fertile west (Fig. 15.28); the Middle Hills area, with a terrain rising as high as 3000 metres and containing a few broad populous valleys including the Kathmandu valley, which had a population density of almost 1000 per square kilometre and about 5% of the country's inhabitants; and the Himalayan mountains, comprising 30% of the land surface but containing only 5% of the population. Very few people crossed the Nepal–China border, but travel across the Nepal–India border was unimpeded and frequent.

With only 680 kilometres of paved roads and 2 short railway lines (Fig. 15.27), there was little easy communication between the different areas of Nepal, although a network of footpaths connected the 29 000 villages and market centres in which 95% of the population resided. Kathmandu (population in 1971, 150 000) and Biratnagar (population, 45 000) were the only significant urban centres. On the other hand, contacts between the Terai and Kathmandu and India were numerous and were facilitated by the few motorable roads between the two countries.

The Nepalese of the Terai are Hindu and ethnically similar to their Indian neighbours. Many resisted vaccination for religious reasons; temples to Sītalā mata, the goddess of smallpox, were to be found throughout the

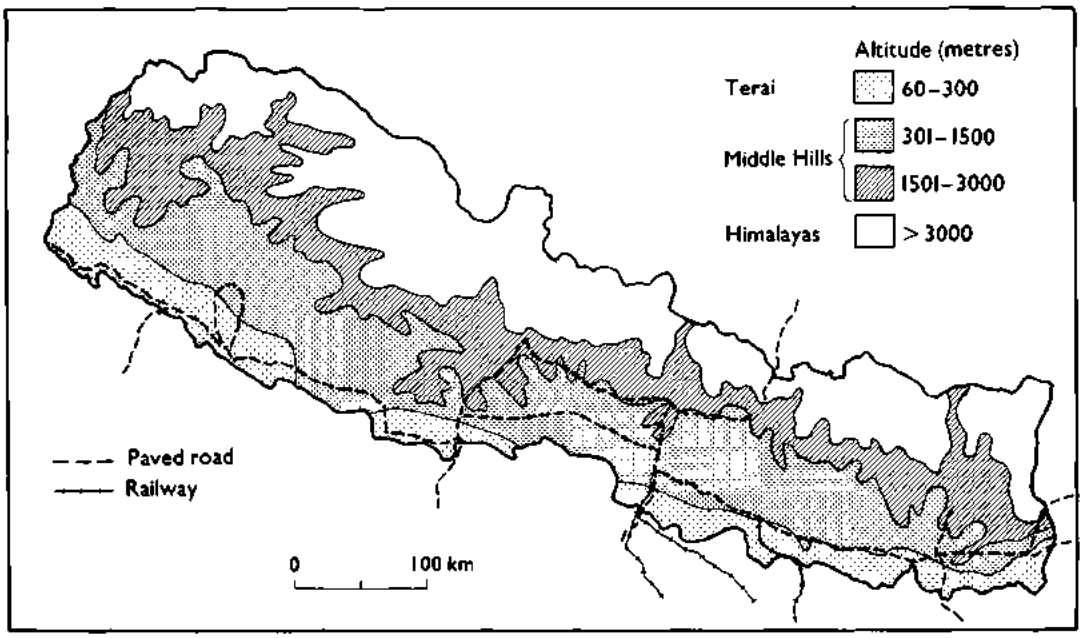

Fig. 15.27. Nepal: physical topography, showing paved roads and railways.

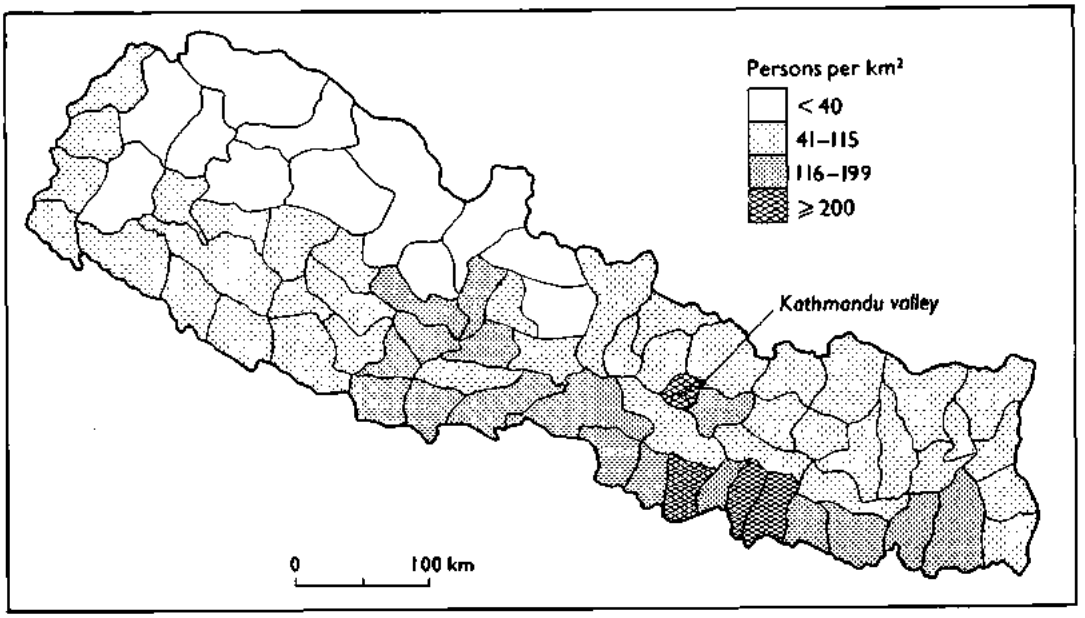

Fig. 15.28. Nepal: population density, by district.

region. The relatively rich agricultural and industrial area of the eastern Terai attracted numerous Bihari and Bengali seasonal migrants, who formed a sizeable proportion of the labour force. Travel to and from the less prosperous western Terai was limited primarily to family visits, and few travelled long distances. Those living in the Middle Hills were predominantly Hindu, but with the exception of some segments of the Newar ethnic group in the Kathmandu valley most people readily accepted vaccination. Travel to and from the Middle Hills was less frequent than within the Terai, although many moved to the Terai and to India for the winter months. Numerous inhabitants of the Eastern Hills worked on tea estates and as forest labourers in the Indian state of Assam and those in the Western Hills travelled to western Uttar Pradesh and cities of western India for work and trade. In the sparsely populated Himalayas, villages were isolated. To reach most districts from the endemic areas of India required a trek of more than 14 days—longer than the incubation period of smallpox. Because of these factors, smallpox proved to be primarily a problem of the Terai, only 4 outbreaks ever being detected in the extensive northern mountainous areas (SME/77.1, Shrestha et al.).

A Smallpox Control Pilot Project Begins, 1962

A smallpox control pilot project was initiated in 1962 in the 3 districts comprising the Kathmandu valley, which had a population of about 500 000 at that time (WHO/SE/69.10, Singh). With assistance provided by a WHO nurse already employed in another project in Nepal, a house-to-house mass vaccination campaign was begun, utiliz-

ing the multiple pressure method of vaccination and freeze-dried vaccine provided by WHO. As in India, all records were maintained in family registers in which the names of all residents of households were laboriously compiled, revised and updated. The programme was poorly funded, poorly supervised and poorly executed and with the additional impediment of resistance to vaccination progress was slow. A sample survey carried out late in 1964, 2½ years after the programme began, revealed that only 31% of the population had vaccination scars. In 1963, for the first time Nepal began to report cases of smallpox to WHO, but virtually all of them had occurred within the city of Kathmandu. In 1966, a WHO medical officer was assigned to assist the programme, but no effort was made to develop a national reporting system, and until 1968 the programme remained what it had been—an ineffective vaccination campaign confined to the Kathmandu valley. Repeat surveys in May 1967, conducted among various population groups in that area, showed that only 40–65% of the people examined had vaccination scars or the pockmarks of smallpox (WHO/SE/69.10, Singh).

The Programme Extends Beyond the Kathmandu Valley, 1968

In 1967 the government and WHO agreed on a phased plan to extend the programme zone by zone throughout the country. This commenced the following year with the hope that the last of the zones would be included in the programme by 1972. Additional resources were made available by the government, and WHO provided support in the form of personnel, vehicles and equipment and also covered the cost of petrol (Table 15.35). Staff were recruited, trained and assigned to district offices to serve as "senior vaccinators". During the first 3 months of a new vaccination campaign in a district, temporary vaccinators were hired to vaccinate widely throughout the district. Subsequent vaccination and surveillance were then the responsibility of the senior vaccinator. The family registers were abandoned and multiple puncture vaccination with bifurcated needles was introduced.

The number of districts covered by the programme grew from 3 in 1967 to 15 in 1968 and to 41 by the end of 1970. The number of vaccinations performed increased 10-fold, from 201 000 in 1965–1966 to 2 196 000 in 1968–1969 and to 2 823 000 in 1970–1971 (Table 15.36).

Community leaders and such health staff as were available were contacted and requested to report cases, but the numbers of cases notified remained few: 110 cases were reported in 1967, 249 in 1968, 163 in 1969 and 76 in 1970 (Table 15.37). Although reporting was very incomplete, it is probable that the true incidence in Nepal during these years was not high because the corresponding

incidence in the neighbouring Indian states of Bihar and Uttar Pradesh was low.

The Programme Strategy Changes, 1971

Early in 1971, a new strategy, unique to Nepal, was adopted and effectively executed by an energetic Nepalese programme director, Dr P. N. Shrestha, and an experienced WHO smallpox adviser, Dr M. Sathianathan, from Sri Lanka, assisted by 2 United States technical officers—veterans of the western Africa programme—Mr Jay Friedman and Mr David Bassett. It was decided to extend the programme as soon as possible to cover the entire country. Forty-five Nepalese district supervisors were recruited and assigned to most districts in the Terai and Middle Hills, and assistant supervisors or senior vaccinators were sent to the other 30 districts, where each worked under the direction of one of the district supervisors. A senior supervisor was responsible for managing the programme in each of Nepal's 14 zones. In 6 districts, responsibility for smallpox eradication was assigned to a newly planned integrated health services project office (Fig. 15.29).

WHO and Nepalese staff decided that the vaccination campaign would be conducted during a single month in the winter of each year, and for this purpose temporary vaccinators (1 for each panchayat, comprising about 3000 persons) were recruited and trained during a 3-day training session. Simple tally sheets replaced the more elaborate record forms. During the remaining 11 months of the year, the assigned permanent smallpox eradication staff, numbering in all

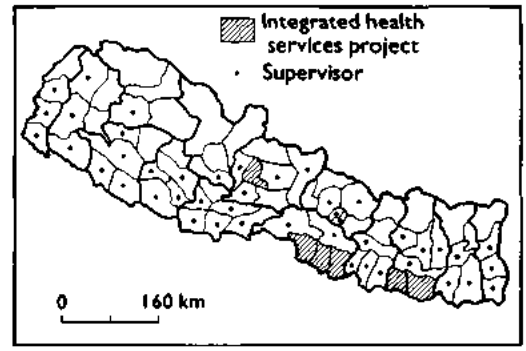

Fig. 15.29. Nepal: administrative divisions and location of district supervisors, 1971.

about 600 persons, travelled from village to village throughout the districts seeking information about smallpox from local leaders, schoolteachers and the personnel of health units. When cases were discovered, the staff were responsible for containment. Four central containment teams were formed to assist in this effort but were soon disbanded, since it proved impossible for them to reach the site of an outbreak before several days—or even weeks—had elapsed because of problems of communication and travel.

Despite the fact that mass vaccination was conducted during the course of a single month each year, the number of reported vaccinations increased to more than 6 million in 1971–1972—a number equivalent to 50% or more of the population—and continued at this level over the next 5 years. Surveys of vaccinial immunity, conducted in 1975 in many of the more accessible areas, revealed that in most of these areas more than 95% of the population bore vaccination scars.

Reporting improved as the programme extended its operations; by early 1973 weekly telegraphic reports were being received from each district regardless of whether any cases had occurred.

Because of the difficulties of travel, responsible district supervisors proved to be the vital element in the programme. They were brought to Kathmandu annually for refresher training and were visited as often as possible in the field by Nepalese and WHO staff, who, beginning in 1972, undertook to visit the site of each outbreak to assess the efficacy of the containment measures. To facilitate travel to the most remote districts, arrangements were made by WHO to permit the charter of a helicopter; it was used on perhaps a dozen occasions during the subsequent 3 years.

Plate 15.19. **A**: Purushollam N. Shrestha (b. 1939), the director of the smallpox eradication programme in Nepal from 1971. **B**: Jay S. Friedman (b. 1940), a WHO technical officer, being presented with a certificate of appreciation by the Prime Minister of Nepal, Tulsi Giri.

In 1972, the programme was extended to include all districts in the Terai and Middle Hills—the districts of greatest concern. Because of the isolation of the villages, most outbreaks were readily contained, and by the end of June 1972, transmission appeared to have been interrupted. During the last 6 months of the year, only 5 outbreaks, with 34 cases, were discovered (WHO/SE/74.71, Shrestha et al.); 4 resulted from importations from Uttar Pradesh and 1 from Bangladesh, whose north-western border with India was less than 50 kilometres—merely a day's journey—from Nepal.

However, as epidemic smallpox swept across Uttar Pradesh and Bihar in 1973, increasing numbers of cases began to be imported into Nepal (Fig. 15.30). In all, 43 outbreaks and 277 cases were reported that year, of which 35 outbreaks resulted from importations from India. Twenty-eight more cases occurred in these outbreaks that were not officially notified until 1974. Most of the imported cases had been infected in bordering districts of Uttar Pradesh and Bihar. The sources of the outbreaks included 12 districts in Uttar Pradesh and 9 in Bihar. One infected traveller came from the state of Maharashtra, although he was probably infected while travelling through Uttar Pradesh. All but 4 of the importations occurred in districts bordering on India.

Smallpox did not spread extensively, however. From the 35 importations, secondary spread to other villages occurred on only 7 occasions, one of these villages being the source of a further outbreak. The number of cases in each outbreak ranged from 1 to 38 with a mean of 8.3 cases, of which almost one-third (13 out of 43) were single-case outbreaks (Table 15.38).

In November and December 1973, the number of importations began to increase

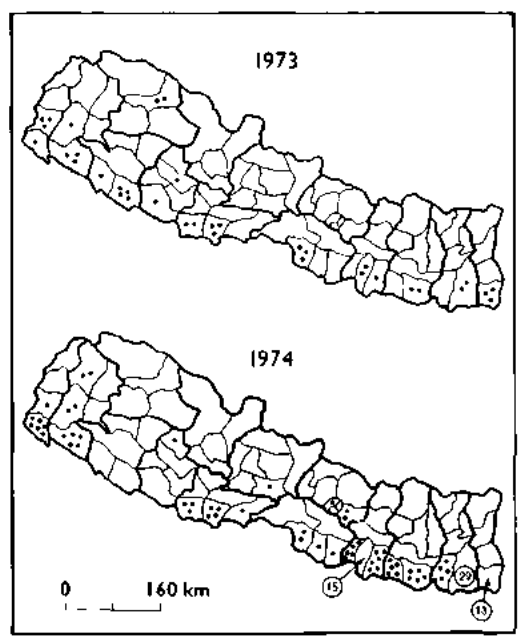

Fig. 15.30. Nepal: importations of smallpox, 1973 and 1974. Each dot denotes one outbreak.

Table 15.38. Nepal: number of outbreaks of smallpox, by number of cases in each outbreak, 1973–1975

Year	Total number of outbreaks	Number of cases in each outbreak					
		1	2–4	5–8	9–15	16–20	≥21
1973	43	13	8	7	5	4	6
1974	180	42	54	27	24	15	18
1975	16	7	4	2	0	1	2
Total	239[a]	63	65	36	29	21	25

[a] Data for 28 outbreaks not available.

and in January 1974, 14 importations were detected, of which 8 were from Bihar and 6 from Uttar Pradesh (Fig. 15.31). The number rapidly increased during May and then abruptly diminished, which was consistent with the seasonal decline in smallpox. In all, 180 outbreaks and 1549 cases occurred, of which 115 outbreaks were due to importations. As was the case in 1973, most of them (106 out of 115) occurred in districts bordering on India, the eastern districts of the Terai being the most heavily infected. In contrast to 1973, when the sources of infection were widely dispersed geographically, 68% of all importations during 1974 came from 5 heavily infected districts in Bihar. These districts, besides being among the most heavily infected in India, experienced severe food shortages in the spring of 1974 and, in consequence, many people migrated to Nepal.

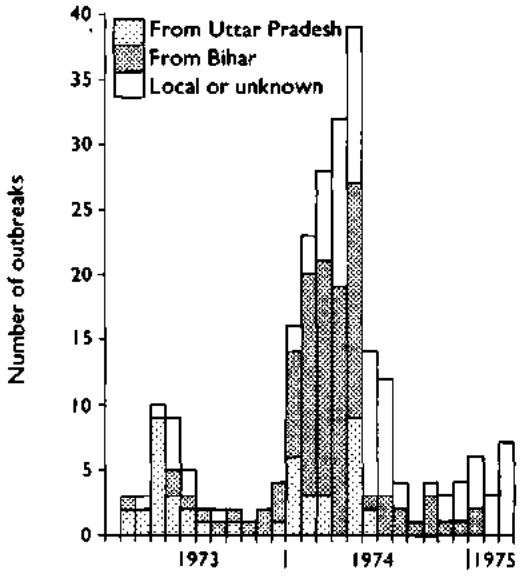

Fig. 15.31. Nepal: number of outbreaks of smallpox, by source, by month, 1973–1975.

In early 1974, WHO arranged for the prompt, reciprocal cross-notification by telegram between India and Nepal of possible sources of infection in each country. Programme staff agreed to investigate every report of this kind and to confirm whether an outbreak had been found. Nepalese staff fulfilled this responsibility well and detected a number of outbreaks not previously known. In India, especially in Bihar, the system operated far less well: with numerous outbreaks and a poorly organized health system, many reports were ignored (WHO/SE/74.71, Shrestha et al.).

The increase in the number of outbreaks in Nepal taxed the resources for surveillance and containment, and a greater number of outbreaks began to result from local spread. Nineteen out of 57 such outbreaks (167 cases) occurred between February and September following 2 importations into the Kathmandu valley. Most were in the Newar ethnic group, who had resisted vaccination for religious reasons, and among whom it was a common practice for the relatives and friends to visit those who were ill with smallpox. Detection was also difficult because families did not report cases and sometimes hid the patients from health officials. Smallpox could therefore spread widely and containment was difficult.

A second problem area was in the western Terai, in which another ethnic group who also resisted vaccination had the custom of granting any wish to a child with smallpox in the belief that the child was possessed by the goddess of smallpox, Sītalā mata. The child's wish was frequently to be taken to see relatives or friends in other villages. In this area, smallpox spread unusually rapidly among groups of villages (SME/77.1, Shrestha et al.).

A third area which proved difficult was a south-eastern district, Morang, which experienced 29 importations in 1974 and 1 in 1975. It was the centre of jute production in the eastern Terai and contained the industrial town of Biratnagar. Numerous migrant labourers from India were attracted to the area and, in the autumn of 1974, because of food shortages in Bihar, many beggars from India arrived there. Quite a few of the migrant labourers and most of the beggars belonged to a tribal group which worshipped Sītalā mata and resisted vaccination (SME/77.1, Shrestha et al.). The last chains of transmission began in December 1974 and

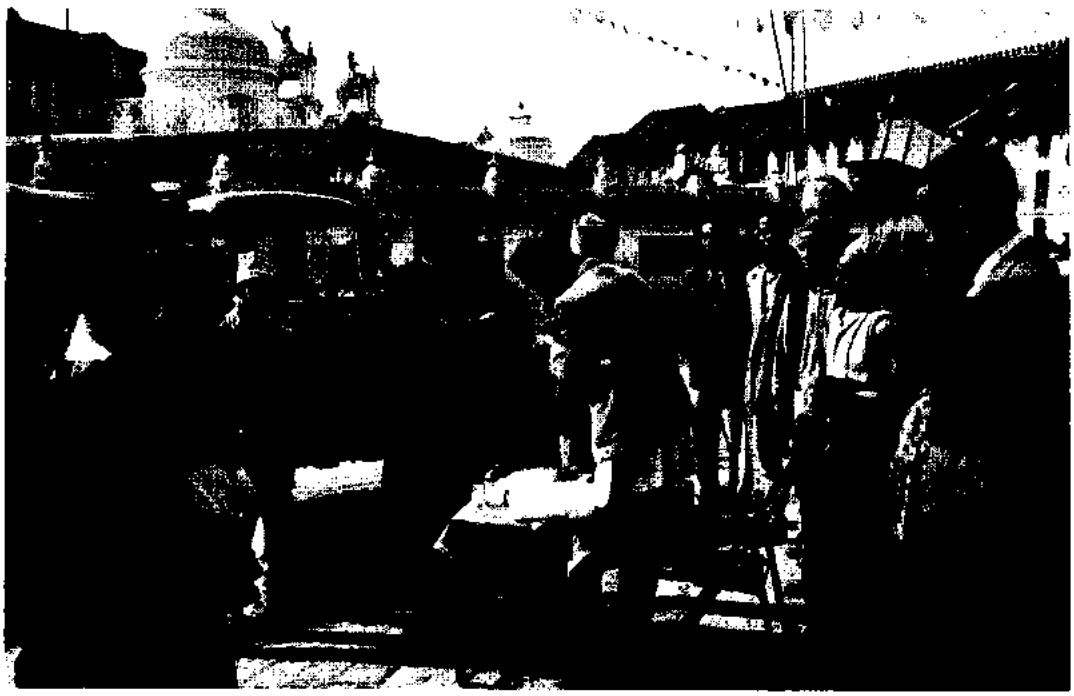

Plate 15.20. Tibetan pilgrims being vaccinated in front of a Buddhist temple at Bodnath in the Kathmandu valley, Nepal.

January 1975, when 21 cases, primarily among beggars, occurred in a large market area, and from there smallpox spread to 6 nearby villages. More vigorous containment efforts were required; thus, in January, watchguards were posted at each infected house, as was done in India. In addition, systematic search and vaccination programmes were conducted over wide areas encircling the site of an outbreak. The system had been in use in many states of India for more than a year but in Nepal, in which the population was sparse, the containment of outbreaks had been less of a problem and, with fewer personnel, it had been impossible up to this time to adopt the Indian methods of containment. With the numbers of outbreaks diminishing both in India and in Nepal, a more elaborate scheme was possible. Resistance to vaccination was usually overcome with verbal persuasion although, on occasion, police accompanied the vaccinators to lend their authority. The number of outbreaks declined rapidly, and on 6 April 1975 the last cases occurred in Nepal.

Data regarding the age distribution of cases are available for 1286 of the 1921 cases which occurred in the period 1973 1975 (Table 15.39). Smallpox in Nepal occurred more frequently among older children and adults than in India. Less than one-third of all cases were in children under the age of 5 years and 29% were in persons over 15 years of age. The fact that more cases tended to occur in the older age groups in Nepal than in India probably reflected lower levels of vaccinial immunity throughout the population as well as a lower level of naturally acquired immunity due to the relative isolation of villages. Although villages in Afghanistan were comparable in their degree of isolation, vario-

lation had been extensively practised there and many persons were immune as a result. In Nepal, however, the procedure had been largely discarded in recent decades.

Only 40 out of 1915 patients (2.1%) for whom data are available had been vaccinated before exposure—a far lower proportion than that reported from India. Several factors could account for this. In India, in which rotary lancets had long been in use, many apparent vaccination scars resulted from sepsis rather than successful vaccination. In Nepal, few had been vaccinated with the rotary lancet. Moreover, in the vast majority of instances the vaccination had been performed after 1967 so that vaccinial immunity was likely to be at a higher level.

The case-fatality rate was 21.5% (411 deaths among 1915 patients), a figure consistent with observations elsewhere in the Asian subcontinent.

At the time that the last case occurred, a reward of 100 rupees (US$9.50) was being offered to anyone reporting a case, and later this sum was increased to 1000 rupees. After 6 April 1975, however, no reported case was

confirmed and no further cases were detected in subsequent laborious house-to-house searches.

Cost of the Programme

The total outlay on smallpox eradication by the government of Nepal and by WHO during 1962–1976 amounted to US$2 378 982, or just over US$0.15 per head of population. For the period 1972–1976, approximately 2% of the Ministry's health budget was spent on the programme. The expenditure, however, was low compared with the cost of other programmes such as that for malaria control, on which, in the year 1976–1977 alone, Nepal spent more than US$4.5 million (SME/77.1, Shrestha et al.).

SIKKIM AND BHUTAN

East of Nepal in the Himalayan mountains lay 2 small sparsely settled political entities—Bhutan and Sikkim (Fig. 15.32). Bhutan, an independent monarchy, had an estimated population (in 1967) of 987 000, which was concentrated in the central and southern parts of the country and had contact through trade and travel with the inhabitants of Assam, West Bengal and Bihar in India. Between Nepal and Bhutan was the even smaller and less populous Indian protectorate of Sikkim (population in 1967, 196 000), which in 1975 became a state of India. Both areas shared a northern border with China, but few travellers crossed it.

Sikkim and Bhutan were both at risk of smallpox imported from India, although in neither area had it seemed likely that smallpox transmission could be long sustained among the population of the scattered mountain villages. Thus, until smallpox transmission was interrupted in India and Bangladesh, little support was provided by WHO to either Sikkim or Bhutan and, in fact, information about the smallpox situation in both areas was scanty until late in the Intensified Programme. With the interruption of smallpox in India, attention was directed to these and other more remote areas of the subcontinent to ascertain something of the history of smallpox and smallpox control in recent years and to confirm that transmission was not continuing.

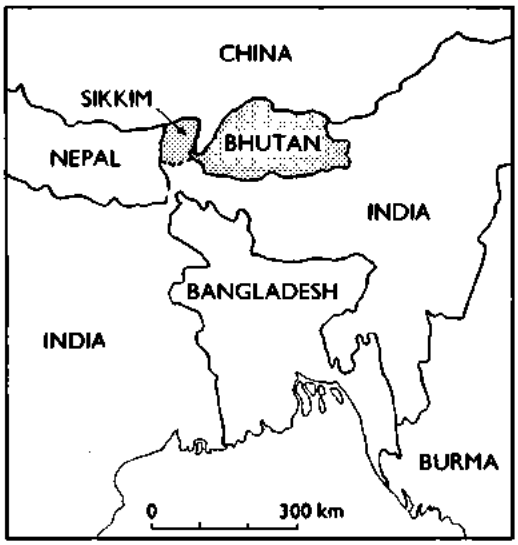

Fig. 15.32. Bhutan and Sikkim and adjacent countries.

Sikkim

Cases of smallpox had been officially reported in Sikkim since 1954. In 1966–1967, 78 cases in all were recorded at a time of high incidence in northern India. After this, no further cases were reported until 1973, when an outbreak of 34 cases occurred in Gangtok, the capital, the first case having been infected in Darjeeling, West Bengal. A second outbreak, of 11 cases, occurred that year in 2 villages along Sikkim's southern border, the source of infection again being West Bengal. No further cases were detected subsequently. Although reporting was undoubtedly very incomplete, the sporadic occurrence of smallpox was characteristic of an area in which importations were rare, and when they did occur, the disease did not spread easily.

Vaccination had been offered at the 4 district hospitals and 27 dispensaries, and the

Table 15.40. Sikkim and Bhutan: number of reported vaccinations, 1967–1975

Year	Sikkim	Bhutan
1967	114 575	35 944
1968	57 879	18 117
1969	71 812	9 029
1970	49 095	8 114
1971	36 832	43 052
1972	39 652	18 518
1973	45 801	57 375
1974	36 331	53 822
1975	28 846	25 599

number of vaccinations relative to population, at least from 1967, was quite substantial (Table 15.40). That vaccinial immunity was comparatively high was confirmed during a vaccination scar survey in November 1975, which revealed that 79% of the population had scars and only 42 of 1495 persons (2.8%) had the facial pockmarks characteristic of smallpox (Basu et al., 1979).

Bhutan

Information about Bhutan is less complete than for Sikkim. Until 1961 no health department had been established in the country. In 1964, the government created 19 posts for vaccinators, and increased the number to 25 in 1966, when a mass vaccination campaign was begun following an outbreak of 74 cases of smallpox in 1965–1966 in the capital city of Thimbu. The outbreak had begun among Indian and Nepalese workers employed in a road-building project and then spread to the local population. The number of vaccinations reported to have been performed between 1967 and 1975, however, was small in relation to the population of 987 000 (1967 estimate).

After the 1965–1966 outbreak, only 4 further outbreaks were reported. In 1967, 2 outbreaks originating in Assam caused 14 cases. The third outbreak, of 6 cases, occurred in April 1973 in a village near the south-western border with India, the initial case having been infected on a tea estate in West Bengal. The fourth outbreak, near the same border area, occurred in February 1974 and consisted of 3 cases, of which the first had been infected in Assam. Surveys conducted in 1976 to detect individuals with facial pockmarks, as well as interviews with village officials, indicate that other, unreported, outbreaks had occurred although none had produced more than a few cases. This was attributed in part to the fact that the villages were scattered and isolated, and in part to the sensible traditional practice of isolating the patient and his family at the onset of illness in a place some distance away from the village. In these circumstances, the spread of smallpox was difficult.

Sample surveys conducted in Bhutan in the autumn of 1976 confirmed that vaccinial immunity among children was generally low, especially in the central and northern parts of the country (Table 15.41).

Facial pockmarks indicative of past smallpox were not seen in anyone under 15 years of age in central and northern Bhutan but were observed in 11 children in southern Bhutan. In northern Bhutan, where adults also were examined, only 10 out of 244 persons (4%) over 15 years of age had the facial scars characteristic of smallpox, the youngest being in his late twenties.

In addition to the 11 children with facial pockmarks detected in the village surveys of southern Bhutan, 3 others were discovered during surveys of schools in this area. Nine of the 14 had experienced illness in 1967 or later, and in each instance efforts were made to identify the source of infection; all were traced to India. One had contracted smallpox while living in Allahabad, Uttar Pradesh, before moving to Bhutan. The other 8 became ill in outbreaks resulting from importations (Table 15.42).

Summary

The surveys confirmed the belief that the continuing transmission of smallpox in these sparsely populated, isolated countries had not occurred recently—even in Bhutan, in which vaccinial immunity was low. The tradition of isolating the patient and his family, observed in Bhutan, undoubtedly contributed significantly to stopping transmission. This custom, interestingly, was current throughout most mountainous areas of Asia, but was much less frequently practised in the lowlands.

CONCLUSIONS

From 1961, when India first decided to embark on a national eradication programme, to 1975, when the last case was detected, the programme gradually improved—in the quality of vaccine employed, in the vaccination technique used, in the reporting system, in the extent and intensity of surveillance and containment and, most important, in the quality of supervision. To undertake a national programme in a country so vast, with a population so large and a bureaucracy so complex, was inevitably difficult. To modify and redirect such a programme proved no less difficult. The dimensions of the effort, which involved at least the part-time participation of more than 150 000 field staff and contact with more than 550 million persons, are hard to grasp or communicate.

India's population, in 1967, constituted almost half of the total number of inhabitants of the endemic countries and, indeed, 15% of the world's entire population. The central direction of the enormous national campaign then in progress rested with only 1 medical officer and a small staff of clerks. In the states, of which 7 each had a population of more than 40 million, direction was generally entrusted to a single medical officer, for whom, in most instances, smallpox eradication was but a part-time responsibility. Working in the cities, towns and villages, however, were tens of thousands of vaccinators, basic health workers, family planning and malaria eradication programme staff and many other categories of health worker. Many were responsible, experienced individuals, conscientious about their jobs and willing to work, but they were seldom provided with much in the way of support or stimulus or the necessary supplies to carry out their assigned tasks. New directions or new policies were more often than not impersonally communicated by official memoranda which frequently demanded the impossible for example: "All persons in the state will be vaccinated cent per cent [100%] during the next 12 months." Vehicles stood idle and refrigerators remained inoperative for want of petrol or a few spare parts because the monetary resources provided had proved inadequate and/or fiscal procedures were so cumbersome as to prevent the disbursement of the funds. Vaccine deliveries were erratic and numerous batches were unfit for use because of the lack of refrigerated storage.

In the opinion of many, the solution to the disappointing level of productivity throughout the health sector was to eliminate special programmes such as that for smallpox eradication and to integrate all programmes into a unified primary health care programme in which each health worker would assume a multiplicity of responsibilities as a "basic health worker". This was the panacea which had been repeatedly proposed by both Indian and WHO expert groups since the 1950s. It was the course of action recommended in 1966 as India's intensive national vaccination campaign drew to a close, with smallpox almost as widespread as it was before the campaign had begun. In a number of states such integrated programmes were started in the mid- and late 1960s but the productivity of the workers was, if anything, even lower than it had been before.

Given the difficult problems and the paucity of senior leaders, the achievements of the smallpox eradication programme between 1967 and 1973 were remarkable. By the summer of 1973, smallpox transmission had been virtually interrupted in the southern states and was declining in the western states. It seemed that a comparatively modest investment in time by senior epidemiologists to help to develop surveillance and containment activities in the other states should rapidly succeed in interrupting transmission throughout India. The deplorable condition of the health services in some of these states, especially Bihar, Assam and Uttar Pradesh, was not then comprehended, nor were the coming disastrous epidemics anticipated. However, the administrative changes which were made in the summer of 1973 had profound consequences in that they permitted the vast resources of health man power in India to be utilized effectively and gave scope to the imagination and problem-solving abilities both of senior staff and of field workers. With the active support of the Minister of Health and Family Planning and

an adequate complement of senior Indian and WHO staff to travel to the field to explore alternative solutions to problems, to instruct, to assess and to measure results, field staff took an increasing interest in the programme. Knowing what should be done, they themselves sought new solutions. The onerous fiscal constraints were ultimately resolved through the use of the flexible imprest accounts provided by WHO. With the most senior Indian staff, initially Dr Diesh and later Dr Sharma, not only travelling to state capitals but also visiting field staff in districts and villages, the example was set for otherwise desk-bound lower-level supervisory staff to do likewise. By doing so, they motivated and inspired staff at all levels.

The strategy adopted for the programme also played an important role, the country being divided into 3 different areas, with the objective of preventing smallpox from re-establishing itself in smallpox-free states, of eliminating the few remaining foci in states with a low incidence, and of conducting a major offensive in the 4 states with the highest endemicity. Each of the states thus had specific goals and programmes appropriate to those goals. Measurable indices of progress in achieving eradication were important. These were identified first in terms of the numbers of cases of smallpox occurring each week and then in terms of the numbers of outbreaks in which a case had occurred during the preceding 4 weeks. In the last year of the programme, other standards were formulated to measure the quality of surveillance, of containment and of outbreak investigation. With specified and achievable objectives, all personnel could assess progress in their own area, be it a primary health care centre, a district or a state. Monthly meetings and regular surveillance reports served as refresher training, permitting new approaches to be introduced and serving as a stimulus to all concerned.

The problems that emerged after the intensive campaign was launched in the summer of 1973 were far greater than anyone had expected, but the conviction of the senior leadership and the programme's momentum were sustained in the face of often hostile criticism by some senior Indian and WHO officials, natural calamities of flood and famine, civil disorder and strikes, and the inevitable bureaucratic inertia. The programme improved so rapidly that the transmission of smallpox was interrupted in India less than 20 months after the first search had begun. Because of the quality of the programme and the confidence achieved through assessment of its merits, it was possible only 3 months after the occurrence of the last case to celebrate India's freedom from smallpox on India's Independence Day in August 1975. In no other country up to that time had it been possible to feel so confident so soon. However, over the next 2 years, the programme staff conducted the most elaborate and extensive search programme of any in Asia to confirm for themselves and—just as important—to convince an incredulous world community that India was truly free of smallpox.

What many failed to appreciate was that the achievement was not the product of a special army dedicated to smallpox eradication, but one in which existing health staff of all types participated actively in managing and executing a programme with measurable objectives. When eradication was certified in 1977, only a handful of long-term smallpox vaccinators and a few senior staff remained to be reassigned to other programmes.

As had been expected, smallpox in Nepal, Bhutan and Sikkim reflected the experience in the neighbouring densely populated Indian states. In Bhutan and Sikkim, the only special activities undertaken, aside from routine vaccination programmes, were those concerned with certifying the absence of smallpox. In Nepal, far more populous and epidemiologically more closely related to India, a special programme was required.

The programme of vaccination and later of surveillance and containment in Nepal represented its first national health programme, and one which extended to all parts of this mountainous rugged country. Since travel throughout much of Nepal was of necessity by footpath, and health facilities were non-existent in many parts of the country, district smallpox supervisors played a vital role. With encouragement from national staff and repeated refresher training, most of these local workers responded well to their responsibilities. The first national disease reporting system was established, and vaccination—all but unknown in most of the country in 1967—reached more than 90% of the population within a period of little more than 5 years. It was an impressive achievement, especially in view of the fact that the ratio of programme staff to population was at

best 1 to 20 000. Nepal's successes were different from India's but no less remarkable.

The programme in India was slow to gain momentum and undoubtedly eradication might have been attained far sooner if an adequate complement of well-motivated senior supervisors had been provided at an earlier stage. In all probability, the greatest catastrophe of the Intensified Programme would have been averted—namely, the 1971 epidemic in the Calcutta Salt Lake Refugee Camp, which led to the reintroduction of smallpox into Bangladesh and to tens of thousands of deaths.

INTRODUCTION

The last case of smallpox in Asia and the last case of variola major, the more severe form of the disease, occurred in Bangladesh (Fig. 16.1) on 16 October 1975. It might not seem surprising that Bangladesh was the last Asian country to eliminate smallpox. Of all the countries of the world, it was one of the poorest and most densely populated. However, Bangladesh (East Pakistan until December 1971) had already succeeded once in interrupting transmission 5 years earlier, in August 1970. The achievement had been remarkable and unexpected, occurring just 8 months after limited resources had been diverted from an extensive mass vaccination campaign to a simple surveillance and containment programme. Most observers believed that other undetected foci would become apparent during the subsequent dry season, from October 1970 to the end of March 1971, when more rapid transmission occurred. However, 6 months went by without further cases being found. Suddenly, in March 1971, a tragic and violent civil war broke out, 10 million refugees fled to India, and health programmes and organized surveillance activities virtually ceased. However, up to the end of December 1971, no smallpox patients were admitted to the infectious disease hospitals, no cases were reported by health staff and none were detected among the continuing flood of refugees entering India.

Many of the refugees who fled to India were housed in special camps, hurriedly set up in areas near the border. They were supposed to have been vaccinated on arrival, but in several camps, including the largest, near

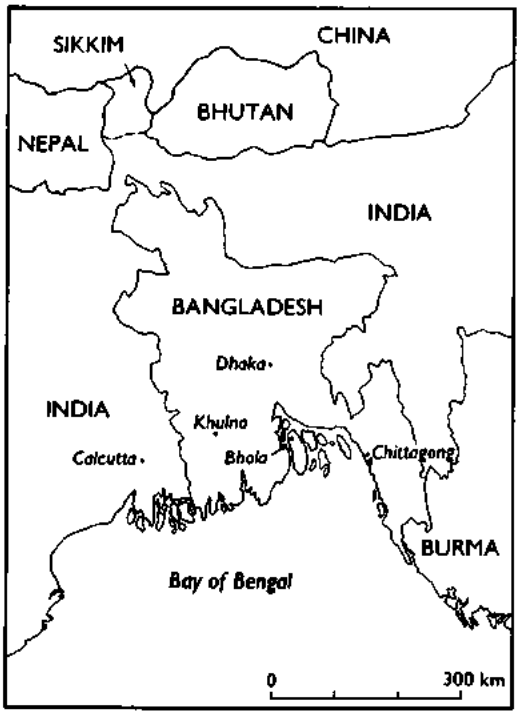

Fig. 16.1. Bangladesh and surrounding countries.

Calcutta, few were, in fact, vaccinated. Smallpox broke out in November 1971 and spread rapidly. Because cases were incorrectly diagnosed, nothing was done to contain the epidemic until late in January 1972.

Meanwhile, on 16 December 1971, Bangladesh became an independent state, and every day thereafter thousands of refugees, many of whom were infected with smallpox, began to return home. This mass migration took place at the beginning of the season of highest transmission. The health service, devastated by civil war, could not cope with the situation; epidemic smallpox swept through temporary refugee camps, cities and rural areas.

The eradication programme was reconstituted and strengthened, but, despite far more intensive efforts than had been made in 1970, transmission persisted year after year between 1971 and 1975, as one disaster followed another. At different times, famines, floods, civil disorder and the forcible displacement of urban slum dwellers caused hundreds of thousands of people to flee their homes. The national health services were reorganized at a critical time, in 1973, seriously hampering field activities; and national leaders periodically redirected the smallpox eradication programme towards mass vaccination campaigns.

In the spring of 1975, a greatly strengthened although frustrated and demoralized staff made one more concerted effort to stop transmission and ultimately succeeded in October 1975, when the last case occurred.

During its final year the eradication programme in Bangladesh utilized and further developed methods that had been elaborated over the preceding 8 years of the Intensified Smallpox Eradication Programme and employed experienced personnel from many other countries. The national programme is thus of special interest. However, if the refugees in the camps in 1971—amounting to perhaps 300 000 persons—had been vaccinated, this chapter would have been very brief; 223 000 fewer cases of smallpox would have occurred and more than 40 000 deaths would have been averted.

Of the national smallpox eradication programmes, that in Bangladesh is one of the better documented; much of the material for this chapter is drawn from a book by Joarder et al. (1980), *The Eradication of Smallpox from Bangladesh*. The book also describes the eradi-

cation staff's experience in the practical application of techniques for surveillance and assessment in other health programmes.

BACKGROUND

The richly fertile country of Bangladesh lies at the delta of three of Asia's great rivers—the Ganges, the Brahmaputra and the Meghna. More than nine-tenths of the country is less than 15 metres above sea level, and as much as one-third of the agricultural land is flooded during the June–September monsoon. In 1967, Bangladesh had a population of some 62 million, one of the fastest growing and with the highest density of any major country (428 persons per square kilometre). The central and southern parts of the country were the most densely settled (Fig. 16.2). Even in areas in which vaccinial immunity was comparatively high, the number of susceptible individuals per square kilometre was greater than in most endemic countries.

There was considerable population movement throughout the country. Nearly 95% of the people lived in rural areas, but 30% were landless and even those with some land of their own often sought part-time work elsewhere as tenant farmers or labourers. At planting and harvest times, hundreds of thousands of people travelled up to 200 kilometres in search of work. Although there were only 3 cities in 1974 with populations of more than 300 000—Dhaka (1.8 million), Chittagong (970 000) and Khulna (480 000)—all cities and towns had large unenumerated transient populations entering and leaving each day. A study in Dhaka in 1976, for example, showed that more than 110 000 persons passed daily through its main

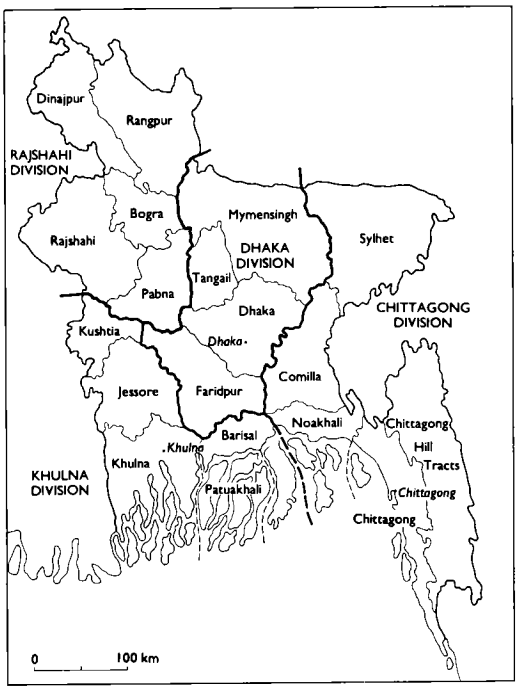

Fig. 16.3. Bangladesh: divisions and districts as of 1972.

points of entry. However extensive the movement of people, village and family ties remained especially important in this traditional Muslim society, so that those who fell ill frequently travelled long distances to be cared for in their home villages by their families. In this setting, the transmission of smallpox from urban to rural areas was rapid and widespread.

Undernutrition and malnutrition were common even when harvests were good. In 1962–1964, it was estimated that the residents of only 54% of rural households were adequately fed, and by 1975–1976 this proportion had decreased to 41%. Because of the precarious nutritional situation, even a small decrease in food supplies had a disproportionately heavy impact, causing hundreds of thousands of people to migrate from one area to another, many to the cities. At such times, smallpox spread with facility.

Travel by land was time-consuming and difficult, making it hard to supervise the programme effectively and to transport supplies to smallpox eradication staff in the field. A network of 4000 kilometres of all-weather roads radiated from Dhaka to district towns but major ferry crossings were encountered frequently and roads were often damaged or

Plate 16.1. River-boats provided transportation for many travellers in Bangladesh and, with the large crowds, smallpox spread rapidly and widely across the country.

washed out by monsoon rains. Hundreds of thousands of river-boats provided transport for many travellers; although they were slow, they were inexpensive and permitted extensive population movement, especially during the monsoon season.

The various administrative units, to which reference is made later, as well as their average area and population size, are enumerated in Table 16.1. Division and district boundaries are shown in Fig. 16.3.

Each village was composed of a number of *baris*. A *bari* usually corresponded to a household, but it also referred to a compound occupied by an extended family and sometimes included the houses of servants and other employees in the wealthier families.

In each district and subdivision, civil surgeons were responsible for all curative and preventive services except for the malaria eradication programme, which operated as an autonomous activity until late 1973. One or two medical officers were usually assigned to each *thana*, the basic administrative unit, but preventive measures were the responsibility of a sanitary inspector, who supervised some 5–10 government health assistants. Each government health assistant—a category of staff usually recruited locally—was in charge of a union. Many of the government health assistants had had no more than an elementary-school education; none were well paid or adequately supervised. Until late 1973, the malaria eradication programme, one of the best of its kind in Asia, had an independent but roughly parallel structure. Its staff, however, was of a generally better quality, received higher pay and was far more reliably supervised.

SMALLPOX AND ITS CONTROL BEFORE 1968

As elsewhere in the Indian subcontinent, only the variola major variety of smallpox was known to have occurred, and this fertile, heavily populated delta area may well have been one of the earliest endemic areas in Asia. Until late in the 19th century, protection was afforded primarily by variolation, performed by indigenous practitioners. Vaccination, with liquid vaccine produced in Calcutta, was introduced in 1860 in areas near Calcutta and in certain of the district towns of what is now Bangladesh. In 1874, the authorities decided that variolation should be abolished and they encouraged the variolators to replace variola

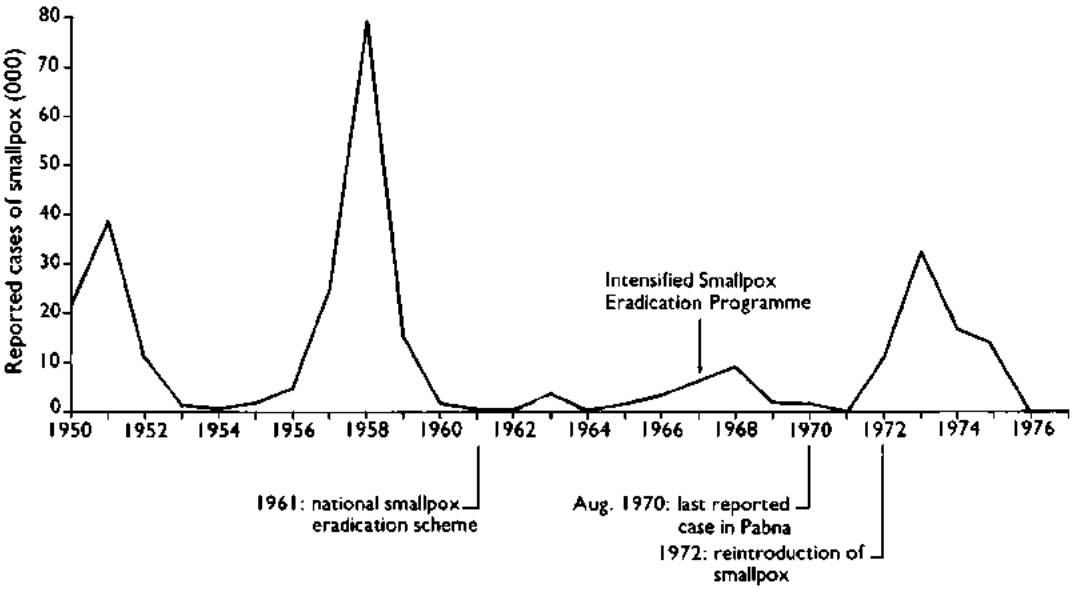

Fig. 16.4. Bangladesh: number of reported cases of smallpox, by year, 1950–1977.

virus by vaccinia virus. By the turn of the century, as vaccination became more widely available, variolation ceased altogether. In 1947, the production of liquid vaccine began in Dhaka, and up to 1961, vaccination was performed throughout the country by government-paid vaccinators supervised by health inspectors in each *thana*. The extent of vaccinial immunity is unknown but with only the thermolabile vaccine available in this subtropical area, many vaccinations were probably unsuccessful.

Smallpox was known in Bangladesh as *boshonto*, the Bengali word for spring, the season of highest incidence of the disease. As in India, major epidemics were recorded every 4–7 years. After 1947, the year in which Pakistan became independent, major epidemics were recorded in 1951 and 1958 (Fig. 16.4), the latter being so extensive that assistance for its control was sought from other countries. In all, 79 060 cases with 58 891 deaths were reported that year, a figure which, because of poor reporting, was undoubtedly one-tenth or less of the actual total. One of the groups providing assistance was a team from the United States Communicable Disease Center (later, the Centers for Disease Control), Atlanta. This team estimated that 60–70% of the people had vaccination scars but could find no correlation between the level of vaccinial immunity and the intensity of the epidemic in different areas. The team members were impressed by the size of the epidemic and the density of the population and suggested that "the number per square mile of unvaccinated persons would be a better index of the susceptibility ... than the index that is ordinarily used, the proportion of the population that has been vaccinated" (Usher, 1960). They concluded that the "feasibility [of global eradication] under presently existing circumstances is dependent on the likelihood of success in countries where eradication is likely to be most difficult to accomplish and the obstacles greatest. One of these countries is Pakistan ..." (Usher, 1960). As an outcome of the epidemic, it was decided to develop a laboratory in Dhaka capable of producing freeze-dried vaccine, but substantial quantities of such vaccine did not become available until 1966.

Resolution WHA12.54, adopted by the Twelfth World Health Assembly in 1959, called on all countries to join in a mass vaccination programme with the aim of eradicating smallpox. This initiative was enthusiastically supported by the Pakistani government and a campaign commenced in East Pakistan in 1961. The intention was to vaccinate the entire population within two or three years.

During the 3-year period 1961–1963, 72 million vaccinations were reported to have been performed and, during the succeeding 3

years, 68 million more—in all, more than twice the population of the country (Table 16.2). From field observations in 1967 and 1968, it was apparent that the reported number of vaccinations was greater than the number actually performed and, as was the case elsewhere in Pakistan and in India, the most accessible persons, such as schoolchildren, were vaccinated repeatedly while others were not vaccinated at all. Nevertheless, vaccinial immunity in the population undoubtedly reached higher levels than ever before. Only 69 cases of smallpox were reported in 1964, and 316 in 1965. In 1966, the number of cases again increased, reaching 3207 that year and 6648 in 1967.

During the summer of 1967, epidemiologists who had conducted studies of smallpox in West Pakistan (see Chapter 14) decided to undertake similar studies in rural East Pakistan. A combined team from the Pakistan Medical Research Centre in Lahore, the Cholera Research Laboratory in Dhaka, and WHO studied the epidemiology of smallpox in an area in which cholera vaccine trials were then in progress. These investigations, along with those in West Pakistan, were the most comprehensive epidemiological studies conducted during the entire global eradication programme and provide an interesting overview of the smallpox situation at that time in one subdivision of the country (Thomas et al., 1971a,b).

The area studied was Matlab *Thana*, Comilla District, 65 kilometres from Dhaka; it included 132 small rural villages (population, 113 000) scattered over approximately 200 square kilometres. Vaccinators had been employed in the district since 1930, travelling from village to village to vaccinate newborn children and revaccinate others, using the rotary lancet and liquid vaccine. Comilla District had served as a pilot programme area for the 1961–1963 mass vaccination campaign and, for this operation, additional vaccinators had been employed. Therefore, as the investigators noted, vaccinial immunity among individuals over 5 years of age may have been better than in other parts of East Pakistan.

In May 1967, experienced interviewers, employed in the cholera vaccine trials, visited each house throughout the area to assess vaccinial immunity; in all, 103 539 persons were examined. In July, each house was again visited in an effort to identify, by means of an interview, all cases which had occurred between 1 July 1966 and 30 June 1967.

Of the people examined, 80.8% had a vaccination scar, the largest proportion of the unvaccinated being among children under 5 years of age (Table 16.3). This age group should have been vaccinated during the "maintenance vaccination" campaign, but, as is apparent, that programme was far from satisfactory.

Thirty different outbreaks, occurring in 27 villages, with a total of 119 cases, were identified. Of these, only 5 outbreaks and 13

[a] Population estimates from United Nations (1985).

cases had been officially reported but, as in West Pakistan, the reported outbreaks included 5 of the 6 largest, in which 54 cases had occurred. In 7 outbreaks, special vaccination control campaigns had been conducted by government vaccinators but with little apparent effect.

The age distribution and case-fatality rates (Table 16.4) were similar to those observed elsewhere in Pakistan and in India. Thirty-four (29%) of the cases were in children under 5 years of age, 55 (46%) in individuals aged 5–19 years and 30 (25%) in those aged 20 years and over. Thirty-four of 111 persons (31%) of known vaccination status had previously been vaccinated, all except 6 of them being 10 years of age and older. With data available regarding the vaccination status of the population as a whole, it was possible to calculate vaccine–efficacy ratios by age based on vaccination at some time in the past (WHO/SE/69.11, Thomas et al.). The ratios showed 94–96% protection for those aged up to 14 years; 89% for those aged 15–24 years; and 74% for those aged 25 years and more. The ratios were remarkably high, although not so great as those found in South America, in which only the mild variola minor variety of smallpox was present.

The epidemiological pattern of spread was of special interest. Thirteen of the 30 outbreaks consisted of only a single case, and in 9 others the disease was not transmitted beyond the initially infected *bari*. Moreover, 24 of the outbreaks terminated after less than 2 generations of spread. Despite the density of population and a lower level of vaccinial immunity, smallpox tended to spread less rapidly and to remain more localized than in West Pakistan. The sources of 22 outbreaks were identified. All but 1 of the sources were outside the study area and 15 of the 22 originated in cities of 100 000 inhabitants or more, in which only 5% of the population of the province resided. In this study population, continuing transmission of smallpox from village to village had not occurred and, in fact, no cases whatever were detected whose onset took place between September and December 1966.

The investigators concluded that it was even more important in East than in West Pakistan to eliminate smallpox from urban areas, an objective which, if achieved, would prevent a high proportion of rural cases. Moreover, it appeared that most outbreaks in rural areas might be contained simply by vaccinating the inhabitants of the affected and neighbouring *baris* rather than the population of the entire village. Noting the high vaccine–efficacy ratios, the investigators recommended that a continuing programme of maintenance vaccination should concentrate on vaccinating those who had never been previously vaccinated, especially children aged 5–14 years not attending school and landless labourers working in urban areas—identified as the two groups most likely to transmit smallpox from place to place.

For a settled population and one which was as well vaccinated as that of Matlab *Thana*, the recommendations were sound and in 1970 the programme would substantiate their validity. However, when mass migrations of refugees took place, as happened repeatedly after the country became independent, and when smallpox outbreaks occurred in areas in which vaccinial immunity was low, more extensive containment measures were found to be required.

Table 16.3. Matlab *Thana* study area, Comilla District: vaccination scar survey, 1967, by age group[a]

Age group (years)	Number examined	With vaccination scar

THE WHO-SUPPORTED ERADICATION PROGRAMME BEGINS, 1968

In July 1967, Dr Ehsan Shafa, the regional smallpox adviser from the WHO Regional Office for the Eastern Mediterranean, and Arita held meetings with government officials in Islamabad, the national capital, and Dhaka, the capital of East Pakistan, and developed a draft plan of operations. The government agreed to the plan in principle and submitted a letter to the WHO Regional Office requesting assistance. This letter permitted funds to be obligated and supplies to be procured well before a more formal agreement was signed by WHO and the government, inevitably a long process. (The agreement was not, in fact, signed until 26 April 1968.)

The principal component of the plan was a mass vaccination campaign, as in West Pakistan. It was thought that a well-organized campaign and concurrent assessment of the results, coupled with the use of freeze-dried vaccine and bifurcated needles, would achieve a higher level of vaccinial immunity than had previous campaigns. Provision was made for surveillance teams in areas in which mass vaccination campaigns were in progress, but the concept of a national surveillance programme did not take shape until 1969. Although the findings and recommendations of the research team were available to national and WHO staff by early 1968, they were almost wholly ignored in the implementation of the national programme.

The plan called for a special full-time staff comprising a headquarters office with physicians and supporting staff, 2 medical officers in each district, a medical officer in each subdivision and vaccination teams totalling some 1500 persons. The programme was to begin in 6 of the 17 districts and was to be completed in these districts during the first year of operation. Vaccination campaigns would subsequently be conducted in the remaining districts during the second and third years. The vaccination teams would move progressively from one union to the next and assessment teams would check the coverage. It was expected that sufficient freeze-dried vaccine could be produced by the Dhaka laboratory for both East and West Pakistan. For the first year, WHO provided the following items: 10 motor vehicles, 130 motor cycles, 5 boats and 1500 bicycles, in addition to other supplies. Up to the end of 1971, WHO support to the programme ranged between US$ 67 000 and US$ 201 000 per annum (Table 16.5). It did not increase significantly until 1974.

A WHO epidemiologist, Dr Karel Markvart, arrived in January 1968 to help with the

Plate 16.2. **A**: Mohammad Ataur Rahman (b. 1925) as deputy director of the vaccine production laboratory in Dhaka, Bangladesh, played an important role in its development and, later, as health adviser to the Planning Commission, provided essential support for national mobilization for smallpox eradication in 1975. **B**: Karel Markvart (b. 1933) was a WHO adviser to the programme in Bangladesh from 1968 to 1971.

NOTE: WHO records for 1967–1971 reflect support to both East and West Pakistan. Approximately half (the figures shown in parentheses in this table) was provided to East Pakistan. The principal contributors to the WHO Voluntary Fund for Health Promotion were Canada, Denmark, Norway, Sweden and the United Kingdom. The United Nations Relief Operation, Dacca (UNROD), provided US$415 000; UNICEF provided US$20 000.

organization of the national mass vaccination campaign. The problems in mobilizing and training so large a staff were staggering. Additional government funds were required to implement the programme (2.5 million rupees—i.e., US$ 250 000) but because the agreement was not signed by the government until April 1968 no funds were made available before the fiscal year beginning 1 April 1969. A full-time national counterpart—Dr A. M. Mustaqul Huq, an able and dedicated public health officer—was not assigned until July 1969.

In 1968, the organization of health services in 12 of the 19 districts was chaotic. In the 12 so-called "non-provincialized" districts, there was a dual management structure. A district council appointed and paid the salary of a district health officer, who was responsible for preventive activities, while the provincial government appointed and paid a civil surgeon, who was responsible for both curative and preventive activities. At the next lower level, the subdivision, health activities were under the direction of a subdivisional medical officer of health, appointed and paid by the provincial government. He was required to supervise sanitary inspectors, who were appointed and paid by district councils. In their turn, they were expected to supervise vaccinators, who were recruited and paid by the provincial government. In addition, municipal staffs were independently directed by municipal committees and were not responsible to provincial or subdivisional government health staff. Appointments by district councils and municipal committees were as often decided by political considerations as by qualifications; discipline in performance and coordination were chronic problems which plagued the programme throughout its course. In the remaining 7 districts, the health services had been "provincialized" and there, with all health staff appointed and paid by the provincial government, the health structure operated more effectively.

At the end of 1968, the Dhaka municipal committee was persuaded to provide funds and staff to undertake a mass vaccination campaign, in part as a pilot study, but also in recognition of the role of this urban area as the country's principal focus of the spread of smallpox. The campaign was reasonably successful as measured by a vaccination scar survey; by the end of the campaign, more than 90% of the population had vaccination scars (Table 16.6). After May 1969, no smallpox cases were detected in Dhaka for more than 2 years.

Table 16.6. Dhaka Municipality: vaccination scar survey, 1969, by age group

Age group (years)	Number examined	% with vaccination scar
0–4	1 387	76.8

⩾15	1 695	98.0
Total	5 033	90.4

Table 16.7. Bangladesh: vaccine production at the Dhaka laboratory and vaccine donations, 1972–1977

Year	Number of vials	
	Produced by the Dhaka laboratory	Donated by other countries
1972	343 380	26 000
1973	807 000	190 000
1974	963 500	453 000
1975	730 152	1 136 000
1976	458 750	0
1977	703 600	0

Vaccine production, meanwhile, proved to be an unexpected problem. The quantity of vaccine produced was less than had been expected and barely sufficient to supply East Pakistan. Between 1966 and 1971, the laboratory produced an estimated total of 4 million vials of freeze-dried vaccine. Vaccine quality was said by the laboratory director to be satisfactory, but when samples from 7 batches were tested in the WHO smallpox vaccine reference centre in Bilthoven, Netherlands, in late 1968, only 3 met the accepted standards. Thereafter, the director permitted no one to have access to the laboratory's records. He asserted that the vaccine was satisfactory, but examination of a further 10 batches in 1969 showed that only 3 were up to standard. Because of production problems, a consultant was recruited by WHO to work with the laboratory staff and after this the quality of the vaccine improved and the records again became accessible. However, some difficulties in producing a stable vaccine persisted throughout the programme.

Vaccine production data by year are available only for the period 1972–1977. The quantity produced was gradually increased after the provision by WHO of additional equipment and supplies, so that by 1973 more than 10 000 vials a week were being manufactured. Nevertheless, up to 1975, additional vaccine was required and this shortfall was met by a number of donors through contributions to the WHO vaccine reserve stocks (Table 16.7).

In April 1969, the government-funded posts for the vaccination campaign were finally established, but recruitment proved to be such a cumbersome procedure that not until January 1970 did sufficient staff become available to permit mass campaigns to begin in 15 of the 21 subdivisions in 7 of the country's 19 districts. In the execution of the programme and in the reporting of cases, it was agreed that the divisional and district health authorities would be bypassed, thus streamlining the structure so that only 4 levels would be involved in administrative direction and case reporting—headquarters, subdivisions, *thanas* and unions.

The vaccination campaign made slow progress, however. By November 1970, the teams had vaccinated only 4.5 million persons, little more than 6% of the population of the country (Sommer et al., 1973). Meanwhile, local vaccinators reported that they had vaccinated 32.8 million people in 1968 and 31.6 million in 1969, although these figures were considered to be inflated. In 1970, vaccination scar surveys in the 7 districts in which mass vaccination had been performed showed 4 in which the proportion of the population with vaccination scars ranged from 64.9% to 72.1%, substantially lower than the 80.9% found by the research team in Comilla. In the other 3 districts, the proportions with vaccination scars were, respectively, 75.6%, 77.5% and 86.2%.

The number of reported cases reached a peak of 9039 in 1968, the highest total in a decade, but declined to 1925 in 1969. What, if anything, this implied was unknown since little had been done to improve the reporting system.

INITIATION OF SURVEILLANCE–CONTAINMENT AND THE INTERRUPTION OF TRANSMISSION, 1970–1971

It had been agreed that in addition to the vaccination staff, there should be a surveillance team for each subdivision in which the mass vaccination campaign was conducted. As the plan of operations stated, the team would (1) control any reported attack of smallpox, and (2) if no cases were reported, vaccinate any person who had been missed after the operational (vaccinator) group had left the area. This first official recognition that there should be surveillance teams was encouraging but, conceptually, still far removed from the objective of establishing teams solely responsible for developing the reporting system, detecting cases and containing outbreaks throughout the country.

In November 1969, a WHO intercountry seminar on smallpox was convened in Dhaka which illustrated, on the basis of reports from western Africa and Brazil, what could be

achieved with more effective case detection and outbreak containment. East Pakistan had reported only 4 cases in September and 1 case in October 1969. With so few reported cases, it was decided that from January 1970 an effort would be made to investigate every reported case. A surveillance section, headed by a medical officer, was established and 1 central and 4 divisional surveillance teams were recruited to improve reporting and to investigate outbreaks throughout the country. Because government travel allowances were too meagre to cover even the most modest board and lodging, WHO agreed to provide the teams and other senior supervisors with a supplementary per diem allowance to permit them to travel in the field. The leaders of the 4 divisional teams, Dr M. A. Sabour, Dr M. Yusuf, Dr M. Shahabuddin and Dr M. A. Khan, proved to be exceptionally able and dedicated and served in this capacity throughout the entire programme. In January 1970, the first monthly surveillance report was issued, and this series continued to appear, with interruptions due to civil war, throughout the programme.

Because the time of Dr Markvart and Dr Huq was fully taken with the complex logistics of the mass campaign, Arita was assigned from WHO Headquarters for the months of February and March to help to develop the surveillance programme. In collaboration with the newly constituted surveillance teams, he investigated reported outbreaks in various parts of the country. To the surprise of all concerned, the teams discovered that cases being reported from the central and southern parts of the country were not smallpox but chickenpox and other skin diseases. On the other hand, in a northern district, the investigation of a newspaper report of 6 cases led to the detection of 93 cases of smallpox. By the end of March, it appeared that smallpox was localized in only 5 northern districts of the country. Arita suggested that the vaccination campaign should be temporarily suspended in favour of an emergency surveillance–containment campaign whose objective would be to interrupt transmission before the monsoon rains. With the agreement of a newly appointed and highly competent Minister of Health, Colonel M. M. Haque, and after the surveillance teams had been specially trained, such a campaign began; it was one of the most dramatically successful of the entire global eradication programme.

To facilitate surveillance, the reporting system was changed. The detection and identification of cases had depended on a traditional routine in which a local government employee, the chowkidar (who served also as the village watchman), was responsible for the weekly reporting of births, deaths and notifiable diseases to the *thana* headquarters. The chowkidars were frequently illiterate, poorly paid and ineffectual. Reports received at the *thana* were forwarded by mail to the subdivision, and then to the statistical section of the Ministry of Health. Reports were submitted sporadically, often after delays of several weeks, through a mail system that was anything but reliable.

Beginning in April 1970, all health workers and the malaria eradication programme staff were asked to report each suspected case of smallpox they encountered to the *thana* sanitary inspector. The better-paid, better-supervised and generally more responsible malaria eradication workers visited all houses throughout the country once every 2 weeks, searching for persons with fever who might have malaria and confirming this by the examination of blood smears. For them to report suspected cases of smallpox entailed little additional work and no disruption of activity. *Thana* sanitary inspectors were instructed to forward weekly reports of all cases in their *thana* to the subdivisional medical officers. They in turn were to report cases by telegram rather than by mail to the Dhaka smallpox eradication programme headquarters. When outbreaks were detected, the subdivisional medical officers as well as the *thana* health inspectors were instructed to investigate and contain them. This system brought health workers into the reporting system and streamlined reporting by introducing telegraphic notification directly from the subdivision to the smallpox eradication headquarters, thus bypassing the largely uninterested bureaucracy of the statistical section of the Ministry of Health.

The investigation of outbreaks generally confirmed the findings of the Comilla study: that most outbreaks originated in cities; that the spread of smallpox from village to village was surprisingly infrequent; and that outbreaks could be readily contained by vaccinating the inhabitants of an infected *bari* and those of a few *baris* surrounding it. In the northern part of the country, in which health services were less adequate and vaccinial

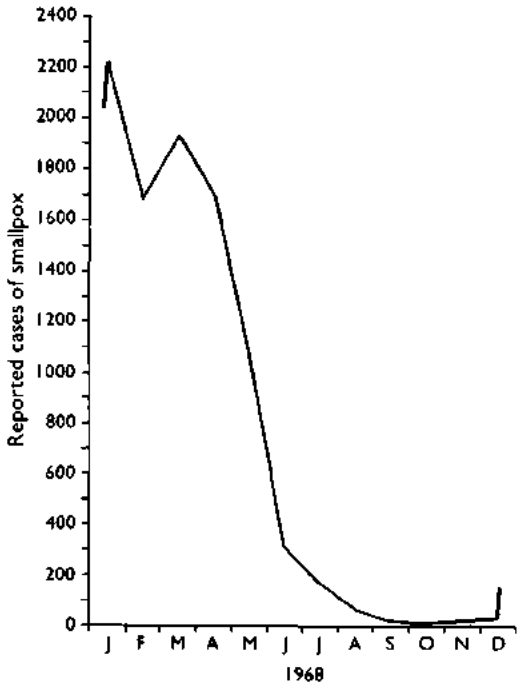

Fig. 16.5. Bangladesh: typical seasonal variation in smallpox incidence, as shown by the number of reported cases in 1968.

immunity was lower, village-to-village spread was documented in 3 *thanas* in which 13 outbreaks and 149 cases had occurred. Even here, however, the spread of smallpox was slow and although 3–7 months had elapsed between the introduction of smallpox and its detection, there were comparatively few cases in each generation of transmission and the outbreaks were readily contained (*Wkly epidem. rec.*, 1970b). Between January and March 1970, 1024 cases were detected and reported but many of these represented cases which had occurred some months previously. Few active cases were discovered.

In the entire country, only 263 cases were detected in April and only 116 in May. Moreover, the cases were localized: 4 out of 19 districts accounted for all but 59 cases. In June, the 5 surveillance teams were assigned to work intensively in the remaining infected areas and 10 surveillance teams previously working with the vaccination teams were also sent to these areas to contain outbreaks. Thirty-eight cases were discovered in June, 23 cases in July, and 9 cases in August. In August, the teams detected and contained the last known outbreak—in Pabna District. Effective surveillance continued for another 6 months but no further cases could be found.

In March 1971 civil war broke out, and until December 1971 the country was totally disrupted. During this period, it is estimated that between 1 and 3 million civilians died, 10 million refugees fled to India and an estimated 16.6 million people left their homes for other parts of the country (Chen & Rohde, 1973). Bridges were blown up, 1.5 million houses were destroyed, and severe famine occurred (Greenough & Cash, 1973).

Such evidence as is available substantiates the belief that, until 16 December 1971, when Bangladesh became independent, endemic smallpox was absent from the country—a smallpox-free interval of 16 months. During the period of civil war, no cases were found in any of the major cities, the usual sites of endemic transmission. The divisional surveillance teams were proud of their achievements and continued to travel widely throughout the country—albeit at considerable risk—seeking information about possible cases but finding none. The refugees who streamed ceaselessly across the border throughout this period were reasonably thoroughly screened by Indian civilian and military health staff in an effort to detect cases of smallpox, but none was discovered. Moreover, when smallpox was reintroduced into Bangladesh, investigation revealed that the primary source of each outbreak was a refugee who had contracted the disease in 1 of 4 infected refugee camps in India or on the way home. During April 1972, almost all cases occurred among returning refugees and their immediate contacts (Sommer et al., 1973).

The comparative ease and rapidity with which smallpox transmission was interrupted in Bangladesh in the summer of 1970 was in stark contrast to the staggering difficulties which were to mark the 4 years following its reintroduction. In retrospect, the timing of the 1970 spring surveillance–containment campaign had been ideal, from the standpoint both of the season and of the longer-term periodicity of smallpox. It had begun in the late spring, when rates of transmission customarily declined and many outbreaks terminated spontaneously (Fig. 16.5). With regard to the longer-term periodicity, smallpox incidence had peaked in 1968, with 9039 cases, and in 1969 the annual reported incidence had declined sharply to 1925 cases. In 1970, it is probable that no more than 150–200 cases would have been reported had not

Plate 16.3. Bangladeshis, infected with smallpox while living as refugees in India, returned to their newly independent country, only recently freed of smallpox, from December 1971. Travelling in crowded trucks and trains, many lived in resettlement camps until their houses could be rebuilt. Smallpox spread widely and rapidly through the camps and across the country.

the special programme improved the completeness of notification. Even so, only 1473 cases were recorded. Moreover, at this time, neither flood, drought nor civil disorder resulted in famine and the extensive refugee movements which were to mark succeeding years. In some ways, the success of the 1970 campaign had a negative effect by engendering an unwarranted degree of optimism that such a favourable outcome could be achieved as readily and as rapidly again in Bangladesh as well as in other parts of the subcontinent.

THE REFUGEE CAMPS AND THE REINTRODUCTION OF SMALLPOX, DECEMBER 1971–MAY 1972

Of the estimated 10 million persons who left the country, most were housed in crowded camps. The largest, near Calcutta, was the Salt Lake Camp which sheltered an estimated 200 000–300 000 refugees. Government priority was given to supplying food, shelter and sanitary facilities. As noted in one report (Rohde & Gardner, 1973):

"The provision of relief to 10 million refugees ... represented a monumental humanitarian achievement. That mass starvation and galloping epidemics did not consume a greater portion of the refugee population is a tribute to the leadership, dedication and energy of the Indian Government ...

"In contrast to the efficient conduct of the overall relief effort, authority over health programs was not invested in any one group or person ... As a result, health policies and programs often lacked focus, direction, and coordination."

The provision of smallpox vaccination was one of these policies.

The Indian Ministry of Health had instructed state governments to ensure that all refugees were vaccinated against smallpox. In some camps, vaccinations were given by government staff and/or the personnel of voluntary relief agencies, and the conscientious performance of this task was confirmed by visiting Indian and WHO staff. However, state officials did not permit national health personnel or WHO staff to visit the camps in West Bengal so confirmation there was not possible. Medical care in the Salt Lake Camp was under the supervision of a voluntary relief agency; at that camp, as it was learned later, vaccination was ignored. It is likely that cases of smallpox began to occur in November, the source of infection being villages in West Bengal. The cases were recorded as chickenpox by the health staff.

BY COURTESY OF D.J.M. TARANTOLA, 1976

Plate 16.4. *Left to right*: D.J.M. Tarantola, WHO smallpox eradication adviser in Bangladesh, 1974–1977; M. Sathianathan, a medical officer in Bangladesh, who had previously served as the WHO adviser for smallpox eradication in Nepal; A.K. Joarder, Assistant Director of Health Services of Bangladesh and director of the national smallpox eradication programme, 1972–1977.

The epidemic was discovered by chance. On 19 January 1972, an American epidemiologist thought he could identify cases of smallpox in a television film of the camp transmitted to the USA. He telephoned the Communicable Disease Center, which telephoned WHO Headquarters. WHO telexed the government of India, which in turn contacted the West Bengal Ministry of Health. Although the state Director of Health Services categorically denied there were cases, one of the national staff flew to Calcutta and immediately found numerous patients. The isolation of cases and vaccination began on 23 January, but by then it was too late. On 16 December 1971, Bangladesh had become an independent country and refugees began returning home forthwith. By mid-January, an estimated 50 000 had left the Salt Lake Camp. Infectious cases, patients in the incubation period and unvaccinated contacts were all loaded together on trucks for the trip to the border. It was the season when the transmission of smallpox was most rapid and with 26 million displaced persons moving from place to place, herded together in temporary camps and crowding the bustees (city slums), smallpox spread rapidly.

Under the best of circumstances the problem would have been difficult to cope with but at this time the health services were

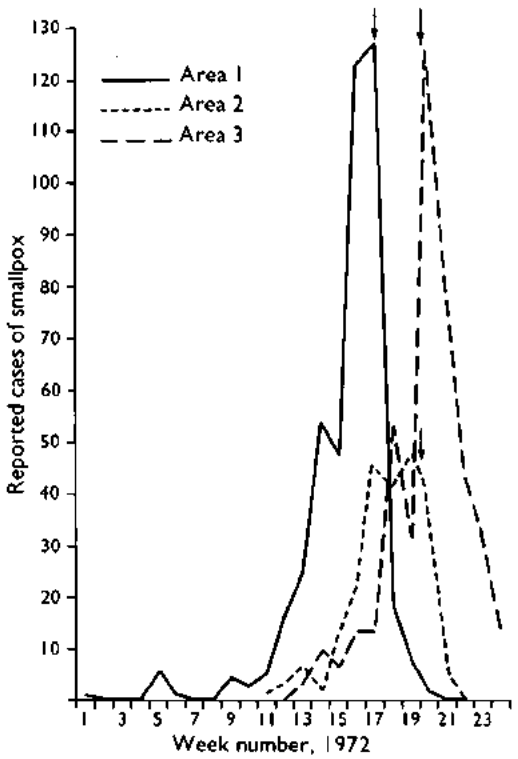

Fig. 16.6. Khulna Municipality: number of reported cases of smallpox in 1972 by week of onset in 3 areas of the city. Arrows indicate the week surveillance–containment activities started in each area.

seriously disrupted. So many motor vehicles had been damaged or stolen that less than half remained in working order, and only one-third of the number of bicycles required were available. Boats had been damaged or sunk and because of the destruction of roads, bridges and ferries, travel from place to place was difficult and time-consuming.

Arita, then on duty travel in India, flew immediately to Dhaka, and working with Dr M. Huq, the Director of Health Services, endeavoured to control the outbreaks. By March 1972, the smallpox eradication headquarters had been re-established under Dr A. K. Joarder, Assistant Director of Health Services; divisional surveillance teams had been reconstituted and were endeavouring to detect and contain outbreaks as best they could. Smallpox continued to spread, however, and 4 WHO epidemiologists were hurriedly dispatched. Among them were Dr Stanley Foster, who had previously served as the chief smallpox adviser in Nigeria, and Dr Nilton Arnt, one of the principal epidemiologists who had worked in the eradication campaign in Brazil. Some 3800 temporary vaccinators were hired to perform vaccinations, primarily in the large temporary refugee camps and surrounding districts. At first the epidemic was largely confined to 3 south-western districts—Barisal, Faridpur and Khulna. Active search, however, revealed the presence of smallpox in 27 of the country's 57 subdivisions, although most had only a few cases. The refugees were mainly Hindus and initially the outbreaks afflicted Hindu areas and villages, but within a few generations of disease transmission, other groups were infected as well. In March, epidemic smallpox was detected in Khulna Municipality, the third largest city in Bangladesh. The control of smallpox in urban areas was recognized to be vital, and here a vigorous and remarkably successful programme was begun on 28 April (Sommer, 1974; Sommer & Foster, 1974). Eight 4-man surveillance teams were organized and trained to identify infected cases through interviewing patients at the Infectious Disease Hospital and by visits to the bazaars. When a case was found in the city, all persons in the household and compound were vaccinated and house-to-house searches were conducted throughout the village or bustee. The area was revisited after 2 or 3 days and again 3 weeks later to vaccinate individuals who had been missed during the first visit and to be certain that transmission had stopped. Containment measures were necessarily limited in scope because of the paucity of staff and the extent of the epidemic. In fact, it was

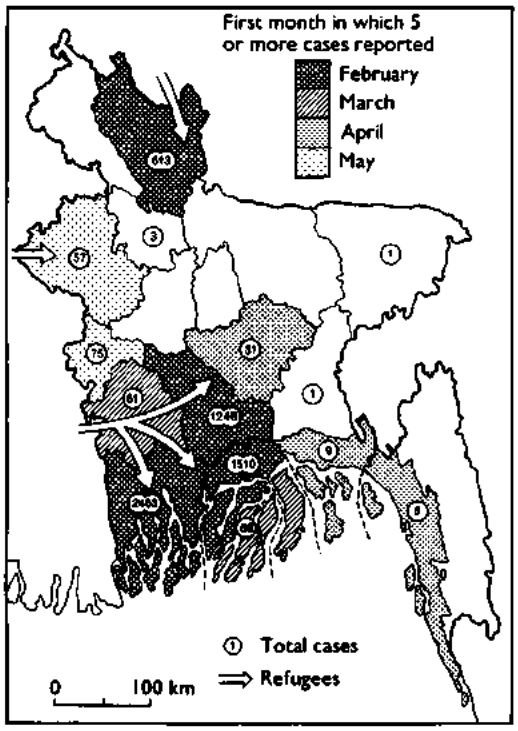

Fig. 16.8. Bangladesh: infected districts and number of reported cases of smallpox as of 30 June 1972.

necessary to divide the city into 3 segments and to deal with each in turn. Although 1073 cases were detected, smallpox was effectively contained within a matter of 4–6 weeks in each of the areas (Fig. 16.6). Meanwhile, the disease had broken out in a city refugee camp housing 30 000 persons. It was decided to vaccinate everyone in the camp by the simple expedient of making vaccination a prerequisite for the receipt of relief supplies. Altogether 233 cases were detected; however, the outbreak was as successfully dealt with as the one in Khulna Municipality (Fig. 16.7). To have achieved so much so quickly, with so few health personnel, at a time of considerable civil turmoil was a remarkable accomplishment and encouraged staff in the belief that the flood of importations might yet be successfully contained.

However, smallpox was spreading rapidly through rural as well as urban areas, wherever returning refugees settled. A survey of one rural *thana* in May revealed 2298 cases among 250 000 inhabitants—approximately 1 case per 100 population. Meanwhile the disease continued to spread through refugee resettlement camps, some of which housed Bangladeshis of Bihari origin. From these camps, it spread to adjoining *thanas*. Small outbreaks developed in Dhaka and Chittagong but these were controlled. Intensive studies of a number of the outbreaks in which cases and deaths were thoroughly investigated revealed case-fatality rates of up to 28%, higher than those found elsewhere in the subcontinent and undoubtedly reflecting the extensive malnutrition then prevailing.

By the end of June 1972, 6144 cases had been reported in Bangladesh, of which 5834 (95%) were from only 4 districts (Fig. 16.8). Although reporting was recognized to be incomplete, it sufficed to indicate that large parts of the country had few or no cases. With a concerted effort such as had been made in Khulna and conducted throughout the monsoon period of diminished transmission, the staff hoped that the epidemic spread could be contained. Special assistance was given to the programme by the United Nations Relief Operation, Dacca, in the form of motor vehicles, boats, outboard engines and bicycles. WHO provided motor cycles and additional bicycles to facilitate the effort (Table 16.8). However, much of the transport served only to replace that which was worn out or had been destroyed during the civil war.

Of the 4 WHO epidemiologists who had assisted during the spring emergency, Dr Arnt and Dr Foster continued on permanent assignment in what proved to be one of the most arduous and taxing endeavours of the global eradication programme. They were soon joined by 3 other staff, who remained with the programme essentially full time

Foster (b. 1933), a United States epidemiologist who had previously served as senior adviser to the smallpox eradication programme in Nigeria, 1966–1972, then served in Bangladesh as a WHO adviser for smallpox eradication, 1972–1977.

until transmission had been interrupted: Dr Nicholas Ward, who had previously been employed as a District Medical Officer in Botswana; Dr Stanley Music, a Bengali-speaking epidemiologist who had previously been stationed in Dhaka on assignment from the Communicable Disease Center; and Dr Daniel Tarantola, a physician who had been working at a hospital in northern Bangladesh with a French voluntary organization.

THE PROGRAMME IS RE-ESTABLISHED, JUNE 1972–SEPTEMBER 1973

The reporting system, which required weekly telegraphic reports from each of the 57 subdivisions, was reinstituted in March 1972 (Foster et al., 1980). Reports to the subdivisions were provided through *thana* sanitary inspectors by government health assistants, each of whom worked in a union, the health assistant/population ratio being approximately 1 to 15 000. During the summer, 4-man surveillance teams, headed by a sanitary inspector, worked in each infected subdivision; in each infected *thana*, vaccinators were grouped into 3-man teams for active search and containment. Particular emphasis was placed on the search in weekly markets by health workers using megaphones. This approach was later shown to detect approximately 80% of all outbreaks within an area of 65 square kilometres.

A mass vaccination campaign in the 4 most heavily infected districts had begun in the spring, but was stopped when it became apparent that it would accomplish little more than the 1970 campaign. As Dr Huq and his colleagues stated in a report dated October 1972: "It is now clear that eradication through mass vaccination is not feasible ... The orthodox principle of blind, systematic vaccination has already been given up."

Between June and October 1972, 400–800 cases were detected monthly, a substantial number for that season of the year. However, up to the end of October, outbreaks had been documented in only 88 of the 409 *thanas* in the country, and by then only 36 were still infected. By the end of 1972, 10 754 cases had been reported, approximately one-tenth of the number which had actually occurred, as a survey for facial pockmarks carried out 4 years later was to show (Hughes et al., 1980; Fig. 16.9; Table 16.9). The system for detecting and reporting cases, although well designed, lacked adequate supervision.

After the monsoon, with the season of high transmission approaching, it was decided to concentrate resources in the subdivisions of the 4 most heavily infected districts. A 10-man team, headed by an assistant health inspector, was assigned to each of the infected *thanas* to search for cases and to contain any outbreaks that were found. A national surveillance team with 5 assessment staff supervised these efforts and made repeated visits to the sites of outbreaks to ensure that they had been contained. Four surveillance teams, working under the supervision of the national eradication headquarters, travelled throughout the areas which had reported only a few imported cases to strengthen surveillance and to contain outbreaks.

The strategy was based on the assumption that smallpox would tend to remain localized in the areas already identified as infected. A key factor in the strategy was the control of smallpox in Dhaka, the capital and largest city in the country, and the potential focus of spread of smallpox into the largely smallpox-free areas of central and eastern Bangladesh. In April and May 1972, 26 cases had occurred among refugees in Dhaka but the outbreaks

were contained. Only a single case was recorded in July and another in August, but early in October scattered outbreaks began to occur in densely populated urban slum areas and resettlement camps, in which the night-time population densities were estimated to be as high as 195 000 per square kilometre, or 1 person to every 5 square metres. Twenty-nine cases were detected in October, 80 in November and 216 in December (Table 16.10). The containment of outbreaks in the densely congested areas seemed all but impossible short of an area-wide mass vaccination campaign.

In January 1973, Dr Ward assumed responsibility for the development of a special programme in Dhaka to control smallpox more rapidly. A municipal headquarters was established and 18 mobile surveillance units were formed.

● The Infectious Disease Hospital and the major graveyards of the city were visited daily to collect information on smallpox cases and deaths.

● Fixed check-points were established at transport terminals to collect information and to vaccinate passengers.
● Vaccination of the inhabitants of slum areas and refugee centres was carried out at night as well as during the day.

During 1973, 1 747 000 vaccinations were performed in Dhaka City alone, but the epidemic did not begin to abate until April. Although only 4907 cases were detected, it was apparent from the large number of deaths attributable to smallpox that there were many more cases than this—an estimated 14 000 or more.

Meanwhile, during the spring of 1973, 26 surveillance teams worked throughout the country; 5 of these were national teams each with responsibility for a region, 9 were district teams, 4 were municipal teams and 7 were assigned to the heavily infected subdivisions. Each team moved from *thana* to *thana* searching for cases in major markets, schools and selected villages. When an outbreak was discovered, local health staff were mobilized to vaccinate the residents of the 30 houses nearest to those with cases.

The programme staff worked frantically to contain the outbreaks but, with Dhaka heavily infected, smallpox quickly spread across Bangladesh. The number of reported cases increased from only 1019 in December 1972 (Fig. 16.10) to 3919 in January 1973 and to 5282 in February; in February, cases were reported from every district in the country (Table 16.11).

The epidemic reached its peak in April and once again began to subside with the onset of the monsoon. The number of reported cases was substantially greater than during the preceding year, but since the number of surveillance teams had increased and notification was more complete, it was hoped that during the monsoon season transmission could be brought under control. To facilitate this, containment procedures were changed, since it was found that outbreaks were persisting because of failure to vaccinate household contacts who were absent during the day. Accordingly, each team was required

to carry out house-to-house vaccination in each infected village at night or in the early morning.

REORGANIZATION OF THE HEALTH SERVICES, OCTOBER 1973

In October 1973, only 646 cases were notified. Reports were being received promptly from 95% of the subdivisions and there was increasing confidence that few outbreaks were being missed. On the assumption of an average of 4 cases per outbreak, it was calculated that there were perhaps 150–175 infected villages in the entire country. Dhaka was free of smallpox, as were most subdivisions of Rajshahi and Chittagong Divisions. To ensure a closer supervision of activities throughout the country, programme staff decided in October to set up 25 district surveillance teams, 1 for each of 19 districts and an additional team for each of the 6 largest districts. Each team, which consisted of 5 persons, led by a health inspector, was given transport (a motor vehicle, a motor cycle or a boat).

The plan experienced a serious setback, however, when in November, the government decided to suspend health activities temporarily in order to reorganize the health services. The field staff of the hitherto autonomous malaria eradication programme were to be merged with other health workers into a single integrated health care service. The new workers were to be called "family welfare workers", each assuming responsibility for a specific geographical area containing approximately 5000 people. The tasks assigned to them included preparing individual family health cards, registering married couples and births, performing smallpox vaccination, searching for cases of malaria and smallpox, and distributing vitamin A capsules and contraceptives, as well as providing health education and family-planning materials.

The integration of all health services had long been a tenet of WHO but practical approaches to its accomplishment had never been satisfactorily elaborated. Bangladesh's experience did not provide a model. A training programme was hastily concocted and, for a period of 4 weeks, virtually all health staff

except smallpox surveillance teams were withdrawn from the field for training. They returned to the field to begin a whole range of new and unfamiliar activities for which few of the necessary supplies were provided. Their first task, which required some 2 months to complete, was to prepare a separate health card for each family on which the name and age of each family member were to be listed. Despite the integration of field staff, however, 2 separate supervisory structures were left in place: the malaria eradication programme structure and the previous health service structure. Former malaria eradication staff and health service staff looked to their respective former supervisors for direction. The entire health service, which had not been functioning well, deteriorated further; many employees abandoned their jobs and returned to cultivating their small plots of land.

All activities—case detection, containment and vaccination—sharply diminished after November, but despite less adequate reporting by the health staff the number of cases which were detected doubled between October and December. Smallpox cases, widely but sparsely distributed throughout the country immediately after the monsoon, suddenly began to occur in large numbers in the northern districts of Rangpur and Mymensingh (Fig. 16.11), both of which, up to then, had been free from the disease.

In December 1973, the surveillance system was modified to enumerate "infected villages" as well as the numbers of cases and deaths, a practice that had been adopted earlier in the year in several states of India. In Bangladesh, each village was designated infected until 6 weeks had elapsed after the onset of the last case. (India continued to use a 4-week interval until later that year.)

During the first 4 months of 1974, the number of infected villages increased from 309 in January to 949 in April (Fig. 16.12; Table 16.12). Rangpur and Mymensingh Districts accounted for 660 (69.5%) of the total. In April, Khulna Division, which had been the epicentre of smallpox after the return of the refugees, had only 41 infected villages. The concentration of resources and supervisory personnel in 1972–1973 in the initially heavily infected areas had been remarkably successful in stopping spread, but the programme in other areas had consequently received less attention. With the withdrawal of health staff from the field and

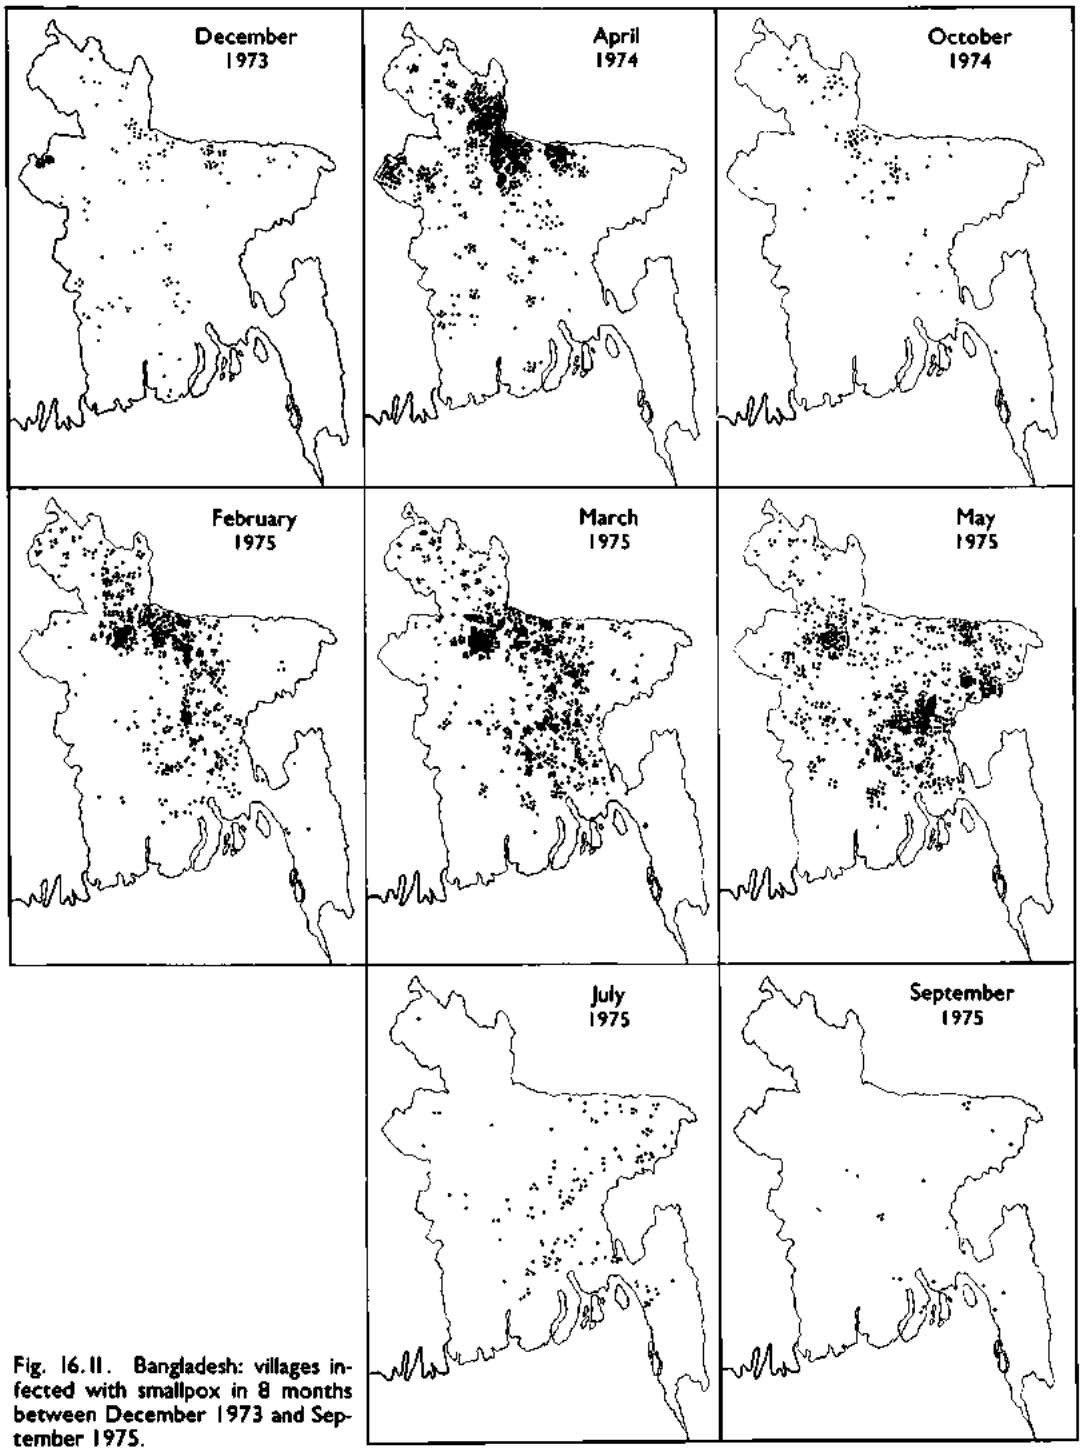

Fig. 16.11. Bangladesh: villages infected with smallpox in 8 months between December 1973 and September 1975.

Plate 16.6. **A**: Surveillance during the monsoon season was an especially arduous task as streams washed out roads, and foot-bridges often consisted of little more than a single bamboo pole. **B**: Alan H. Schnur (b. 1948) served as a US Peace Corps volunteer with the smallpox eradication programme in Ethiopia from 1971 to 1974 before being recruited as a WHO consultant for service in India and Bangladesh.

the subsequent confusion accompanying the reorganization of health services, a potentially manageable situation had developed into a major problem.

AN EMERGENCY PLAN FOR SMALLPOX CONTROL, APRIL 1974–JANUARY 1975

By April, it was apparent to everyone that the integrated health service scheme was achieving little. A redefinition of the responsibilities of supervisors and workers and of the management structure was required. Accordingly, on 9 April the government issued a detailed "Emergency Plan for Smallpox Eradication under the Integrated Health and Family Planning Programme", of which an important component provided for unified direction of the health services. Dr Mahboober Rahman, former director of the successful national malaria eradication programme, was asked to supervise all health activities, including smallpox eradication. Within the new administrative structure, responsibilities specific to smallpox eradication were defined. For operational purposes, new posts were created for staff at subdivision and *thana* levels. Civil surgeons, responsible for health matters in the subdivisions, were requested to appoint an area smallpox eradication officer for each of the 57 subdivisions and a *thana* smallpox eradication officer for each of the 424 *thanas*. In some areas, the incumbents were health services staff and in others malaria eradication staff. To assist family welfare workers in containment measures and to improve liaison with villagers, the order also authorized the temporary appointment and remuneration (6 *takas*, or about US$ 0.75, per day) of an emergency field worker for each outbreak. The field workers were to be recruited and trained in the villages. The employment of emergency field workers afforded an unexpected bonus in that they provided temporary accommodation in the villages for smallpox programme staff.

When a case of smallpox was discovered in a village, the family welfare worker was to cease other duties and initiate containment, with the help of the emergency field worker, and to inform his supervisors. The family

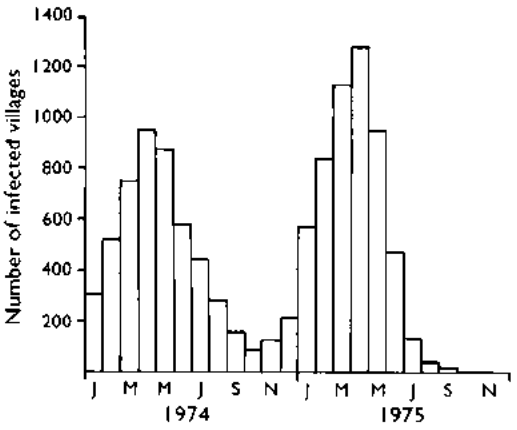

Fig. 16.12. Bangladesh: number of smallpox-infected villages, by month, 1974–1975.

welfare worker was to reside in the infected village for not less than 10 days and to vaccinate all its residents as well as all persons living within a half-mile (800 metres) radius. The newly designated *thana* smallpox eradication officers were given the responsibility for organizing and coordinating all outbreak containment programmes. The area smallpox eradication officer was required to visit each *thana* not less than once a month and to send a weekly progress report to Dhaka.

A monthly national meeting of all area smallpox eradication officers was instituted to review progress and to decide on plans for the next month. As was the case in India, the meetings proved to be especially valuable in motivating staff, in providing continuing education and in allowing for an ongoing appraisal of progress and any necessary redirection of the programme.

Each week an epidemiological report of newly detected cases and deaths was compiled at the subdivision level and sent by telegram to the national headquarters. A more detailed written report was prepared every month.

Provision needed to be made for the isolation of patients in the densely crowded areas of Bangladesh. Here it was a more difficult problem than in many other parts of the subcontinent. In rural areas, the patients could be isolated in their houses, but in the urban slums and in refugee resettlement camps, they had to be isolated in a special facility. In the cities and towns of Khulna, Chittagong, Sylhet, Rajshahi and Dhaka, there were infectious diseases hospitals which provided for the isolation of cases but, as elsewhere, they more often became centres for the dissemination of smallpox. Hospital superintendents rarely ensured that patients and visitors were vaccinated on entry. Consequently, smallpox eradication programme staff were obliged to organize and staff vaccination check-points at each hospital, sometimes with local police support. In heavily populated areas in which there were no hospitals, isolation wards or camps were set up in government buildings or even in tents, if necessary.

With 10 500 family welfare workers in the field, a defined supervisory and reporting structure, 25 special motorized surveillance teams, and 12 WHO epidemiologists, it seemed all but certain that transmission would be interrupted during the monsoon and post-monsoon period. Just 4 years previously, with far fewer surveillance teams, assisted by only 2 WHO epidemiologists, and a much less effective reporting system, transmission had been interrupted in less than 6 months.

The number of infected villages fell steadily, from 949 in April to 280 in August, of which 217 (78%) were in the northern districts of Rangpur, Rajshahi and Mymensingh. Even the distribution of the remaining outbreaks, similar to the pattern in 1970, suggested that the situation in 1974 might replicate that obtaining in 1970. The number of cases being detected remained high—1069

in August compared with 2110 in April (Table 16.13)—but detection was occurring earlier and more than 50% of all outbreaks consisted of only 1 or 2 cases. As an incentive for family welfare workers to report cases, it was decided in August to offer a reward of 50 *takas* (about US$6.50) to anyone who detected an outbreak. The system had proved successful in many states of India and its application at this time in Bangladesh seemed

appropriate. Additional help was provided by the United Nations Relief Operation, Dacca (UNROD), which was in the process of concluding its activities; it turned over to the smallpox eradication programme a central transceiver and 8 field radios. Six more field radios were added later and thus a valuable network of communication was established between the smallpox eradication programme headquarters and epidemiologists in the field.

In October 1974, only 91 infected villages remained, and periodic village-by-village searches were initiated. A similar search programme had begun in India a year before and more recently in Pakistan, but such searches in Bangladesh had not been possible before late spring because of the turmoil caused by the reorganization of the health services. During the monsoon months of 1974, national and WHO staff alike felt that searches were not required, in view of the existence of a unified health service and the assignment of a family welfare worker in each population unit of 5000 persons. Since each worker was expected to visit every house within his jurisdiction every 5 weeks and was motivated by the promise of a reward of 50 *takas* (about 5 days' pay) for the discovery of a case, it seemed unlikely that many outbreaks would be missed. The initiation of a search programme in October was intended as the first stage in the development of a scheme to confirm that transmission had been interrupted rather than as an operational tool to detect cases, as in India.

The late summer months, however, had brought still another tragedy to Bangladesh. The most extensive and severe floods for more than two decades swept through major

WHO / L. DALE

Plate 16.9. When isolation of smallpox patients in their own houses was not possible, hospitals were used, some of which were specially constructed, as was this one in Sylhet District.

An Episode Indicative of Frustration and Misguided Effort

The climate of feeling in Bangladesh oscillated between optimism—that the interruption of transmission was only months away, an opinion prevailing in October and November 1974—to profound pessimism and doubt that eradication could ever be achieved. The early months of 1975 represented an extreme of the latter mood. Frustration and exasperation sometimes compromised judgement, as was exemplified in Bogra, a municipality and district in north-central Bangladesh.

By the autumn of 1974, Bogra District, once heavily infected, had interrupted smallpox transmission at the conclusion of a thoroughly competent but exhausting campaign. However, in late December 1974 and in January 1975, outbreaks began to recur following importations from the famine-stricken area to the north, and cases were detected in the municipality. The smallpox eradication staff were concerned about the prospects of wide dissemination of smallpox from an urban area and decided that a mass vaccination campaign throughout the city was urgently required. While such a scheme might seem attractive, similar efforts in the past had always proved costly in time and manpower and were rarely successful, in part because of the continual migration of the population. Following a 10-day house-to-house mass campaign, assessment revealed that only 50% of the inhabitants had been vaccinated. A second campaign proved no more successful. Yet a third campaign was organized, this time employing 3 WHO advisers who had been withdrawn from supervision of outbreak containment in rural areas. During the course of 2 weeks, with the staff working 15 hours a day, 7 days a week, a coverage of 93% was finally achieved. No sooner had this task been completed than a major privately sponsored fair opened which drew upwards of 20 000 visitors per day. Thenceforth outbreaks began to recur throughout the district, of which most could be traced to contact with infected persons at the fair. Efforts were made to persuade the organizers of the fair to close it down or to allow all those attending it to be vaccinated when they bought their tickets. The entrepreneurs, however, were also the principal civic officials and they were not anxious to discourage attendance by making vaccination a requirement. Six weeks of discussion were to elapse before the fair was finally closed by order of the central government. By then, Bogra was the world's second most heavily infected district. Not until May did smallpox begin to subside.

parts of the northern districts, where most of the remaining infected villages were located. Some refugees began to move from the area at that time, but in November and December, the season when crops were usually harvested, severe famine struck.

During the first week of October, only 24 cases were detected, but in succeeding weeks the numbers began to increase sharply. By mid-December, there were 168 infected villages, of which only 23 were outside the two flood-afflicted districts, but 20 outbreaks had occurred as a result of spread from these districts. Outbreaks were being detected unusually rapidly—55% within a week of onset and 88% within 3 weeks. The containment of outbreaks was not optimum but, still, in 84% of them no cases were detected more than 21 days after the onset of the first case.

Because of population movement and crowding, however, smallpox spread explosively. In Rangpur District, a beggar living in a market-place died of smallpox on 2 December; 48 second generation cases in 18 villages occurred among those who had visited the market. In Faridpur District, south of Dhaka, a fatal case in a village was the source of 37 second generation cases in 4 different villages (WHO/SE/74.65, Rangaraj & Yusuf). In mid-December, cases were discovered among famine-stricken refugees in Dhaka and in the district towns of Bogra and Mymensingh. Efforts to control the spread of smallpox among refugees sleeping shoulder to shoulder in the extensive slum areas of the cities was an all but impossible task.

The occurrence at this particular time of the most widely celebrated Muslim holiday,

Plate 16.10. Increasing numbers of staff and additional resources were provided to the programme in Bangladesh during 1974–1975 in a final intensive effort to eradicate smallpox from Asia. **A**: Andrew N. Agle (b. 1937), a veteran of smallpox eradication programmes in western and central Africa, 1966–1971, then in Afghanistan, 1972–1974, was the WHO administrative officer in Bangladesh. **B**: Jane Brown (b. 1942), seconded from WHO Headquarters for 6 months, directed radio communications. **C**: CARE, a private charitable organization registered in the USA, built an operations building, "Smallpox Zero", to house additional programme staff. Additional buildings were constructed for the storage of parts and a garage for maintenance of a new fleet of Indian-made Jeeps.

the *Eid* festival (*Id ul Fetre*), further compounded the problem, since this feast was the occasion for large family gatherings, entailing extensive travel.

Meanwhile, in Nepal and Pakistan, transmission had been interrupted; in India, the incidence of smallpox and the number of infected villages were declining steadily. It became increasingly apparent that the course of events in Bangladesh would determine the success or failure of the endeavour to eradicate smallpox from Asia. Additional international staff were assigned to strengthen the programme in Bangladesh, the number increasing from 8 in June 1974 to 21 in January 1975. But smallpox continued to spread. As has already been mentioned, only 91 villages were infected at the end of October, but the number had increased to 130 by the end of November, to 223 by the end of December, and to 572 by the end of January. This last number was almost twice the figure recorded for the corresponding period one year earlier.

A catastrophe from the viewpoint of smallpox eradication occurred when the government decided that urban bustees should be demolished. In a matter of a few weeks, bulldozers and police dispersed an estimated 50 000–100 000 additional refugees from the cities throughout the countryside. Some had smallpox or were then incubating the disease. A frustrated, demoralized staff was called upon to regroup and to mount yet another national effort.

NATIONAL MOBILIZATION FOR SMALLPOX ERADICATION, FEBRUARY 1975

Beginning in December 1974, national health personnel and WHO staff stationed in Bangladesh, New Delhi and Geneva met repeatedly to decide on a revised strategy and additional measures that might be taken. With the extensive continuing movement of population, it was apparent that efforts would need to be greatly intensified, and that substantial additional funds would be required. However, WHO's Voluntary Fund for Health Promotion, as well as discretionary funds in the WHO regular budget, had been exhausted in strengthening the programme in India. Additional support would have to be sought, but this would require the approval by the Bangladesh Planning Commission of a revised plan of operations and the concomitant financing. Although the Secretary of Health and the WHO Representative in Bangladesh supported the programme, they were of little help. Both were adamant that eradication could be achieved only through a national mass vaccination campaign conducted through the basic health service structure. They were not persuaded by the argument that this would be futile in an already well vaccinated population, nor could they accept the fact that the newly created basic health service structure had all but ceased to function. Fortunately, the recently appointed principal health adviser to the Planning Commission, Dr Mohammad Ataur Rahman, had a far better and more realistic understanding of the problem and the resources needed. Dr Rahman was a knowledgeable and skilful administrator and virologist who had played a key role in the development of smallpox vaccine production in Dhaka, and subsequently had closely followed the progress of the eradication programme. Through his efforts, the Planning Commission was persuaded to direct an appeal for assistance to a number of international agencies. The Swedish International Development Authority responded—as it had in India—most rapidly and generously, making available US$ 3.5 million. Significant contributions were also made by Canada, Denmark, Norway and the United Kingdom.

In February 1975, a presidential directive was issued which declared smallpox to be a national emergency and ordered the mobilization of all available resources to assist in its eradication. Thirty-five Jeeps of Indian manufacture were hurriedly procured and driven to Bangladesh; others were loaned from other programmes. Additional radios, motor cycles, boats and outboard motors were obtained. Mr Rodney Hatfield, a young volunteer from OXFAM (a charitable organization registered in the United Kingdom), assumed responsibility for transport maintenance and repair; an old garage was transformed into a fully equipped workshop with a staff of 12 mechanics; and numerous Ministry of Health vehicles that had long been in disrepair were made roadworthy. An operations building was rapidly constructed by CARE (a charitable organization registered in the USA), using a new technique of jute and fibreglass construction. To coordinate field operations, WHO's former senior smallpox adviser in Afghanistan, Dr A. G. Rangaraj, joined the

staff. Dr Stephen Jones and Dr Donald Francis came from India to assist in adapting the most effective techniques employed there to conditions in Bangladesh.

Numerous other WHO staff and consultants were urgently recruited from countries around the world (Table 16.14), many of them having served in Africa, South America and other parts of Asia. It was a group remarkably diverse in nationality, being composed of Brazilian, British, Czechoslovak, Egyptian, French, Soviet, Swedish and Swiss citizens. The Center for Disease Control and OXFAM were especially helpful in recruitment. New colleagues arrived every 2 weeks, to rendezvous in New Delhi for a Monday briefing. On Tuesday they flew to Dhaka and over the next 3 days received intensive field and classroom training before being dispatched to the field. Because there was a shortage of hotel accommodation, a house was leased which could accommodate 18 persons—unofficially called WHOSE House (an acronym for World Health Organization Smallpox Eradication). By May, 71 international staff were working in the field, and during that month the recruitment of Bangladeshi epidemiologists from universities and other settings was initiated.

A formidable challenge was presented by the administrative coordination and financial monitoring of a programme which, operating with US$12 000 a month in September 1974, was spending US$125 000 a week by February 1975. This daunting task was capably handled by Mr Andrew Agle, who had served in the western Africa and Afghanistan eradication programmes and had joined the Bangladesh programme staff in September 1974. He and Mr A. Alim Mia, a Bangladeshi administrator

Plate 16.12. WHO consultants. **A**: Pierre P.L. Claquin (b. 1947), a French epidemiologist, engaged for 3 months in March 1975, eventually spent a total of 27 consultant months in Bangladesh. **B**: T. Stephen Jones (b. 1941) was one of the many epidemiologists provided to WHO by the Centers for Disease Control in the USA. He served for 3 months in India in 1974 before spending 3 months in Bangladesh in 1975.

who had served with the programme since its inception, dealt with a considerable array of problems, both expected and unexpected. One of the more vexing was that of disbursing funds to the field epidemiologists for the payment of temporary staff to cover board and lodging, as well as petrol and repairs. The telegraphic transfer of funds to bank branches in peripheral areas would have been the most logical way of coping with the problem, but was technically impossible for many months. The only workable alternative approach was to disburse the funds at monthly meetings of supervisory field staff. However, the largest banknote then available was a 10-*taka* note (about US$1.25) and, during the intensive period of activity, field staff were receiving 30 000 *takas* or more each month. The inevitably large bundle of banknotes was difficult to handle, but the problem was solved by using capacious gunny sacks and carrying them into the field tied to the back of a motor cycle; although there was no attempt at concealment, thefts never occurred.

Under the national mobilization plan, and with many additional field epidemiologists available, containment measures were greatly expanded from previous strategies which called for one family welfare worker and one emergency field worker to vaccinate everyone living within a half-mile (800-metre) radius of each case. The containment measures were basically the same as those that had evolved in India.

A worker who discovered a case was instructed to isolate the patient immediately and to vaccinate all household members. A resident supervisor was appointed, usually the health worker in the area, who recruited 4 house guards responsible for keeping the patient in the house and for vaccinating all visitors. Food and water were provided if needed. (For the recording of activities, special "house guard books", such as had been used in India, were introduced in April.) The resident supervisor then hired 4–6 emergency field workers at 6 *takas* each a day. He trained them to register and vaccinate all residents and visitors within a half-mile radius of the infected house, and to search for cases in all markets, schools and houses within a 2-mile (3.2-kilometre) radius (Fig. 16.13). When these tasks were completed, the workers revisited all persons within the half-mile radius to detect and vaccinate any newcomers or others who had been missed during the intensive vaccination phase.

Resident supervisors were provided with a "containment book" in which the following information was recorded:

- a list of patients and the stage of their illness;
- information pertaining to the source of infection and contacts of the cases;
- a list of household members and temporary residents of Zones A and B (i.e., those living within a 100-yard (90-metre) and a half-mile (800-metre) radius, respectively, of the infected house);
- a list of staff and work schedules for all involved in containment;

Dr A. B. M. Kamrul Huda

Dedication and sacrifice were characteristic of many who served the programme, and a few gave their lives. One young medical officer who did so was serving at the time as the Subdivisional Medical Officer of Health in Chittagong. He was notified late one night of possible smallpox on an offshore island and arose early the next morning to take a ferry to the island. Because of high winds the ferry was cancelled. Dr Huda was anxious to investigate the rumour and took a small local boat instead. The boat capsized en route and Dr Huda drowned. He died on 3 March 1975, leaving a wife and two young children.

- a record of visits of supervisory staff from *thana*, subdivision and district levels;
- a map of the outbreak area showing each house, all houses being numbered;
- a record of all financial transactions—e.g., payments to emergency field workers for petrol, etc.

Check-points were set up on strategic paths and roads to collect information about other areas in which cases might exist and to vaccinate passers-by.

The source of infection of each case was examined and all possible contacts were vaccinated. Any contact with fever was isolated and members of the household were vaccinated. Whenever the suspected source of infection was in another *thana*, or whenever a contact had left the village for another area, a special message (cross-notification) was sent by messenger, telegram or radio. District, subdivisional and *thana* officers, surveillance teams and epidemiologists made periodic surprise visits to assess the efficacy of the work.

At the monthly meetings of supervisory field staff, problems were reviewed and procedures changed as required. An example of an unexpected event was the discovery by a Bangladeshi epidemiologist, Dr M. A. Sabour, that in 11 out of 17 outbreaks for whose containment he was responsible, cases were recorded 15 days or more after containment had begun. As he discovered, most of the cases were relatives of patients and should have been identified and vaccinated. He learned, however, that when a family in an infected home was asked to give the names of all recent visitors, they omitted to mention the names of relatives—since relatives, in their culture, were not considered to be visitors. The steady improvement of containment could be measured by the diminishing proportion of outbreaks in which cases occurred more than 15 days after detection of the outbreak (Fig. 16.14). In November, cases occurred in 27% of the outbreaks more than 15 days after detection; by June, the proportion was less than 10% (Foster et al., 1980).

With increasing numbers of epidemiologists in the field to investigate the source of outbreaks, to trace contacts who might have left the scene of an outbreak and to discover rumours of outbreaks as yet undetected, many possible additional cases were identified in more distant areas. The radio network was used extensively to forward such information for other staff to investigate. Beginning in February 1975, each cross-notification was recorded and the results of the field investigations were tabulated (Table 16.15). Between February and December 1975, 1468 cross-notifications were transmitted, leading to the discovery of 28 previously unknown outbreaks—not a large yield for the number of reports transmitted and investigated but important, nevertheless, in hastening the interruption of transmission. Three addi-

tional outbreaks were discovered through notifications received from India.

SPECIAL SEARCH PROGRAMMES

A special 6-day village-by-village search for cases had first been organized in October 1974 and a second was conducted in December of that year. It was believed that if the family welfare workers could be carefully instructed to perform well only one of their many assigned functions—i.e., that of smallpox case detection during a 6-day tour of their area—the results would be better than if this activity were but one of the numerous tasks required of them. *Thana* supervisors reported that the searches in October and December were reasonably successful but assessment by district and subdivision staff and surveillance teams indicated that there were large areas in which no search had been carried out and few in which searches had been conducted competently.

With additional staff to assist in supervision, some of whom had had experience with this technique in India, more energetic search programmes were introduced in April 1975; these were repeated every 4–6 weeks. Approximately 14 500 staff were engaged in each search, following special training programmes at each operational level.

The workers were asked to visit markets, tea-stalls and every 20th house. They were instructed to show the smallpox recognition card at each location, and ask the viewers whether they recognized the disease—which most of them did. The health workers were told to inform their audience of the reward for reporting an unknown case of smallpox and where to report it; to record any information obtained about persons with rash and fever, including the deaths of any of them; and to report cases to the *thana* supervisor.

After each survey, 1500 villages were randomly selected to assess the efficacy of search. Assessment in Bangladesh was greatly facilitated by the fact that every house in the country was numbered—a practice begun by the staff of the malaria eradication programme and kept up by the smallpox eradication personnel. An assessment of the results of the April search revealed that surprisingly few villagers knew of the reward for reporting a case. On further investigation, it was found that health workers, wanting to claim the 50-*taka* reward for themselves, did not publicize it. This situation was corrected in May, when the reward was offered both to the person who reported the outbreak and to the first health worker to confirm it. The April assessment showed that only 30% of villagers knew of the reward, but by September this proportion had increased to 70%.

In contrast to the experience in India, the number of outbreaks discovered during each search was not high (Fig. 16.15). However, in India, the reward was not offered until many searches had been conducted, while in Bangladesh its existence was announced even before the first searches began. The searches in Bangladesh were more effective in increasing public awareness of the reward and in stimulating reporting than in detecting outbreaks. As an illustration, a review of the last 119 outbreaks which occurred showed that 55 (46%) had been detected by reports from the

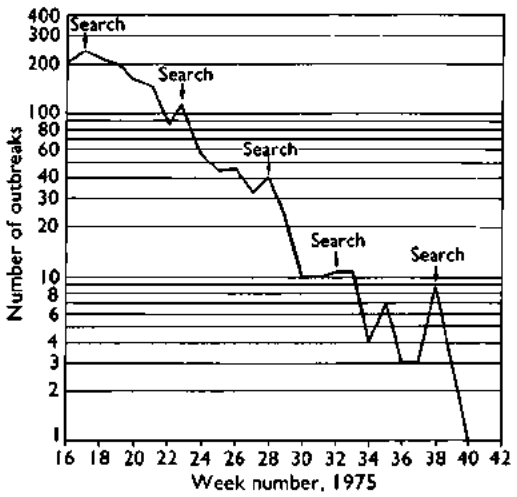

Fig. 16.15. Bangladesh: number of outbreaks detected by week, 1975.

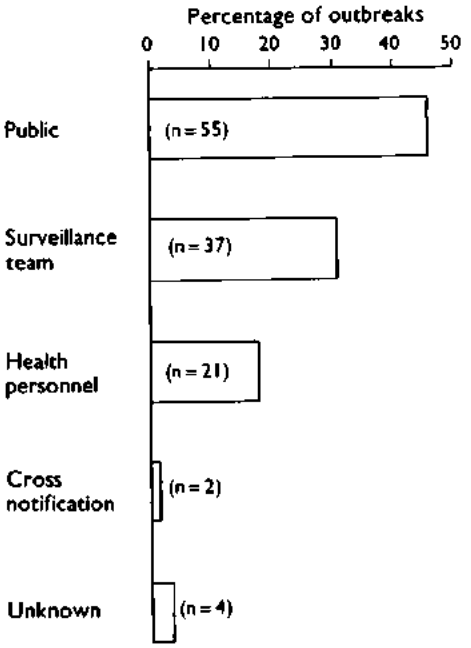

Fig. 16.16. Bangladesh: source of report of the last 119 outbreaks of smallpox.

public and 37 (31%) by surveillance teams (Fig. 16.16).

The number of personnel engaged in the programme was far larger than it had ever been. An estimate during the 3-month period of greatest activity revealed that an average of almost 12 000 persons were working each day (Table 16.16).

Between February and April, the number of reported cases steadily increased, from 1703 in February to 2467 in March and to 3948 in April. Smallpox appeared to be as great a problem in 1975 as it had been in 1974 although, on the basis of later surveys, it was estimated that 83% of all cases were reported in 1975 compared with only 49% in 1974 (Hughes et al., 1980).

The occurrence of epidemic smallpox extending throughout Bangladesh for a fourth year was politically uncomfortable for the Secretary of Health, a former surgeon. He fully accepted the idea of mass vaccination but was uneasy about the concept of a programme for detecting cases and containing outbreaks. The success of surveillance–containment operations in 1970 did not convince him. His personal experience with smallpox control in the Ministry had been confined to the period since Bangladesh's independence, and for the last 4 years optimism had been expressed by the staff during and immediately after the monsoon each year, but epidemics and emergency programmes inevitably followed in the spring. For advice he turned most often to the WHO Representative in Bangladesh, a public health physician but one who understood neither smallpox epidemiology nor the eradi-

Table 16.16. Bangladesh: personnel employed during the 3-month period of maximum containment of the smallpox eradication programme, May–July 1975

Personnel category	Number	Number of days per man per 3 months	Total number of man-days in 3 months[a]
Headquarters staff	80	75	6 000
Epidemiologists	90	80	7 200
Area and *thana* surveillance officers	500	30	15 000
Surveillance team members	400	75	30 000
Health staff for 2 searches	12 000	12	144 000
Containment:			
Health staff	1 000	70	70 000
Emergency field workers	10 000	90	900 000
Total	24 070	–	1 072 200

[a] The number of man-days per month totalled 357 400, or an average of 11 913 persons working every day.

cation strategy any better than the Secretary of Health. With smallpox incidence rising and with increasing international interest as to whether Bangladesh could or would be able to stop transmission, tensions were great. The Secretary of Health and the WHO Representative repeatedly and vehemently demanded that the surveillance–containment programme should be stopped and the entire population vaccinated forthwith. Dr Mahboober Rahman and his national and WHO colleagues argued that mass vaccination was futile, that vaccinial immunity was already high and that the surveillance–containment approach offered the only possible solution. Indeed, the level of vaccinial immunity, as shown in a 1976 national survey was 91% overall.

However, without notice to the programme staff, the Secretary of Health would periodically order the health staff in a district or subdivision to stop all other activities and to vaccinate everyone in the area concerned. Usually, this was accompanied by threats of punishment if any unvaccinated person was discovered at the end of 7 days or some such brief period. After lengthy discussions, the Secretary would eventually be persuaded to rescind the order, but, not infrequently, for many days outbreak containment programmes were abandoned and surveillance was stopped. Further problems occurred when the Secretary and the WHO Representative made one of their frequent visits to the field. The Secretary would announce that on his trip, he would stop at villages along his route and expect to find that every single person had been vaccinated. A flurry of activity ensued to vaccinate everyone along the route he was expected to follow, again at the expense of outbreak containment measures. An even more serious problem arose when he required senior staff to pledge to resign if cases of smallpox were found after a certain date, an action which resulted in the suppression of reports of cases. The problem was not finally resolved until April, when the WHO Representative returned to Geneva and was replaced by the able Dr Eung Soo Han. The Secretary's continuing concern about his and his country's image was reflected in May 1975 by his decision not to attend the World Health Assembly. Instead, he dispatched Dr Rahman to respond to the anxious inquiries he knew would be expressed about the Bangladesh smallpox eradication programme.

THE FINAL CHAPTER

From April to August, the number of infected villages decreased at a substantially more rapid rate than in preceding years—from 1280 in April to 131 in July. The staff began to chart weekly the number of "active cases" still present—i.e., the number of cases in which the scabs had not yet been shed. In a progress report to WHO staff in July 1975, Henderson wrote: "Some years ago . . . we had plotted progress on a country and provincial basis, subsequently on a district basis and then by blocks/*thanas*. In now monitoring the numbers of individuals capable of transmitting infection, I believe we've reached a final stage." The last case in India, the last of 32 importations from Bangladesh, occurred in May, leaving Bangladesh the only endemic area in the whole of Asia. The search in July detected 33 outbreaks and that in August only 7. With the extensive resources available and a programme functioning so well, the end once again appeared to be in sight. There was, however, one further tragic event.

On 15 August, Sheik Mujibur Rahman, the first President of Bangladesh, revered as the father of the country, was assassinated in a military coup. The airport was closed and the borders sealed. Communications by radio were suspended for 2 weeks and although field staff continued to work, movement in and out of Dhaka was limited. Fearing that vehicles might be seized, the smallpox eradication staff hurriedly dispersed them from the motor pool to locations all over the area. For nearly a month, most of the staff remained apprehensive that civil war might again occur and, with it, the movement of hundreds of thousands of refugees—and renewed epidemics of smallpox. India, meanwhile, greatly strengthened its complement of staff in border areas. Fortunately, the country remained quiet, the monsoon rains were plentiful, an excellent crop was harvested and the enormous movement of refugees ceased.

The post-monsoon period was not, however, without incident, as a Japanese scientific team arrived in Dhaka bringing with them a new laboratory technique for the rapid diagnosis of smallpox. It was a propitious moment at which to undertake the investigations, since Dr Farida Huq, a highly competent virologist, was present in Dhaka at that time and able to perform confirmatory studies on specimens from suspected cases. The new immunofluorescence technique seemed capa-

Plate 16.13. Smallpox eradication programme offices in the field were simple but functional like this one in Chandpur *Thana*.

ble of identifying variola virus in pus or scabs within hours (instead of days) after a specimen had been submitted. Only 19 villages were infected in September as the team began its work, but many of the first specimens examined were reported as positive for variola virus. Surveillance teams were then taking many specimens from cases which they had diagnosed as chickenpox, simply to confirm by laboratory test that smallpox was not present. Many of these specimens were reported to contain variola virus and for weeks consternation and bewilderment prevailed as containment operations were begun and then stopped in numerous presumed outbreaks. There was a strong suspicion that something had gone seriously awry when immunofluorescence staining showed that material taken from a boil on the back of one of the WHO advisers contained variola virus. A technique which had worked well in the laboratory had failed when used in the field, and was soon stopped (Tarantola et al., 1981).

THE LAST OUTBREAK

When the conflicting laboratory and clinical data had been resolved, it became clear that smallpox transmission had apparently been terminated– the last known case having occurred on 14 September. Over the succeeding weeks, 8 previously undetected outbreaks were discovered in Patuakhali, Barisal and Dhaka but in none had cases occurred after 14 September. The monthly programmes of systematic search continued and, except in these three districts, independent assessement showed excellent results. At the beginning of November, civil disorder erupted, with local fighting breaking out in three different parts of the country. The United Nations was sufficiently concerned to recall its personnel to Dhaka. Only the WHO smallpox eradication staff remained in the field. But no additional cases could be found.

The progress of the smallpox campaign in Asia had been followed closely by the press, which believed, as did the personnel involved, that eradication of smallpox from Asia was the most formidable obstacle to global eradication. Early in November, 6 weeks after the onset of the last case, the only active outbreak in Asia was scheduled to be removed from the list. It was agreed, however, that caution was required and an additional 2 weeks should be allowed to elapse before an announcement was made. No cases occurred, and on 14

November 1975 WHO announced at a press conference that 2 months had passed since the onset of the last case in Bangladesh; and while the intensive search for cases would continue in Bangladesh and other countries, there was at that time no known patient in the whole of Asia, indeed in the world, with variola major. On the following day, 15 November, the eradication programme's telex control room received the following cable from the densely populated Bhola Island, off the southern coast:

"ONE SUSPECT SMALLPOX CASE DETECTED VILLAGE KURALIA [UNION COUNCIL] SOUTH DINGALDI [POLICE STATION] BHOLA DATE OF DETECTION 14/11/75 DATE ATTACK 30/10/75 CONTAINMENT STARTED DETAILS FOLLOW".

(The date of onset was later confirmed to be 16 October 1975.)

A team of epidemiologists immediately left Dhaka for Bhola Island expecting to find a misdiagnosed case of chickenpox. They reached the infected house only after a 24-hour journey by speedboat, steamer, Jeep, motor cycle and finally on foot. The diagnosis was not in doubt: it was smallpox, and this was confirmed days later by the laboratory. Everyone was concerned. It was November, the monsoon was over, and the season when smallpox was most rapidly transmitted was at hand. If there was one case, there had to be others in the chain of transmission.

Bhola Island, located at the mouth of the Ganges, had a population of 960 000 and an area of approximately 2600 square kilometres. Regular ferries connected the island with the mainland and other islands and these were heavily used.

In 1970, Bhola had been devastated by a tidal wave, which was followed by a relief operation that included a smallpox vaccination campaign. Because of this, the proportion of persons with a vaccination scar was higher than in most of the country. During 1974 and 1975, few smallpox cases had been reported. However, in August 1975, it was discovered that a medical officer had failed to report known outbreaks. Subsequently, surveillance had been reinforced, and since the beginning of August 141 cases and 33 deaths had been detected. All but 2 of the outbreaks, one of 43 cases and one of 44, had ceased before discovery. Once again, investigation revealed the suppression of reports and so, early in October, an additional surveillance team had been sent from another area, the Bhola surveillance team reorganized, and an epidemiologist posted to the island for full-time work.

On 6 November 1975, while conducting a search of markets, the Bhola surveillance team received information about an outbreak in Kathali village. During the course of investigating and tracing the sources of infection, the team discovered outbreaks in 3 other villages with cases extending back to 2 March. A search began within a 5-mile (8-kilometre) radius of each of these villages. During a tea break in one of the markets, the surveillance team obtained information about the death of a person with rash in the village of West Joynagar, 5 kilometres to the south.

The death had been reported to the *thana* smallpox eradication officer, who had sent a family welfare worker to investigate. His conclusion had been that the death was caused by measles. On investigation, the surveillance team was in no doubt that it was due to smallpox. A search revealed an outbreak of 7 cases and 3 deaths. One of the patients was a heavily pockmarked 8-year-old girl who informed the team that there were other cases in Kuralia village, some 200 metres to the west of her house. Investigation there revealed 2 cases, one of which was in a 10-year-old boy whose onset of illness was on 6 October and the other in a 3-year-old girl, Rahima Banu, who had become ill on 16 October.

By the time of investigation, Rahima Banu was the only known patient with active smallpox in all of Asia. Accordingly, extraordinary efforts were begun immediately to contain the outbreak and to discover other possible cases. The surveillance team which had detected the outbreak was soon joined by teams of epidemiologists from Dhaka and other areas. A launch brought vaccine, light transport (motor cycles and bicycles), speedboat engines, drums of petrol, kerosene lanterns, loudspeakers and other equipment. The patient, who still had a few scabs on her legs, was isolated at home. House guards were posted 24 hours a day; food and money were supplied to the family so that no one would have to leave the house. Vaccination of the 18 150 people living within a radius of $1\frac{1}{2}$ miles (2.4 kilometres) of the infected house was begun immediately. This task included day and night house-to-house vaccination, the enumeration of every household member, the checking of vaccination results, and the vaccination or revaccination of any newcomers to the village.

WHO / D. J. M. TARANTOLA

Plate 16.14. Rahima Banu, a 3-year-old girl from Bhola Island, Bangladesh, was the last case of smallpox in Asia and the last naturally occurring case in the world of variola major, the more virulent form of the disease. Her illness began on 16 October 1975, approximately 3 weeks before this picture was taken. The depigmented areas of her skin are sites where lesions were present.

The area within a 5-mile (8-kilometre) radius of the infected house was searched repeatedly by successive teams; each team searched for cases with fever and assessed the performance of the preceding team. The 7 markets and 9 schools, as well as all healers in the area, were visited repeatedly to pick up rumours of other cases. Each house on Bhola Island was searched by health staff under the guidance of epidemiologists and surveillance teams, which had been allocated specific geographical areas. This search also covered all public meeting-places such as markets, schools and tea-shops. Whenever it was reported that a member of any household in the outbreak area had left, the responsible authorities were notified so that the person concerned could be found, vaccinated and kept under surveillance.

A difficult problem was the poor means of access from the centre of the island to the shore, where most of the outlying villages could be reached only after a difficult journey by bicycle or on foot. Frequently, the paths leading to these villages were cut by small rivers caused by fluctuating tides. The settlements along the shore were occupied by landless peasants or fishermen, who were the most distant from health centres and the least likely to be visited by health staff. They were generally much less well vaccinated than other groups and unlikely to report any cases of smallpox. Accordingly, a dispensary-launch began a methodical village-by-village search, which had to be planned daily according to the tides. Local launches were used also.

A 500-*taka* (US$33.00) reward was offered to anyone reporting a case of smallpox. This was widely publicized through the use of posters, pamphlets, handbills, loudspeakers and, from Dhaka, the press and other media. Check-points were established at such places as bus stations, ferry docks and crossroads, where travellers converged. Information was collected about cases with rash and these were checked by mobile teams.

About 10 kilometres north of the site of the outbreak, in Bhola town, a control room was established where progress could be recorded on maps and charts. Radio communication was established to permit regular contact between the control room, the dispensary-launch travelling along the shore areas, and Dhaka.

The health staff engaged in this outbreak alone (within a 5-mile radius) consisted of 3 epidemiologists and more than 40 health staff and temporary workers. For the rest of the island there were 3 epidemiologists, and 180 specially deputed health workers to assist the subdivisional staff in the house-to-house searches. In addition, 16 emergency field workers worked at check-points and conducted municipal searches.

By 19 November, the fifth day after the discovery of the outbreak, the first round of vaccinations within the 1½-mile radius of the infected house had been completed. A second round was begun, covering the same area, and was completed 8 days later. Of a listed population of 18 150, 16 295 were vaccinated. A later assessment showed that 100% of the residents living within a half-mile radius and 95% of those living within a 1½-mile radius of the infected house had been vaccinated.

WHO / P. ROBERTS, 1975

Plate 16.15. Mohammed Matiur Rahman (b. 1932), a medical officer with the national programme in Bangladesh, questioning villagers about possible smallpox cases during the search on Bhola Island.

Meanwhile, 2 consecutive house-to-house searches within the 5-mile radius were completed by 8 December. Among the 120 000 population, 52 individuals with fever and rash were found, including 17 with chickenpox and 11 with measles, but there were no cases of smallpox. During the following 2 months, 2 additional house-to-house searches of Bhola Island were conducted. During these operations, 2 more unreported smallpox outbreaks were discovered: one had occurred in 1974 and had resulted in 18 cases and 6 deaths; the second involved 1 person, who had become ill in July 1975.

At the end of December, the additional staff who had been sent to Bhola began to be recalled to their respective districts. Kuralia was declared smallpox-free and the 2-year post-epidemic surveillance period commenced.

MORBIDITY AND MORTALITY DATA

To obtain precise data on the age distribution and case-fatality rates for smallpox, special studies were undertaken in 1976 to enumerate all cases and deaths in 165 outbreaks, including 115 that constituted the last outbreaks in the country, and 46 others, which were investigated in northern Bogra District. In all, 1127 cases were recorded (Table 16.17).

Cases occurred among all age groups but the youngest were the most heavily afflicted. Of the total, 55% occurred among children under 10 years of age, a group that made up only 34% of the population. Overall, the case-fatality rate was 18%, comparable to that in India. The much higher case-fatality rate among males over 20 years than among females in the same age group was notable but no explanation was found for this disparity.

CONCLUSIONS

The programme in Bangladesh was uniquely distinguished by extremes—with peaks of optimism and success alternating with catastrophic setbacks resulting from natural disasters of flood and famine and man-made disasters inflicted by civil war and the disruptive reorganization of the health services. The frustration and pessimism of the programme staff during the spring of 1975 were matched only by the feelings of their counterparts in Bihar State, India, 6 months earlier and are vividly depicted in the book *Quest for the Killers* (Goodfield, 1985).

The successful application of a surveillance–containment programme in the spring of 1970 had so rapidly and so easily interrupted transmission that it was difficult to believe that the success could not be repeated in 1972 or in the 2 succeeding years. In retrospect, the 1970 experience in Bangladesh to some extent paralleled events in India, where, for example, transmission was so rapidly interrupted in Tamil Nadu State (population, 41 million) in 1968 and in Gujarat State (population, 27 million) in 1971. These successful programmes engendered unwarranted confidence that transmission could be quickly interrupted in a population already reasonably well vaccinated and with so numerous a health staff available. What was not appreciated was the dearth of supervision of the host of health workers in many parts of India and in Bangladesh. Given optimum conditions of population stability, vigorous and enlightened senior programme leadership and the application of surveillance–containment

Table 16.17. Bangladesh: cases of and deaths from smallpox and case-fatality rates in 165 outbreaks, by age and sex, 1975

measures at a declining or low point in the long-term periodicity of smallpox, a modest surveillance–containment programme was rapidly and dramatically successful. When natural or man-made disasters created hordes of refugees, when leadership was deficient or when smallpox was at the height of its periodic wave, it became apparent that the health structure had little in reserve with which to cope with the situation.

Progress in programmes in the northern and eastern states of India had been disappointing and frustrating, but within little more than a year after the special intensified national programme began in September 1973, transmission was interrupted. In Bangladesh, however, the interruption of transmission, once successfully achieved, was frustrated in each of 3 successive years by unexpected disasters. With courageous confidence, bolstered by material support from Sweden and other countries, a remarkably diverse national and international staff made one more heroic effort in 1975 and succeeded in attaining their goal. If civil war had broken out in August 1975, following the assassination of Sheik Mujibur Rahman, transmission would probably have persisted for at least another year and might perhaps still be occurring. History records, however, that Rahima Banu was the last victim of variola major—on 16 October 1975.

INTRODUCTION

Progress in smallpox eradication throughout most of Africa was more rapid than in Asia, despite the fact that the majority of African countries had less developed health service infrastructures, poorer roads and communications and proportionately fewer health personnel. The rapidity with which smallpox was eliminated in an area embracing 21 countries of western and central Africa (Fig. 17.1) was especially significant. Programmes in all but one of the countries in this region were supported by the United States Agency for International Development (AID) with technical direction and coordination provided by the United States Communicable Disease Center (CDC), later called the Centers for Disease Control. Most national programmes in this area began early in 1967 and all were fully operational by January 1968. By September 1969, every country except Nigeria had interrupted smallpox transmission, and in May 1970, only 3½ years after field operations had begun, the last case in this region was detected. Within this brief span of time, smallpox had been eliminated from some of the least developed and most

heavily infected countries in the world—from a contiguous area greater in size than the continental USA, inhabited by 111 million people (the estimated population in 1967).

From November 1965, when the USA decided to support the smallpox eradication effort in western and central Africa, this programme played a pivotal role in the ultimate achievement of global eradication. The resolve of the USA to commit substantial resources lent encouragement to the Nineteenth World Health Assembly's decision in 1966 to embark on the Intensified Smallpox Eradication Programme. Programme staff made important early contributions to the development and improvement of field operations; their observations changed the understanding of the epidemiology of smallpox and served to alter the global strategy. The demonstration that smallpox could be eliminated rapidly throughout such a vast developing area provided a crucial impetus to programmes in other countries and convincingly showed that the goal of eradication was realistic, even in areas in which health services were the least adequate and in which difficult problems—even civil war—had to be surmounted. Finally, many individuals who acquired experience in this regional programme subsequently made important contributions to the development and execution of programmes in other parts of the world.

The activities and decisions leading to the development of this endeavour are thus of particular significance. Interestingly, despite the importance of the programme, the USA's decision to contribute to it did not result from a considered policy judgement to support the WHO Intensified Programme as such. Rather, it began as an ancillary objective in a multicountry programme for the control of measles in many of the less populous countries of this region.

After the programme had begun, the staff of CDC bore full responsibility for its technical guidance and coordination, although they

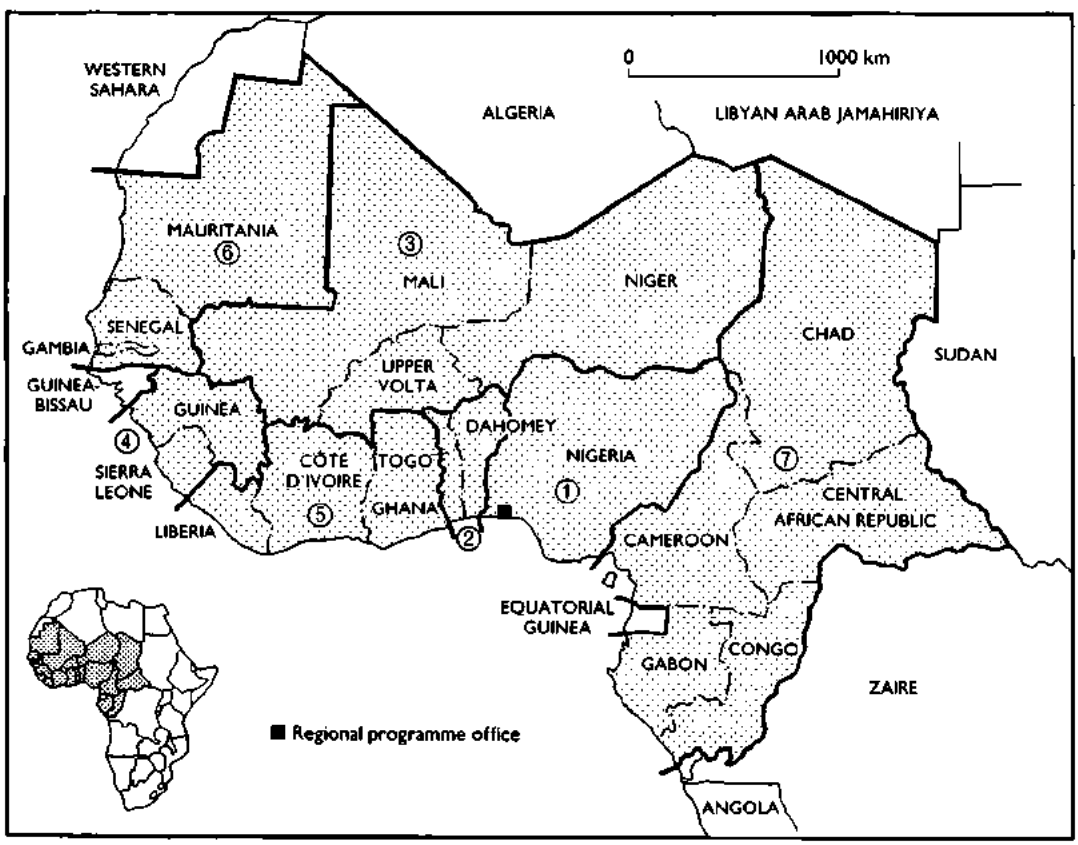

Fig. 17.1. Western and central Africa: countries that participated in the smallpox eradication and measles control programme, 1967–1972. The bold lines and circled numerals indicate the country groupings under which the national programmes are discussed in the text.

Changes in Political Status and Names of Countries

In 1967, when the AID-supported regional programme began, all but 2 of the 21 countries (Equatorial Guinea and Guinea-Bissau) shown in Fig. 17.1 were independent States. Liberia had enjoyed sovereignty since 1847 but 18 others had become independent between 1957 and 1965. Thirteen had been colonies of France and were commonly referred to as francophone countries. These were the Central African Republic, Chad, the Congo, Côte d'Ivoire, Dahomey, Gabon, Guinea, Mali, Mauritania, Niger, Senegal, Togo and Upper Volta. Cameroon, which had been administered jointly by France and the United Kingdom, was officially bilingual. Four—namely, the Gambia, Ghana, Nigeria and Sierra Leone—had recently obtained independence from the United Kingdom.

Equatorial Guinea (population in 1967, 278 000), a colony of Spain, became independent in 1968 and subsequently received supplies and equipment from the USA for smallpox and measles vaccination. Guinea-Bissau (population in 1967, 525 000), a colony of Portugal, became independent in 1974 after assistance from the USA to the regional programme had terminated.

Two countries changed their names after the programme's conclusion. Dahomey was renamed Benin in 1975, and Upper Volta was renamed Burkina Faso in 1984. In this chapter, which describes activities before 1975, the former names, Dahomey and Upper Volta, are used.

kept in close contact with WHO staff responsible for the global programme. WHO's contributions were modest, consisting mainly in the provision of bifurcated needles, an average annual subvention of US$200 000 to cover local costs, technical support to one programme (Mauritania) and the organization of activities pertaining to the certification of eradication in 1976. The remarkable achievements in this part of Africa are therefore primarily those of the national governments and staff, AID and the personnel of CDC.

THE REGION OF WESTERN AND CENTRAL AFRICA

Within the region defined in this book as western and central Africa were 21 countries, of which 14 reported cases of smallpox in 1966 (Table 17.1). The predominant form of smallpox was variola major with a case-fatality rate of 5–15%. Because established health services were few and reporting was very incomplete, the actual geographical extent of smallpox and its true incidence were uncertain when the programme began.

The region was diverse both in ecology and in culture. Rain forests predominated along the coast, giving way to savanna and finally to the Sahara desert. Throughout the region, hundreds of tribal groups speaking their own local language were organized into various tribal and theocratic societies which often transcended national boundaries. Road systems were generally poor, communications were difficult, and newly created governments were only beginning to cope with the array of problems associated with the development of education, agriculture, industrialization and health services. Smallpox was but one of many problems for which resources were few and trained manpower was limited.

CDC and WHO staff were in agreement that if smallpox could be eliminated from this entire region, importations would be infrequent and their containment would probably not present a serious problem. To the north lay the Sahara desert and the smallpox-free countries of Morocco, Algeria and Libya and the Spanish province of Western Sahara. To the east was the Sudan, then free of smallpox. To the south-east of the region was the Democratic Republic of the Congo (later renamed Zaire), the only adjacent country infected with smallpox. It bordered on the Central African Republic and the Congo. The latter two countries, in 1966, were thought to be smallpox-free and there were few travellers

from the Democratic Republic of the Congo into either of them because of the difficult terrain and political restrictions on travel.

In countries which had formerly been colonies of the United Kingdom, health care was provided primarily through government or mission health centres or dispensaries, some of which performed smallpox vaccination using glycerolated or lanolinated vaccine produced in Nigeria or the United Kingdom, although many offered no immunizations whatsoever. Mobile health units periodically augmented the vaccination effort in Ghana and in parts of Sierra Leone and southern Nigeria. The control of smallpox outbreaks was the delegated responsibility of district or local medical officers and, in some instances, mobile medical field units. As in other countries, the health personnel responded with varying degrees of interest, but even where efforts were made to control smallpox, these were frequently unsuccessful because of the use of the heat-labile, sometimes low-potency vaccine. Of the countries relying on this approach, only Ghana and the Gambia had succeeded in achieving a substantial measure of smallpox control. Ghana's success could be attributed to its mobile medical field units and to health inspectors who took special care in preserving the thermolabile vaccine and who diligently investigated and contained reported outbreaks by vaccination. The Gambia, too small in area and population to permit long-sustained transmission of smallpox on its own, was partially insulated from importations by the surrounding, comparatively well vaccinated population of Senegal. Liberia, in which a mass vaccination campaign with freeze-dried vaccine had been conducted in 1962, followed by a WHO-supported programme, reported few cases. In northern Nigeria and Sierra Leone, however, vaccinial immunity in 1967 was especially low and smallpox was a serious problem.

In the former French colonies, disease control was primarily the responsibility of multi-purpose mobile teams of the local endemic diseases control service (Service des Grandes Endémies), which systematically moved throughout the country endeavouring to reach each village once every 2–3 years (Richet, 1965; Labusquière, 1967). Government health centres and dispensaries also existed but were less numerous and generally less well supported than in the former British colonies; mission hospitals and health centres were few. The multi-purpose teams administered smallpox vaccine and undertook other preventive measures, such as those aimed at controlling yellow fever, trypanosomiasis, yaws and leprosy. In most of the countries, a French-produced, freeze-dried vaccine had been used since the early 1920s (Fasquelle & Fasquelle, 1971). The degree of potency and stability of this vaccine is unknown, but when freeze-dried smallpox vaccine of reasonably high titre began to be used extensively in the early 1960s, and in areas in which the multi-purpose teams continued to function, smallpox incidence declined rapidly; in some countries, the disease had disappeared by

Plate 17.1. Villagers in Côte d'Ivoire line up for smallpox vaccination during the campaign that eliminated smallpox from that country in 1966.

1967. Thus, the numbers of reported cases in 1966 were few or nil throughout the former area of French Equatorial Africa (Cameroon, Central African Republic, Chad, the Congo and Gabon), as well as in Mauritania, Senegal and Upper Volta. In Mali, a WHO-supported programme begun in the early 1960s had markedly reduced smallpox incidence, and in Côte d'Ivoire specially constituted mobile smallpox vaccination teams interrupted transmission in 1966. In the other francophone countries, multi-purpose teams functioned less effectively, and in some of them had ceased to function altogether; in Dahomey, Guinea, Niger and Togo, smallpox continued to be an important problem.

ORIGINS OF THE REGIONAL PROGRAMME, 1961–1965

The decision by the USA in November 1965 to support a region-wide programme of smallpox eradication and measles control had its origin in a small-scale field trial of the newly developed Edmonston strain measles vaccine, which was conducted in 1961 in Upper Volta (Meyer et al., 1964a). This vaccine had been found to be safe and effective when given to children in the USA but because it frequently induced high fever, gamma-globulin was given simultaneously to diminish symptoms. Under the difficult field conditions in developing countries, the administration of both the measles vaccine and gamma-globulin was not feasible. Both had to be given subcutaneously, and while a jet injector could be used to administer measles vaccine, a needle with syringe was required for the more viscous gamma-globulin. Expense was another factor, the vaccine and gamma-globulin costing nearly US$2.00 per dose. Most developing countries could not afford to spend scarce foreign exchange on vaccines costing even a small fraction of this amount.

In 1960, Dr Paul Lambin, Minister of Health of the newly independent country of Upper Volta, was told of the new vaccine while visiting the United States National Institutes of Health (NIH). Because of the severity of measles in African children (Morley, 1962; Cantrelle, 1965), the vaccine was of special interest to him. Accordingly, he proposed that a study should be undertaken in Upper Volta to determine whether the

WHO / P. N. SHARMA, 1961

Plate 17.2. Paul Lambin, Minister of Health of Upper Volta (Burkina Faso), obtained support from the USA in 1961 for a national measles vaccination campaign. This was followed by similar campaigns in other francophone countries of western Africa and, eventually, by the smallpox eradication and measles control programme assisted by AID in 20 countries of western and central Africa.

measles vaccine without gamma-globulin could be given safely to African children. Concern about its safety was legitimate, since it was feared that the high fever it induced might prove harmful or even fatal to children suffering from such conditions as tuberculosis or malnutrition.

With support from NIH, Dr Harry Meyer and his colleagues studied a group of 600 children in Upper Volta in 1961 (Meyer et al., 1964a). They demonstrated that the vaccine without gamma-globulin could be administered with safety and efficacy. Dr Lambin was impressed by the results and requested the USA to provide support for measles vaccination for all young children throughout the country. This request was granted and between November 1962 and March 1963, the multi-purpose mobile teams of the endemic diseases control service in Upper Volta, assisted by Dr Meyer and his colleagues, vaccinated 731 548 children (Labusquière, 1967). The number of reported cases of measles declined sharply, and during the next 2 years remained well below previously recorded levels.

Information about this campaign was widely communicated by Upper Volta to other member countries of a regional health organization, the Organization for Coordination and Cooperation in the Control of Major Endemic Diseases in West Africa (Organisation de Coordination et de Coopération pour la Lutte contre les Grandes Endémies en Afrique de l'Ouest —OCCGE), whose headquarters were in Upper Volta. The organization comprised most countries of the former area of French West Africa (Côte d'Ivoire, Dahomey, Guinea (until 1965), Mali, Mauritania, Niger, Senegal and Upper Volta). At the request of OCCGE, AID agreed to support additional national campaigns, and thus it was arranged for Dr Meyer to conduct training and demonstration projects in 6 of the countries (Côte d'Ivoire, Dahomey, Guinea, Mali, Mauritania and Niger) late in 1963. During the following year, AID allocated US$1 478 000 for the provision of vehicles, jet injectors and measles vaccine to vaccinate 25% of the children between 6 months and 6 years of age. Towards the end of 1964, the measles vaccination campaigns began.

AID staff had assumed that the execution of the campaign would be comparatively straightforward, given the success in Upper Volta and the long experience of the multipurpose mobile teams in each of the countries. The fact that not all the endemic diseases control services were of the same quality as that in Upper Volta was not appreciated. The ensuing difficulties were compounded by the problem of introducing a new technology—the jet injector—which at that time required electric power and was difficult to repair and maintain, and a new vaccine, which had to be refrigerated until reconstituted for use. To conduct the mass measles vaccination campaigns, most countries curtailed or stopped the activities of the multi-purpose mobile teams because national resources were too limited to permit the two sets of activities to be continued.

With the beginning of the mass campaigns, it was decided that such technical assistance as might be needed from the USA should be provided by CDC, the agency primarily concerned with the field implementation of disease control programmes. Thus, in December 1964, Dr Lawrence Altman of CDC was requested by AID to spend 6 weeks in the countries to observe the campaigns and to report on progress. He found few of the campaigns to be progressing at all satisfactorily and eventually spent 6 months endeavouring to bring order out of chaos, albeit with little success.

Despite the difficulties, AID decided to offer assistance to an additional 4 countries (Cameroon, Central African Republic, Chad and Togo) to permit them to begin mass measles vaccination campaigns in 1965–1966. The potential scope of the project was even further expanded when, late in June 1965, the manufacturer of the measles vaccine brought the persuasive Dr Lambin to the USA on a special tour. The Director of AID was impressed with Dr Lambin and asked that a plan be drawn up for a comprehensive programme of assistance for measles vaccination in 16 African countries, including all the former French colonies of western and central Africa, as well as the Gambia, Liberia and Sierra Leone. Recognizing that this implied the need for more technical assistance staff than had been foreseen, AID asked CDC whether 9 epidemiologists could be made available in the autumn of 1965, each to serve on temporary duty for periods of 4–6 months in the countries in which campaigns were either in progress or due to begin.

The Addition of Smallpox Eradication as an Objective

Until July 1965, CDC personnel had not been involved in the development of policy or plans for the measles vaccination campaigns. However, if CDC were to provide so many epidemiologists for such extended periods of time, its own programmes would have to be curtailed or substantially altered. Accordingly, an examination of priorities and alternatives was undertaken, a responsibility assigned to Henderson, then Chief of the CDC Surveillance Section, from which most of the epidemiologists would be drawn.

To Henderson and his colleagues, the programme, as then conceived, did not represent sound public health policy. AID foresaw a 4-year programme during which each year all children from 6 months to 6 years of age would be vaccinated against measles in one-fourth of each country. At the conclusion of the programme, AID staff reasoned that all children would have been vaccinated and that the country would assume responsibility for continuing to vaccinate children who were born after the programme had terminated. It seemed unreasonable to CDC staff to assume that the impoverished African countries would be able to bear the recurring expenditures, given that measles vaccine then cost more than US$1.00 per dose; indeed, at that time, few of these countries could afford yellow fever vaccine, which was one-tenth as expensive. Had it been possible to eradicate measles from the area, vaccination conceivably could have been stopped, but this objective appeared unrealistic given the fact that no industrialized country, despite greater health resources, had yet eliminated the disease. At best, the reduction in measles incidence would be transient because almost all cases of measles in Africa occurred among young children and thus, within 3–4 years after vaccination in an area, measles incidence could be expected to approach levels comparable to those observed before the programme had begun. To embark on such a programme implicitly raised public expectations that the vaccine would continue to be made available as a routine preventive measure. If a government were to terminate its use abruptly after 4 years, possible repercussions from the public could be foreseen, particularly in the wake of the measles epidemics that would almost certainly follow.

In July 1965, however, the USA had already undertaken to provide assistance for measles vaccination campaigns in 11 western and central African countries; a proposal from CDC that no programme should be conducted was not acceptable. The combination of this programme with one designed to eradicate smallpox from the region appeared the most logical move, since it would provide an objective which offered hope of longer-term benefits. That the eradication of smallpox throughout a geographical region was feasible had been shown in other parts of the world. If this could be achieved, occasional cases might still be imported into the region and these would have to be contained. Smallpox eradication, however, seemed to be a more reasonable long-term goal than one which called for a continuing campaign of measles vaccination for all children. Moreover, as CDC staff reasoned, WHO and its Member countries were committed to a programme of global smallpox eradication and, although this was not progressing well, it was believed that a successful regional effort in one of the most highly endemic areas would represent an important contribution and perhaps a stimulus to other endemic countries.

Two other considerations—one technical and one political—also lent support to the idea of smallpox eradication. In 1965, CDC

had just completed a series of studies which demonstrated the efficacy and practicability of the intradermal administration of smallpox vaccine utilizing a newly developed nozzle for the jet injector (Millar et al., 1969; Neff et al., 1969; Roberto et al., 1969; Millar et al., 1971). The jet injector itself had been redesigned so that it could be powered by a pedal-operated hydraulic pump rather than by electricity; this offered a substantial advantage in field work. A second important consideration was the commitment made by the USA in 1965 at the Eighteenth World Health Assembly to provide support to the Intensified Smallpox Eradication Programme (see Chapter 9). Although the support then envisaged was for the development of a vaccine production laboratory in Kenya and assistance to smallpox eradication programmes in South America, it seemed reasonable to propose a broader initiative.

CDC therefore suggested that AID should support a region-wide programme of smallpox eradication in western and central Africa, with measles vaccination also being offered in countries selected by AID and where it was agreed by national authorities. This was a much bigger programme than that envisaged by AID, which had anticipated providing support to only 16 countries, with a total population of about 50 million in 1967. Two important countries in the region which were not then included—Nigeria and Ghana—together had a population of more than 60 million (see Table 17.9).

The proposal was strongly endorsed by officials of the United States Public Health Service—Dr Luther Terry, the Surgeon General, and Dr James Watt and Dr Benjamin Blood of the Office of International Health. AID readily accepted the proposal for a programme dealing with smallpox and measles in 16 of the countries but not for the inclusion of Ghana and Nigeria. As noted in an AID memorandum of 19 July 1965:

> "The total scope of the African problem is too great for any one donor to undertake its solution ... With a few exceptions [the 16 countries are among those] in which a modest demonstration of US interest and presence is desired without involving the USA in major dollar or personnel expenditures."

Despite these reservations, planning by CDC staff proceeded throughout the summer for an 18-country programme of 5 years' duration which would provide all supplies and equipment, plus a complement of CDC technical staff for work in individual countries, in an African regional office and at CDC headquarters in Atlanta. If accepted, this would be the first AID-supported technical assistance programme to be administered by CDC. On 20 August 1965, after many discussions between CDC and AID staff, the full proposal was formally submitted to AID. At the suggestion of CDC, Mr Milton P. Siegel, an Assistant Director-General of WHO, and Dr Karel Raška, Director of the Organization's Division of Communicable Diseases, visited Washington to discuss the proposal, and, early in November, the Director-General of WHO, Dr Marcolino Candau, also had meetings with AID and CDC staff. Everyone urged that the plan should be implemented, although a point at issue was whether WHO or perhaps another donor could support the programmes in Ghana and Nigeria. WHO officials stated that the Organization's resources were inadequate for the

He is holding a fetish statue of Sopona, a smallpox deity of some tribes of western Africa.

undertaking, and on the basis of WHO's experience with respect to voluntary contributions from national sources, little hope was offered that the necessary support could be found elsewhere.

AID was faced with a dilemma. Commitments had already been made for measles vaccination campaigns in 11 countries for which technical assistance was needed. It was difficult to find the requisite complement of technical staff at short notice except from the Public Health Service, but this the Public Health Service declined to provide unless all 18 countries were included in a programme that provided for smallpox eradication. The issue was settled, partly in response to a memorandum from the Public Health Service (see box), and the offer of assistance was formally announced on 23 November 1965. Thus began the first coordinated regional smallpox eradication programme.

GOVERNMENT AGREEMENTS AND ORGANIZATION OF THE PROGRAMME

The proposal for the regional programme envisaged that it would begin in January 1967, little more than 13 months after the decision had been made to offer assistance to the 18 countries. The schedule was optimistic, given the need to develop plans and obtain agreements with each of the countries, to recruit and train technical staff and to procure and deliver all the necessary supplies and equipment. Surprisingly, these goals were largely achieved, although not without problems.

Discussions in Africa began with the governments concerned immediately after the formal announcement. From 23 November to 17 December, a team composed of Henderson, Dr Clayton Curtis of AID, Dr Henry Gelfand of CDC and Dr Warren Winklestein, a CDC consultant, held meetings with health staff and discussed the programmes with officials of 16 of the 18 countries -at the ministerial meeting of OCCGE countries; at a technical meeting of a counterpart organization for former French colonies in central Africa, OCEAC, comprising Cameroon, Central African Republic, Chad, the Congo and Gabon (the Organisation de Coordination pour la Lutte contre les Endémies en Afrique centrale, or Organization for Coordination in the Control of Endemic Diseases in Central Africa); and in special visits to Guinea, Liberia, Nigeria, and Sierra Leone. Time constraints precluded visits by the team to the Gambia and Ghana, but government officials there communicated to the respective United States embassies their willingness to participate. Discussions were also held with staff of the WHO Regional Office for Africa attending the OCCGE and OCEAC meetings and by Henderson with the Director-General of WHO and his staff in Geneva.

The only one of the countries noted above for which assistance was not foreseen was the Congo, with which the USA then had no formal diplomatic relations. However, AID agreed to include the Congo, when confronted with the decision by OCEAC leadership that either all or none of its member countries would participate in the regional programme. With this addition, the number of countries increased to 19; when Equatorial Guinea became an independent country in 1968, it too, was included, bringing the number of countries assisted by AID to 20.

The national staff in each country enthusiastically welcomed the proposal for a programme of smallpox eradication and measles control, the latter being the principal attraction to countries in which smallpox was not a significant problem. The inclusion of Nigeria was vital to the success of the programme, since that country accounted in 1965 for nearly three-fourths of all reported smallpox cases and almost half the population of the region. It was most encouraging to learn that a senior health officer in the Nigerian Ministry of Health, Dr G. Adeyemi Ademola, had already elaborated a detailed plan for smallpox eradication which the government had approved and which he was about to dispatch to WHO and AID with a request for assistance.

During the visits in Africa, it became apparent that many United States officials assigned to the countries were not enthusiastic about the programme. As a matter of policy and personal conviction, they attached the highest priority to economic development programmes. Bilateral and multilateral assistance agencies generally considered at that time that improvements in health would follow naturally on economic development and that special programmes in the health sector would serve only to divert resources from the primary objective. Apart from this broader policy issue, the officials concerned anticipated that meeting what were termed

SUBJECT: Scope of the Proposed West African AID–CDC Vaccination Program

The principal scientific objectives of the West African vaccination program, as discussed in repeated meetings between ourselves and AID officials have been two: (1) the eradication of smallpox and (2) the control of measles as a significant health problem in the countries under consideration. Since our earliest meetings, it has been noted repeatedly that smallpox eradication was not a realizable goal unless conducted on a comprehensive regional basis.

We have sensed reluctance on the part of AID to include Nigeria and Ghana in the total scheme. The concept that WHO or the United Kingdom might wish to support the Nigerian program in concert with the AID effort in the other countries in this area has been propounded. From knowledge of WHO plans and programs, Dr Henderson can state categorically that it will be difficult for WHO to assign a high level of priority to a Nigerian project for the next few years. Whether the United Kingdom could and would undertake a Nigerian programme reasonably promptly and aggressively is a moot question. The probability that they would, however, is recognizably slight.

It must be reiterated that any multi-country West African smallpox *eradication* program in West Africa must from its inception include Nigeria in its development and planning. Short of so doing, the program is a *control* program only. As stated at the end of August in meetings with AID officials and Dr Karel Raška of WHO, the Communicable Disease Center does not feel that it is indicated nor does it wish to divert skilled personnel to assume full-time responsibility and direction of a program for smallpox and measles in West Africa limited to control only.

The problem of decision and timing with respect to this program is a second major consideration. To recruit capable medical staff ... commitments to them must be made in the fall of the year for employment beginning the following July. This has been firmly and clearly expressed in every meeting conducted with AID officials since early in the summer.

In the proposed program prepared in mid-August it was stated that, "It is important that this PASA [Participating Agency Service Agreement] be negotiated by mid-September 1965, in order that the USPHS may make the necessary staff commitments." We were later informed, however, that October 15 would be more realistic for a firm AID commitment. Postponement of the decision was again requested by AID to November 1 and then November 5. These dates have passed without decision.

In the meantime, a meeting of the Ministers of Health of the OCCGE countries has been scheduled for late November. It was felt by AID and PHS that Dr Henderson and Dr Gelfand should attend to initiate with the attending countries necessary discussions for programs next year. It was agreed, however, that such a trip would be essentially fruitless unless a commitment on the part of AID for full support to a West African program were forthcoming prior to the meeting. Since Dr Henderson and Dr Gelfand would have to depart about November 15, such a decision would have to be reached almost immediately.

Prospects of success for this program are already fading as a firm decision to undertake this activity is deferred. If decisions on the part of AID for full support to the 18-country program cannot be reached by November 15, the Public Health Service would be forced to withdraw such implied commitments as have been made and when AID decisions have been reached, discussions regarding the technical feasibilities would have to be re-explored from the beginning.

"local costs" would present insurmountable difficulties. During the visits of the CDC team the belief was repeatedly emphasized that most countries did not have adequate resources and that AID, as a matter of policy, did not provide for such local costs as the purchase of petrol and vehicle maintenance and repair. This policy had been adopted to ensure that, as far as possible, national governments would cover these recurrent costs by drawing on their own budgets, thereby fostering the continuity of programmes. For many governments, however, the resources available were so severely constrained that many fully equipped and fully staffed projects were unable to function for lack of comparatively small sums of money needed to buy petrol, for example. This potentially serious problem for the smallpox eradication–measles control programme was averted when the Director-General of WHO pledged to make WHO funds available to cover local costs when required. It was a decision about which he was politically uncomfortable since it meant that petrol purchased by WHO would be used to operate vehicles provided by the USA in a bilateral assistance programme. However, he abided by the commitment, and such support was eventually provided to 13 of the countries.

CDC staff had hoped that the overall regional programme could be phased in during a period of 2 years, some countries beginning operations in 1967 but as many as possible delaying them until 1968 to permit the necessary planning. For various reasons, however, such a delay was possible only in Guinea, Liberia and Sierra Leone. A programme in Nigeria was essential from the beginning of the regional effort, because of the size of the country and the fact that its central location made it the most logical site for the programme's regional office. Programmes had also perforce to be introduced in 1967 in the OCCGE and OCEAC countries because of commitments already made by AID for measles vaccination campaigns. Because of these and other political considerations, it was decided that programmes would have to begin in 1967 in 16 countries and in 1968 in the other 3.

The direction of the regional programme at CDC was yet another problem. A Smallpox Unit had been created in the CDC Surveillance Section in 1962 which, under the direction of Dr J. Donald Millar, had ably conducted studies on the use of the jet injector for smallpox vaccination and on the frequency of complications following vaccination. It was logical that he should assume direction of the regional programme but, in August 1965, he departed for a year's postgraduate study. In December 1965, with Dr Millar temporarily absent and no other suitable leadership available, Henderson relinquished his post as chief of the Surveillance Section to assume direction of the programme until Dr Millar returned. He was joined by his deputy, Mr Leo Morris, as well as by Dr Bernard Challenor, Dr Gelfand and Dr Ralph Henderson, and an administrative officer, Mr Billy Griggs—all CDC staff.

Within a month of the initial discussions with African health leaders, a 60-page document had been prepared which specified objectives and activities and identified needs and costs for personnel and commodities by country (Table 17.2). With minor modifications, this compilation was accepted by AID. The total cost of United States assistance was estimated to average about US$7 million per annum, of which approximately 40% was associated with the measles vaccination component, including storage refrigerators and jet injectors. It was anticipated that, on average, an additional US$1.7 million would be needed annually from WHO for local costs, a figure which, if correct, would have required 70% of all the WHO regular budget funds subsequently appropriated for smallpox eradication. Fortunately, the countries themselves eventually bore most of these local costs—WHO providing US$1.1 million to 13 countries from 1967 to 1972, or about US$200 000 per annum.

The projected size of the staff in the programme's regional office in Lagos and the central office in Atlanta, comprising about one-third of the total personnel, requires comment, as it was considered by some to be excessive and was accepted only with reluctance. The requirements, as outlined, arose from observations of other field programmes by CDC staff. It was believed that such programmes had regularly underestimated the need for central support and, indeed, this proved to be WHO's experience in establishing the Intensified Smallpox Eradication Programme. The regional office in Lagos was expected to exercise broadly delegated responsibilities for administration and field supervision. The personnel concerned were expected to travel extensively to effect coordination and to provide short-term emergency technical support, as well as to assist the Lagos

[b] Expected to be met mainly by WHO.

laboratory in the development of vaccine production. The document proposed the recruitment of 2 medical officers, 2 administrative officers, an equipment specialist, a health educator and a virologist. The CDC staff in Atlanta would be responsible for liaison with AID staff in Washington and with other agencies, for the recruitment and training of staff, for the development of instructional manuals, for the procurement and shipment of supplies and equipment, for the provision of longer-term emergency assistance in problem areas, and for the conduct of special studies pertaining to the programme. Although practical realities eventually required a redefinition of the respective roles of the two offices, experience demonstrated that the proportionately large staff in the central and regional offices, and the flexibility in assigning personnel which this implied, were vital to the rapid progress ultimately achieved.

In the programme document, the primary goal was specifically stated to be the eradication of smallpox, with measles control as a secondary objective, but longer-term objectives were envisaged:

"1. The establishment or, in some countries, improvement of mobile disease control services capable of administering vaccines or other preventive medications efficiently, economically and on a mass scale throughout the country.

"2. The establishment in each country of a system of disease surveillance broadly applicable to a variety of communicable disease problems.

"3. The development of highly simplified statistical sampling techniques applicable in these developing countries which will permit rapid assessment of disease problems.

"4. The establishment of elementary virological laboratories ... for the diagnosis of smallpox. [This objective was soon abandoned, as it was in other areas, when it became clear that the clinical diagnosis of smallpox was usually sufficiently accurate for surveillance purposes, and when it was discovered that laboratory diagnosis by the more sophisticated electron microscopy offered substantial advantages over traditional methods.]

"5. Improvement of the existing smallpox vaccine production laboratory in Nigeria such that it [can produce] vaccine of the multiple puncture type in quantities sufficient for Nigeria and other countries in the area."

PREPARATION FOR THE CAMPAIGN, JANUARY–DECEMBER 1966

As might be expected in the development of a new programme of this magnitude, the preparatory phase, during January–December 1966, was characterized by hectic activity and administrative frustration. A director for the CDC regional office to be established in Lagos, Dr George Lythcott, was recruited early in 1966. He, with Dr Gelfand and Dr Ralph Henderson, travelled throughout western and central Africa drawing up pro-

gramme agreements for each country. Such agreements, however, could not be formally signed nor could the procurement of supplies and equipment begin until the United States Congress had passed the act which appropriated the funds. Although this had been expected before 1 July, when the government's fiscal year began, the Foreign Assistance Act of 1966 was not signed until 19 September. The difficulties in launching the programme were compounded by the fact that, within AID, the interval between the decision to implement field programmes and their actual commencement was usually 3 years, and the Agency's procedures were geared to this pace. As time progressed, it became apparent that the single year allotted for preparation was unrealistic unless special measures were taken.

Fortunately, the recruitment of staff had been authorized and training could begin early in July 1966. Two basic categories of staff were recruited: medical officer–epidemiologists to provide overall assistance in programme development and execution, and non-medical personnel, termed "operations officers", who would deal with logistics—including the maintenance and repair of vehicles and jet injectors, the distribution of supplies and equipment and the handling of financial matters. Priority was given to persons in their twenties and thirties, who were considered to be more likely than older individuals to have the stamina and interest required for extended work in the field. This also reflected the view of African health officials, who argued that they had a very limited need for advisers, in the usual sense of the term, but required, instead, individuals who were willing to participate actively in field operations. One operations officer was recruited for each country and 1 for each of the 4 regions in Nigeria. One medical officer was recruited for each Nigerian region, 1 for each of the larger countries, and 1 for every 2 or 3 of the smaller countries—i.e., 1 for Dahomey and Togo, 1 for Cameroon and Gabon, 1 for Chad and the Central African Republic, and 1 for the Gambia, Mauritania and Senegal.

The medical officers were primarily epidemiologists who had worked in the USA with CDC or who had had international health experience. The operations officers included 4 with experience as United States Peace Corps volunteers, the rest having played an important role in CDC's domestic disease control programmes. The latter group, all of whom were university graduates, had received short-term training in epidemiology and disease control and had proved their merit in field control programmes. Their experience in programme management and field investigations was to prove invaluable. Although the operations officers were initially not well accepted by some senior government health staff because they lacked a medical degree, they rapidly earned respect and, in many areas, eventually served as senior advisers. So impressive was their performance that WHO increasingly recruited such persons for smallpox eradication and other programmes.

During the spring and summer of 1966, a manual for field operations was prepared from which the WHO *Handbook for Smallpox Eradication in Endemic Areas* (SE/67.5 Rev.1) was eventually adapted; other manuals dealing with the repair and maintenance of the jet injectors were prepared and tested in the field by Mr Morris; and orders were drawn up for the procurement of the necessary supplies and equipment.

Numerous problems were resolved during this period but a few of the more important and unexpected deserve mention. The licensing of smallpox vaccine for use in the jet injector caused one, wholly unexpected difficulty. CDC staff had assumed that the inoculation of vaccinia virus into the superficial layers of the skin by the jet injector's high-pressure spray achieved the same result as the administration of the vaccine by the scratch of a needle. However, in 1966, the agency in the USA responsible for biologicals—the Division of Biologics Standards asserted that the vaccine specially produced for the jet injector had to be treated as a new product and because it was intended for parenteral inoculation, it must be sterile. Vaccinia virus, however, was then being grown as it always had been on the flank of a calf, and when harvested it inevitably contained some bacteria. Subsequent steps in manufacture diminished the number of bacteria to very low levels, and tests were performed to ensure the absence of pathogenic species. It was impossible, however, to produce a vaccine which could be stated with certainty to be free of all bacteria unless it were grown in tissue culture. Vaccinia virus could be grown in tissue culture, but at that time no laboratory had succeeded in producing such a vaccine which met WHO's heat-stability requirements. The debate as to whether the vaccine for jet injection

had to be sterile spread from the USA to WHO, where those concerned with biological standards also proposed that vaccine intended for jet injection should be sterile. Although there was agreement that the issue was one of principle rather than perceived risk, those concerned with biological standards insisted that principle should take precedence over all other considerations. Faced with the prospect of having a thoroughly evaluated method for vaccination which was vital to the new programme, but no vaccine, CDC staff carried the debate to higher administrative levels within the United States Public Health Service and the World Health Organization and finally were able to gain agreement that, in this case, principle would not prevail. However, considerable time and effort were spent on resolving the problem—at the expense of other urgent activities.

The vehicles and their spare parts presented a second problem. CDC decided that standard model pick-up trucks rather than custom-designed vehicles were preferable and less costly, and that the refrigerators required for the transport of measles vaccine could simply be bolted to the bed of the truck. The most desirable were British or French vehicles, which were in common use throughout western and central Africa. Spare parts for such vehicles were already widely available and local mechanics were familiar with their necessary maintenance and repair. AID procurement policies, however, required the purchase of vehicles made in the USA, and efforts by CDC to obtain a waiver of this requirement were unsuccessful. To alleviate the problems of repair, arrangements were made with the manufacturer for all of the programme's professional staff to take intensive training in vehicle maintenance and repair. Spare parts had to be procured and specially stockpiled in all countries, but which spare parts and in what quantities was another question, since, curiously, neither the manufacturer nor the various agencies working in Africa, including WHO and UNICEF, had compiled a list of needed spare parts based on field experience. There was no option but to make a "best-guess" estimate of which spare parts to stock and, as might be expected, requirements only roughly approximated available stocks. Over time, and with special assistance from the manufacturers, the design of the vehicles was improved, special repair facilities were established and an effective transport system was ensured.

One of the most contentious problems related to the question of which of two measles vaccines should be procured—the Edmonston strain vaccine, which was produced by one manufacturer and which had been used since the 1961 campaign in Upper Volta, or a more recently licensed, more attenuated product, the Schwarz strain vaccine, produced by another manufacturer. The Schwarz strain vaccine resulted in less frequent and less marked febrile responses, but the initial antibody levels induced were lower (Krugman et al., 1965). The available evidence indicated that the two vaccines conferred comparable immunity but some investigators suggested that immunity following the use of the Schwarz vaccine might not be so long-lasting. Investigators in Senegal and Nigeria (Hendrickse et al., 1965) had evaluated the Schwarz strain vaccine and argued that it was the more desirable, given the fact that it would be administered to ill and malnourished children among whom the higher fevers caused by the Edmonston strain vaccine might be harmful. A number of African countries, however, encouraged by the manufacturer's travelling sales representative, requested the Edmonston strain vaccine. Even the *New England journal of medicine* (1965) entered the dispute, stating in an editorial, "... it may be wise, at least under circumstances such as exist in these countries [of western Africa], not to adopt other vaccines [other than the Edmonston strain vaccine] until the results of future studies become available". The manufacturer translated the editorial into French and circulated it widely in Africa, and eventually obtained support for the product from many United States legislators. One alternative for CDC was to permit each country to decide for itself which strain of vaccine would be used. However, CDC staff not only considered the Schwarz strain to be preferable, but for logistic reasons believed it important to employ only one type of vaccine. Eventually, the issue was decided by the United States Surgeon General, and ultimately all countries were persuaded to accept the use of this strain (which became routinely used). As with the standards for smallpox vaccine for use in the jet injector, the issue was satisfactorily resolved, but again at the expense of considerable time and energy.

The training programme began in July 1966. A month-long course in basic field epidemiology and biostatistics was followed by a month of specialized training which

covered subjects ranging from the history and socio-cultural characteristics of western and central Africa to the maintenance and repair of vehicles and jet injectors. To foster collaboration with WHO, the WHO advisers in Africa, Ladnyi and Dr Hans Mayer, were invited to participate during the first month of the course. When the course ended, however, the staff had to remain in Atlanta, housed in temporary and crowded quarters, because none of the national agreements had yet been signed.

Many discussions with governments about the programme had been conducted during the spring and summer of 1966 but, as has been noted earlier, formal agreements could not be signed at least until September. Nigeria was of the highest priority because of its size and because it was to serve as the site of the regional office. Nearly half the complement of technical staff were expected to live there. Nigeria, however, was then on the brink of civil war. A military *coup* in January 1966 had displaced the existing civilian authority, and 7 months later, a second *coup* coincided with an army mutiny in the north, during which thousands of Ibo tribesmen were killed. The Ibos, whose tribal home was eastern Nigeria, threatened to secede and to establish an independent nation. The signing of an agreement for a smallpox eradication measles control programme was not high on the list of the government's priorities. For many weeks, it appeared that the regional programme might well be doomed, as the United States Ambassador and the WHO Representative endeavoured, unsuccessfully, to obtain the agreement of the Nigerian government. Finally, Dr Lythcott flew to Nigeria to ascertain what might be done. The documents had been approved by the Minister of Health and awaited only the signature of the head of state.

Plate 17.4. CDC field staff received training in the maintenance and repair of vehicles in Atlanta before taking up assignments in western and central Africa. *Clockwise from lower left*: Margaret E. Grigsby, Ralph H. Henderson, Gordon E. Robbins, a vehicle maintenance instructor, Stanley O. Foster, Thomas Drake, E. Ademola Smith, William H. Foege, David Thompson, Donald Moore, Deane L. Hutchins, Hillard Davis, unidentified, Arlen Rosenbloom, Pascal Imperato, Bernard Lourie, Christopher D'Amanda.

During a 6-week period, Dr Lythcott, too, was unsuccessful in working through conventional channels but, at a social function, he was introduced to the President's fiancée. He explained the programme and the nature of his mission to her, and on the following day, the agreement was signed.

Nigeria's agreement, though it was crucial, was only one of 16 which were needed. In other countries, various problems delayed the signing of the programme agreements, and not until March 1967 was the last of these finalized. Agreement in principle to undertake a programme of smallpox eradication and measles control was more readily achieved than agreement on specific operational plans. CDC staff had envisaged a similar type of programme in all countries—in principle, an elaboration of the special mass vaccination campaign against measles. Mobile teams would use jet injectors in the administration of smallpox vaccination to everyone in the population, while measles vaccine would be given to children between 6 months and 4 years of age (Henderson, 1967). Expectations as to the extent of coverage to be achieved were modest—80% of the population in urban areas and perhaps 60% in peripheral areas. Important additional components, not then familiar to any of the countries, were the provision of independent assessment as a quality control measure to determine vaccine coverage and the success of vaccination, as well as a surveillance system utilizing detection sites such as hospitals and aid posts to measure progress in eliminating smallpox.

In countries in which mobile teams had previously been little used, or in which such teams had largely ceased to function, the plan was adopted with few changes. In most of the former French colonies, however, multipurpose mobile prevention units, often referred to as "prospection teams", were well established. As the teams moved from village to village on a planned itinerary they endeavoured to reach all parts of a country over a 2–3 year period, vaccinating the inhabitants against smallpox and sometimes tuberculosis and yellow fever and examining an average of 400–500 persons a day for leprosy, trypanosomiasis, yaws and (where the disease was present) onchocerciasis. The programmes, as well as many of the mobile units, were usually directed by French military medical officers. In these countries, separate programmes for smallpox and measles vaccination were seen

WHO / CHEVALIER

Plate 17.5. Jet injectors were used to administer smallpox vaccine in the left arm and measles vaccine in the right arm. Sometimes the injections were given simultaneously. Aluminium foil covers the vaccine vials to prevent the inactivation of virus by exposure to light.

to be wasteful of petrol and trained personnel. CDC staff, however, considered that the integration of the two programmes would present a problem because it would compromise the speed and efficiency of operations afforded by the jet injectors. In a population of 500, for example, fewer than 100 children would be of a suitable age to receive measles vaccine, a number barely sufficient to warrant the use of the injectors. A second problem was that the health officials in these countries saw no need to provide special teams to assess the results of the programme. Participation in the multi-purpose programmes was encouraged in most countries by giving individual certificates to persons examined and vaccinated by the teams, and by subsequently requiring these documents to be shown for administrative purposes. Because the prospection teams were well known to the people, and their activities were supported by local chiefs, health officials believed that no assessment was required other than to compare the numbers vaccinated by the teams with the estimated population in the area. A third problem was the reluctance of most authori-

ties to divert resources to improve reporting or to investigate cases of smallpox. This was considered to be wasteful because of the common view that the best that could be achieved was the control of smallpox as well as of measles; if a few cases of smallpox did occur they were thought of little consequence in the total context of health problems.

Compromises in the basic strategy were required. Support from the Secretaries-General of OCCGE and OCEAC—Médecin-Général Pierre Richet and Colonel René Labusquière, respectively—helped to resolve many problems. In the OCEAC countries, the smallpox eradication and measles control programmes were eventually fully integrated into the activities of the prospection teams (see box). In Upper Volta, the prospection teams continued to give smallpox vaccine but different mobile teams were created to give measles vaccine. In Côte d'Ivoire, separate measles vaccination teams and smallpox vaccination teams were formed (Table 17.3). In the other OCCGE countries, it was decided that special teams would conduct both smallpox and measles vaccination.

Few of the countries at first agreed to accept the provision of special teams to conduct independent assessments of smallpox vaccination coverage and takes. By the end of 1967, only 6 countries had created such teams—Dahomey, Ghana, Mali, Niger, Nigeria and Togo—although eventually 4 others did so—Chad, Gambia, Guinea and Sierra Leone. At the start, there was even less interest in smallpox surveillance, which fell by default to CDC advisers until late in 1968. Fortunately, assessment and surveillance were best accepted in the countries in which smallpox was the greatest problem.

When the first programme plan had been developed, in January 1966, it had been

Description of a Prospection Team in Action, Central African Republic

From a 1967 field report by Dr Ralph Henderson and Mr Neal Ewan:

"The team began its activities around 7.30 a.m. Zinga and an adjoining village were to be 'prospected' that morning. First, all the children between 6 months and 4 years of age were formed into a line and given measles vaccinations. They were tallied by age and sex as they received their shots. This procedure required about one-half hour, and took place with minimal difficulty.

"The team leader then requested the village to form into a line of males and a line of females. Each line then passed in front of a recorder, who tallied age and sex, and handed each person a metal tag from a box containing tags consecutively numbered from 1 to 1000. The line then moved through a small tent where a nurse performed a screening physical examination, particularly looking for trypanosomiasis, onchocerciasis, leprosy, and yaws. After passing through the tent, the line passed in front of the smallpox vaccination station, where everyone except infants under 3 months and pregnant women was vaccinated using the scratch technique. The line next moved to a table where each metal tag was collected, and yellow OCEAC cloth health certificates were given out, stamped with *rougeole* (measles) and/or *variole* (smallpox) and the date, and filled out with the person's name. People were then either dismissed or proceeded to one or more of three additional sites. Blood, sputum and stool specimens were obtained from suspects referred by the nurse performing screening physicals. The nurse concerned prepared slides to be read by one of two microscopists. Trypanosomiasis and onchocerciasis suspects were referred directly to the microscopists, who made their own slides from fluid and tissue obtained by placing a clean needle into suspected cysts or ganglions and wiggling it.

"The final member of the team dispensed drugs. Patients were either referred from the nurse doing screening physicals, or were passed along by the microscopists. Penicillin shots were given to yaws cases and their contacts. Chloroquine, aspirin and some antifungal skin ointments comprised the remainder of the basic pharmacy. Those with other diagnosed illness were referred to a local hospital or dispensary for treatment. By 11 a.m., about 250 people had been seen in this fashion, and the team packed up to move to the village where they would prospect on the following day."

projected that "smallpox cases should cease by the end of the fourth year of the programme" i.e., by December 1970. In the autumn of 1966, projections were made as to the numbers of reported cases of smallpox which might be expected up to the end of the programme. This was done in the expectation that, with better recording, the reported incidence might actually rise during the first year of operations, thus generating concern on the part of the responsible administrators as to the effectiveness of the programme. Anticipating this problem, Henderson and his colleagues prepared a graph depicting the expected numbers of reported cases throughout the duration of the programme (Fig. 17.2). The graph is of interest, since the predicted incidence up to the end of 1968 was surprisingly close to what was actually found, but thereafter the results were substantially better than expected, one of the few occasions in which progress in the Intensified Smallpox Eradication Programme exceeded expectations.

One by one the programme agreements were signed, and personnel, supplies and equipment gradually began to arrive in western and central Africa. By March 1967, 16 months after the USA's decision to offer assistance, pilot projects had begun in 11 of the countries and a total of 2.5 million smallpox vaccinations had been recorded.

CHARACTERISTICS OF WESTERN AND CENTRAL AFRICA

The estimated 110 million population of the 19 countries included in the programme in 1967 inhabited a diverse ecological area ranging from humid tropical coastal areas with prolonged rainy seasons to rolling savanna and eventually to the vast, sparsely populated and arid Sahel, whose vegetation consisted of thorny scrub and stunted trees (Plate 17.6). Subsistence farmers formed the largest proportion of the population. Chris-

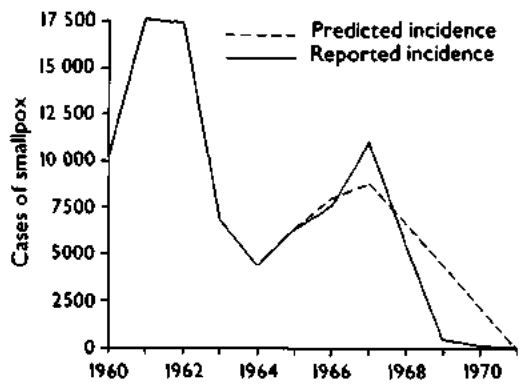

Fig. 17.2. Western and central Africa: number of reported cases of smallpox compared with the numbers predicted in September 1966.

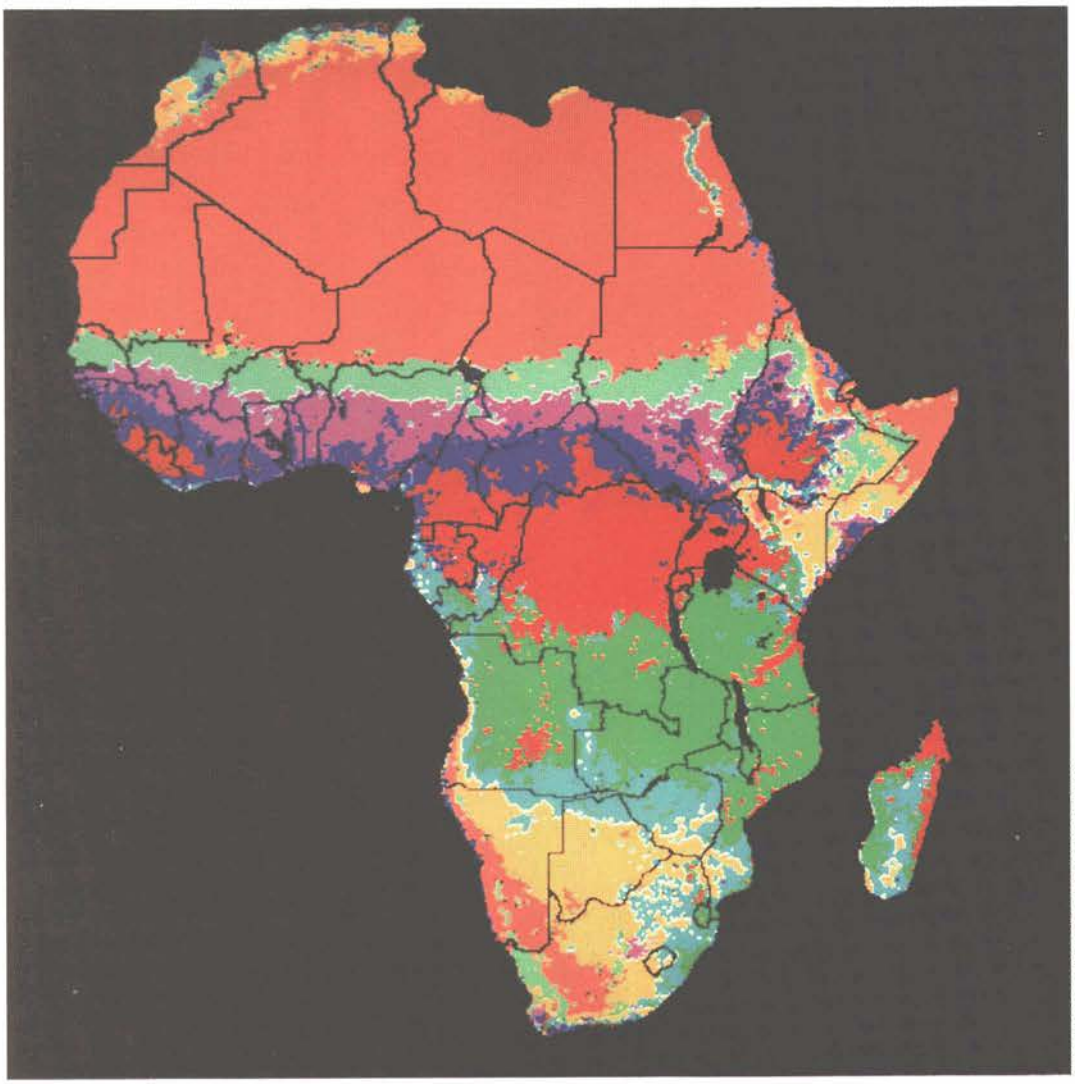

NASA / GODDARD SPACE FLIGHT CENTER

Plate 17.6. Principal land cover components of Africa. The types of vegetation present in different parts of Africa were important in population distribution. Maps developed from satellite observations using very high-resolution radiometer sensors were prepared in 1982 (Tucker et al., 1985); the situation they show was probably not significantly different from that in 1967. The tan areas are desert and semi-desert, the light green are semi-arid wooded grassland, and the light blue are bushland and thicket; all these areas were sparsely populated. The purple areas are woodland and grassland, the dark green are woodland and the yellow are wooded grassland and thicket. The dark blue areas are interspersed tropical forest and grassland, and the red are tropical rain forest and mountain forest; the latter areas were more densely populated.

tians and animists lived primarily in the coastal areas; Muslim herders inhabited the Sahel. Tribes numbering from less than 100 000 persons to many millions, each with its own language, culture and customs, had traditional boundaries, often overlapping one or more national frontiers. In the process of evolving into nation-states, most countries experienced clashes between the new and the established and between religious, traditional, military and civilian leaders. Changes of government occurred frequently.

Paved roads provided limited links between coastal cities and some inland towns, but few connected the major capital cities. In the savanna, most unpaved roads were made of laterite, with a washboard surface that took a heavy toll of vehicles; in the coastal areas, there were clay roads, which were dusty during the dry season and a morass of mud during the rains. Railways were few and frequently out of order. Air transport connected many of the major cities and towns but schedules were followed erratically. Travel between one capital and another was sometimes more readily accomplished by flying by way of London or Paris. Similarly, telephone and telegraph links were generally few, and it was often easier to communicate with other countries through London or Paris.

The inhabitants of western and central Africa were inveterate traders and, despite poor roads, many travelled long distances to buy and sell cattle, textiles, salt, gold and other products. Local markets played an important role in commerce and as social centres. Some were held weekly, others at intervals of 4, 5 or 8 days. Herdsmen moved regularly across the Sahel seeking grazing areas and migrant labourers from the Sahel moved seasonally to coastal and savanna areas to harvest crops. Rapidly increasing urbanization characterized the entire area, the population of Abidjan (Côte d'Ivoire), for example, growing from 5000 in 1921 to 180 000 in 1966 and the population of Lagos (Nigeria) from 100 000 to 665 000 during the same period.

National administrative structures largely reflected the legacy of the previous British and French colonial administrations. In the former British colonies, the authority of the tribal chiefs had been supported and fostered within a decentralized civil structure; in the former French colonies, however, the power of the traditional chiefs was largely subordinated to that of the civil service and a strong centralized government. For the smallpox eradication–measles control programme, the support of the principal chiefs in the former British colonies was therefore as vital as that of the civil authorities; in the former French colonies, the civil service and village leaders provided the essential link with the people. The governmental structure was different in Guinea and Mali, where the authority of a national political party superseded that of traditional leaders. In both countries, the parties greatly facilitated contact with the villagers.

Approaches to the provision of health services also differed, depending on the colonial tradition. In the former British colonies, rural dispensaries operated by African personnel provided basic drugs and sometimes vaccine, but they were rather few and far between and their efforts were devoted primarily to curative medicine. The establishment of mission clinics and hospitals was encouraged, however, and in some areas these were quite numerous. In the former colonies of France, in contrast, health services were more widely available, through the use of mobile multi-purpose prospection teams. The system, conceived during the 1920s by Dr Eugène Jamot, had first been used to control trypanosomiasis in Ubangui-Shari (later the Central African Republic), but the teams' duties were gradually expanded to include the prevention and treatment of other diseases; in time, similar teams were organized throughout French West Africa and French Equatorial Africa (Richet, 1965; Cohen, 1971). The Service des Grandes Endémies, as the mobile service was called, provided basic health services in rural areas, supported by dispensaries, which served as treatment centres for patients referred by the mobile teams. The establishment of mission clinics and hospitals had not been encouraged and therefore not many existed. After the colonial period, health services continued to be supported in most countries by French bilateral assistance. Mobile teams were also used in some of the former British colonies for yaws control and occasionally for smallpox vaccination, but, except in Ghana (Waddy, 1956), they did not operate throughout the entire country.

Thus, in a number of the countries of western and central Africa, a structure and/or tradition existed for executing large-scale vaccination campaigns. Systems for the notification and investigation of cases, however, were poorly developed.

PLANS FOR THE PROGRAMME

With only 13 months allotted before the commencement of field operations, and with available personnel fully committed to working out the logistics, CDC staff had had no time to undertake feasibility studies, pilot projects or field reconnaissance to determine the extent of vaccinial immunity or to assess the epidemiology of smallpox or measles. A number of assumptions were made, some of which were later to prove erroneous. For example, it was assumed that vaccinial immunity was uniformly low throughout the region but, in fact, urban populations were later found to have been moderately well vaccinated, as were the inhabitants of large rural areas in some francophone countries. Especially low levels of vaccinial immunity were observed, however, throughout northern Nigeria, in many parts of Sierra Leone and in the more isolated rural villages in most countries. It was also believed that cases of smallpox would be found to be widely dispersed in all countries but, in fact, 10 out of the 21 countries in the region were found to be free of smallpox or nearly so by 1967. Where smallpox incidence was high, cases and outbreaks tended to be concentrated in specific geographical areas. It was also assumed that, as in Asia, the densely populated cities and market towns would constitute the major reservoir for the sustained transmission of disease, with spread occurring from these foci to rural areas (Henderson, 1967). It was discovered, however, that comparatively few cases occurred in urban areas but rural areas were found to be capable of sustaining transmission over surprisingly long periods.

CDC staff viewed the eradication of smallpox as a feasible objective given its epidemiological characteristics, but less was known about measles, since it was not routinely reported in most countries. However, control rather than eradication was foreseen because of the greater communicability of measles, especially in Africa (Morley, 1962; Senecal et al., 1962), the greater difficulty of clinical diagnosis and the fact that the disease had not been eliminated in any country, as of 1967, even in those with well-developed health services. Whether the objective of the programme should be defined in terms of the control of measles or its eradication had been debated at length. AID staff thought it preferable to establish eradication as an objective, believing that even if it was not achieved, more substantial progress would be made. CDC staff were concerned lest the enunciation of a goal which might prove to be unrealistic, as had been the case with malaria eradication (see Chapter 9), would only serve to erode further the credibility of public health professionals. Eventually, the CDC position prevailed and so the programme bore the somewhat clumsy title of "smallpox eradication–measles control" rather than the simpler "smallpox and measles eradication." As the programme was to demonstrate, effective measles control, let alone eradication, was a formidable task (United States National Communicable Disease Center, 1970; Foege & Eddins, 1973).

The planning process would unquestionably have benefited if more information had been available regarding the incidence of both smallpox and measles and the capacities of each of the national health services, but the seeking of such information would have caused a delay of perhaps 12–18 months. With many commitments already made, so long a delay was not acceptable. Moreover, because of possible changes of government staff and of priorities, there was no guarantee that a better-defined project would subsequently be approved for funding. Thus, with the resources at hand, there was a need to act. Consequently, the project began without preparatory studies, employing such information as was available; a great many assumptions were made in the hope that an able and energetic staff would solve problems as they arose.

It was recognized that the different characteristics of the administrative, health and social structures in each of the countries would dictate somewhat different types of programme. Therefore, instead of a highly prescriptive plan, four principles were formulated for the execution of the national programmes in the expectation that during the first year they would evolve by trial and error: (1) the programmes would be coordinated as a regional effort because of the ready movement of people across national borders; (2) freeze-dried vaccine would be administered by mobile teams employing jet injectors in order to economize on scarce resources; (3) independent assessment of the vaccination campaign would provide a quality control mechanism; (4) a workable surveillance programme would be developed on the basis of regular reporting from case-detection sites, because, as had been stated, "The goal of the

project is a specific one, the reduction of smallpox to the level of zero cases" (Henderson, 1967).

Surveillance, as a principle, was a characteristic which differentiated this from previous smallpox eradication programmes and eventually proved to be critical to its success. It was a concept that had been fostered by Dr A. D. Langmuir at CDC (see Chapter 9); since 1961, CDC's surveillance programme had been under Henderson's direction. With respect to smallpox, it was defined in the following terms (United States Communicable Disease Center, 1966):

(1) The routine, systematic collection of data, amplified appropriately by special field investigations and studies.

(2) The analysis and interpretation of reported data and studies on a concurrent basis.

(3) The initiation of appropriate definitive action, including field investigation, epidemic control, modification of operational campaign procedures, and recommendations regarding vaccination.

(4) Widespread dissemination of the compiled and interpreted data to principal reporting sources and to others concerned with disease control activities.

As has been noted earlier, the concept of surveillance was unfamiliar to health staff in western and central Africa and it was thought that not less than 2 years of sustained effort would be required to develop a surveillance system. The CDC *Manual of Operations* (United States Communicable Disease Center, 1966) pointed out the need to begin the development of a notification system from the inception of the programme but did not then envisage the obligation to investigate and contain all the outbreaks that were detected. As the manual stated:

"In countries with a high endemic occurrence of disease, field investigation activities may focus on comparatively few of the many outbreaks. As systematic vaccination programs progress, the importance of small outbreaks and individual cases becomes increasingly important. As the numbers of cases diminish, the field investigation and control procedures should be instigated for an increasing proportion and, ultimately, for all cases."

Three stages in the development of the surveillance programme were envisaged:

PHASE I Referring to endemic areas with a sustained or frequent high incidence of smallpox as indicated either by official reports or by educated estimates. This would include all countries with a rate of perhaps 1 or 2 cases or more per 100 000 population per year.

PHASE II—Referring to countries with a low continuing incidence of smallpox.

PHASE III—Referring to areas rendered non-endemic by systematic vaccination. No country or subdivision would be classified in Phase III until it had been covered by the attack phase of systematic mass vaccination.

Strategically, surveillance and containment activities in most countries were initially considered as subsidiary to mass vaccination, serving primarily to identify problems or weaknesses in the mass vaccination campaign. When the number of cases had been substantially reduced by the vaccination campaign, surveillance and containment would become essential to eliminate residual foci. The activities deemed appropriate for each phase of the programme are listed in Table 17.4. On the basis of the reported incidence in 1966, Phase I activities were called for in at least 6 of the countries—Dahomey, Mali, Niger, Nigeria, Sierra Leone and Togo.

EXECUTION OF THE PROGRAMME

The first year of the programme was to be devoted to formulating logistic plans, training national staff, and evaluating methodologies for adaptation by both national and CDC personnel. Although it was inevitable that the development of a programme of this magnitude would encounter substantial problems, their extent had not been anticipated. The solution of these problems by CDC ultimately became the responsibility of Dr Millar, who returned from study leave in the summer of 1966 and assumed direction of the programme on 1 November, when Henderson went to Geneva to head WHO's Intensified Smallpox Eradication Programme.

By September 1966, the recruitment and training of staff had been completed as scheduled, but little else was proceeding as planned. The procurement of supplies and equipment lagged far behind schedule and formal agreements with countries were slow to be concluded. Two countries refused to sign programme agreements until they had been formally assured that WHO would provide funds for fuel supplies and travel;

Table 17.4. Western and central Africa: surveillance activities at different phases of the programme[a]

	Phase I	Phase II	Phase III
Reporting	Emphasis on principal medical units to obtain regular reports. Progressive extension to include all medical and paramedical units.	Extension of surveillance network to ensure that detection sites exist in all parts of country and that reports are regularly submitted. Some telegraphic reporting of cases.	As in Phase II. All cases reported telegraphically.
Field investigation	Investigation of significant epidemics or epidemics in unusual areas as time permits.	All outbreaks promptly investigated by competent epidemiological authority. Cases promptly investigated by national or intermediate health jurisdictions. Case investigation forms submitted for every case.	Each case an "emergency". All cases promptly and routinely investigated by competent epidemiological authority.
Control procedures	Special units to undertake epidemic control as necessary.	Prompt control procedures for each case and outbreak by central or intermediate health authority.	Prompt control procedures with central authority participation. Identification, vaccination and, if necessary, isolation of contacts.
Laboratory study of cases	Only in special circumstances, usually for research purposes.	Specimens to be obtained from each isolated case and representative samples from outbreaks.	Every case to receive laboratory study.

[a] From United States Communicable Disease Center (1966).

several objected to the requirements for surveillance; another expressed concern about budgetary obligations; in Upper Volta, in which the measles control programme had first been successfully conducted, the director of the endemic diseases control service refused to endorse the programme on the grounds that smallpox eradication could not be achieved. Continuing discussions eventually led to the signing of 3 agreements in October, 4 in November and 3 in December. The last to be signed were those in the Gambia, Senegal and Upper Volta, in March 1967.

Each national programme experienced different types of problems and each had to be adapted to the health structure and social

Plate 17.7. Health workers of Dahomey's endemic disease control service at a training course on the use of jet injectors, March 1967.

context of the country concerned. As programmes progressed, epidemiological observations and useful techniques for field operations were communicated from one to another through annual meetings of national directors and CDC advisers, through the travel of staff based in Lagos and Atlanta and through periodic surveillance reports which were sent to programme staff in all countries. To attempt to present events throughout the region in chronological order is difficult and confusing, given the number of different national programmes. Accordingly, we shall first describe progress in the programme as a whole before commenting on the salient features of individual national programmes.

In most of the countries, field operations commenced between January and June 1967; in the others, for which assistance had been postponed for a year—Guinea, Liberia and Sierra Leone—these operations had all begun by January 1968.

The proposed method of operation in each of the vaccination campaigns drew extensively on the experience of Dr Harald Frederiksen, a United States adviser to an earlier successful smallpox vaccination campaign in Bolivia (Frederiksen, 1962). It called for vaccination of the population at assembly points. This was achieved through preparatory meetings with local chiefs and civil authorities to explain the programme and to solicit their help. Such meetings took place 1 to 7 days before the vaccination team arrived. The assembly points were usually selected so that no one would have to walk more than 8 kilometres, although, in some areas, even this distance was found to be too great and it was decreased to 3 kilometres. The teams usually consisted of 5 or 6 persons—as many as could conveniently ride in one vehicle. They vaccinated all persons against smallpox and children between 6 months and 4 years old against measles. Although on some days as many as 10 000–14 000 persons could be vaccinated, on average the teams administered between 750 and 3000 smallpox vaccination daily (Millar & Foege, 1969) and about one-fifth of this number of measles vaccinations. The teams usually worked for a consecutive 3-week period, camping out or staying in the villages. As experience demonstrated, living among the local population fostered cooperation and improved vaccination coverage. At the end of the 3 weeks, 7–10 days were set aside for rest and recuperation.

Jet injectors were used for most vaccinations, but in small villages and among special groups, smallpox vaccine was administered by bifurcated needle. Most people readily accepted vaccination, although resistance was encountered in Dahomey, Togo and south-western Nigeria, where an animist cult was active among some small groups, and in scattered, remote areas. In each instance, special efforts were made to persuade village and religious leaders of the benefits of vaccination—usually, but not always, with success.

In urban settings, the vaccination campaign required special planning and the provision of many more vaccination assembly points. In Nigerian towns, it was calculated that one assembly point would be required for every 8000 persons and that arrangements would have to be made for vaccination in the early morning and late afternoon (Smith et al., 1970). The most intensive urban campaign was that conducted in Ibadan (Nigeria), in which, over a 10-day period, 12 teams administered 757 308 smallpox vaccinations and 69 069 measles vaccinations. People connected with the university, local churches and private voluntary organizations, as well as members of the police force, assisted in the effort.

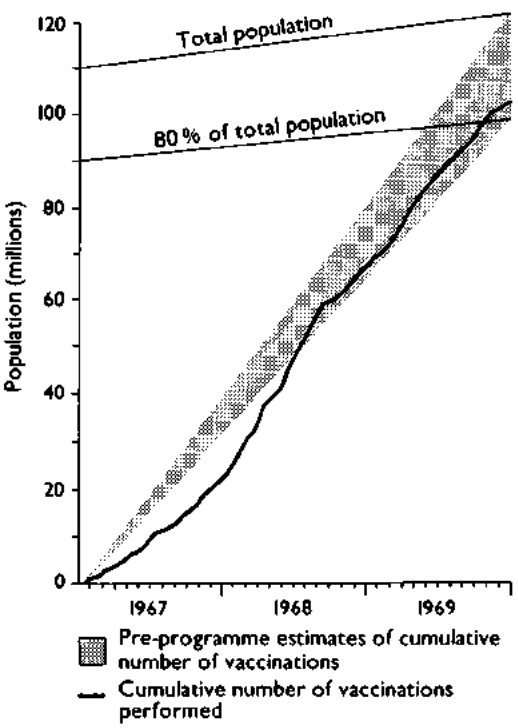

Fig. 17.3. Western and central Africa: cumulative number of vaccinations performed compared with pre-programme estimates. (From Foege et al., 1975.)

Plate 17.8. William Stewart, Surgeon General of the United States Public Health Service, attended a special ceremony in Ghana, in January 1968, to celebrate the 25 millionth vaccination given. George Lythcott (b. 1918), with sunglasses, was Director of the CDC regional office in Lagos from 1967 to 1972. An able and diplomatic administrator, Lythcott played an important role in sustaining the momentum of the programme through many political and logistic crises.

The pace of the vaccination campaign gradually accelerated. By January 1968, a special ceremony in Ghana marked the 25 millionth vaccination and by the summer of 1968 (Fig. 17.3), the numbers vaccinated had reached the optimistic estimates of January 1965.

The concurrent assessment of coverage, although deemed essential, was conducted in only 9 of the countries. The principal objection to assessment was that it wasted resources. Where it was performed, teams of 2 or 3 persons visited a random sample of 5–10% of the villages whose inhabitants had been vaccinated 4 10 days previously to ensure that the proportion of successful vaccinations was satisfactory and that coverage was adequate. Where coverage was found to be low, a repeat vaccination campaign was organized. Assessment data showed that good coverage was achieved in most countries (Table 17.5).

To ascertain the overall efficacy of the vaccination campaign, special surveys were conducted in 1968 in 5 areas—Dahomey, Niger, northern Nigeria, western Nigeria, and Togo under the direction of Dr Ralph Henderson, then deputy director of the Lagos regional office (Henderson et al., 1973). With Mr Donald Eddins and Dr William Foege, he devised for the purpose of this survey a practical method of cluster sampling based on principles elaborated by CDC statisticians for immunization surveys in the USA (Serfling & Sherman, 1965). (The method was later adapted for use in WHO's Expanded Programme on Immunization, in nutrition surveys and in other health status assessments.) The survey revealed a generally satisfactory performance in most programmes. Nearly 80% of the people questioned reported having been vaccinated with jet injectors (Table 17.6). The low rates among those under 1 year of age

Togo	80	88	3.1

could largely be accounted for by children born after the mass campaign; lower rates among those over 45 years were attributable to the fact that a number of older people had declined to be vaccinated, believing (correctly, in most instances) that they were already immune owing to previous disease or repeated vaccinations. The best results were obtained in northern Nigeria, in which cooperative, authoritarian emirs and district chiefs directed their subjects to accept vaccination; the lowest rates were found in western Nigeria, which lacked the tradition of authoritarian leadership and in which no concurrent assessment had been conducted.

Special comment is called for regarding the results obtained among children aged 0–4 years in Niger and northern Nigeria. In these areas, the proportion with a vaccination scar acquired at any time was lower than the proportion reported to have been vaccinated with the jet injector. This paradox can be partly explained by the possibility that some of the vaccinations by jet injector might have been unsuccessful or that parents might have reported that vaccinations had been performed when they had not. Because the surveys were conducted many months after the campaign, it proved impossible to determine the cause or to remedy the situation.

Of particular interest was the much higher proportion of persons in northern Nigeria with facial pockmarks, confirming a growing suspicion that this was the principal endemic focus of smallpox in western and central Africa.

Coordination With International Organizations

Throughout the course of the programme, beginning with the initial planning visits, efforts were made by CDC staff to develop a collaborative working relationship with WHO through its Regional Office for Africa, the WHO representatives in the respective countries and two WHO smallpox advisers based in western Africa—one in Mali and the other in Liberia. These attempts were less successful than had been hoped, partly because the WHO regional adviser in Brazzaville who had been assigned responsibility for smallpox eradication had many other duties and could devote little time to the programme. Dr Mayer, the WHO adviser in

Measles Control

Many valuable observations were made during the course of the programme with respect to the epidemiology and control of measles (Foster & Pifer, 1971), a disease which presented quite different problems from those of smallpox. Case-fatality rates associated with measles were customarily 4–5%, sufficient to identify it as second only to malaria as a cause of death among children. In contrast to smallpox, measles spread rapidly and widely. Studies in urban and in the more populous rural areas revealed that 50% of cases occurred in children less than 15 months of age (Smith & Foster, 1970a). Only in remote villages, where visitors were infrequent, did substantially higher proportions of cases occur among older children (Millar, 1970). In densely populated urban areas, morbidity decreased by about half for only 1 year following a mass vaccination campaign; in more sparsely populated areas, this decrease persisted for 2 years but the incidence then returned to pre-vaccination campaign levels (Smith & Foster, 1970b). In the hot and humid densely populated coastal areas, there was no apparent seasonal change in the frequency of transmission.

The prevention of measles infection was, and continues to be, a difficult problem. Essentially all children are born with circulating maternal antibody, which prevents infection. In some the protection is lost within 5 months, but in others it persists for up to 12 months of age. However, immunization is successful only after maternal antibody is lost, this antibody serving to protect against the attenuated infection induced by the measles virus vaccine. To prevent infection, therefore, it is necessary to administer the vaccine during the brief period between the time the child has lost the protection conferred by maternal antibody and his exposure to infection—in Africa, usually between 6 and 18 months. In a mass campaign in which vaccinations are given, for example, every 2–3 years to preschool children, much of the vaccine has no effect, these children being protected by maternal antibody or having already had the disease. Thus, the effect of a mass campaign on measles incidence is a transitory one. Efforts were made to vaccinate at more frequent intervals in urban areas of western Africa, but usually this had little effect unless the campaigns were conducted every 6 months, a prohibitively expensive strategy. Vaccination at conveniently located health centres was an alternative but in most areas there were few of these and most were not equipped with refrigerators. Thus, although the number of measles cases and deaths could be reduced, sometimes substantially for short periods of time, long-term control was not achieved.

Liberia, was WHO's intercountry adviser for all smallpox programmes in western and central Africa, but he could rarely travel. In 1968, he was transferred to Mauritania, where he served as the smallpox eradication programme adviser, the CDC adviser having had to leave Mauritania when diplomatic relations between that country and the USA were severed. The WHO adviser assigned to Mali rarely left the capital and in 1968 his post was discontinued. In response to requests from Member governments, the WHO Regional Office for Africa provided funds to cover local costs, 13 countries receiving in all a total of US$1 110 675 over the period 1967–1972. However, apart from processing these requests, the regional office and the WHO country representatives had little contact with the CDC programme.

From Geneva, Henderson maintained close contact with the CDC staff in Atlanta. They and selected national counterparts contributed to WHO interregional and intercountry smallpox seminars in Africa, South America and Asia; some WHO staff from the regions participated in the CDC smallpox eradication training programme in Atlanta in 1967 and 1968; and accounts of the progress made in western and central Africa were regularly published in the WHO *Weekly epidemiological record* and in special reports of the smallpox eradication programme. From 1968, supplies of bifurcated needles began to be shipped from Geneva, and in 1969 a jointly sponsored

WHO/AID/CDC conference on smallpox eradication was organized in Lagos. The extensive proceedings, which documented many important observations on smallpox eradication (United States National Communicable Disease Center, 1970), were distributed to WHO and national staff throughout the world.

Collaboration with OCCGE and OCEAC was effective and useful. These organizations, both supported by France, kept abreast of events through written reports and discussions at their semi-annual meetings, which dealt with the progress and policies of this and other regional programmes. The directors of these organizations also participated actively in solving problems of implementation and communication arising in programmes conducted by their member governments. In addition, OCEAC served as an intermediary for the transmittal of national reports and the receipt of supplies and equipment for the Congo, with which the USA did not then have formal diplomatic relations; beginning in 1968, OCCGE performed a similar function with respect to Mauritania.

Changing Roles of the CDC Atlanta Office and the Lagos Regional Office

Flexibility in the management structure was no less important than in field operations. The Lagos regional office had been expected to serve as the principal point of contact for operations and as the conduit for reports and requests from all the national programmes; the CDC Atlanta office was expected to bear primary responsibility for recruitment, training, procurement of supplies and equipment and liaison with AID. This management relationship had originally appeared to be the most logical because of the geographical proximity of the Lagos office staff to field operations and of the less elaborate procedures that would be needed to obtain United States government approval for travel by persons stationed abroad. What had seemed logical during the planning stage, however, proved less functional in practice. It soon became apparent that communication between the individual countries and Atlanta was usually easier than between them and Lagos. When a protracted civil war broke out in Nigeria in 1967, the difficulties became greater as cable traffic increased. Because messages concerned with the smallpox eradication–measles control programme were given low priority, a cable from a national capital sent through Lagos took as long as 1–2 weeks to reach Atlanta. Shipments of supplies by air freight or diplomatic pouch were also delivered more promptly when dispatched from Atlanta than from Lagos. Although it was a major transport centre, Lagos had few direct flights to many of the African capitals, especially those of the francophone countries. In consequence, field staff and personnel in Atlanta, faced with an increasing array of problems, found it necessary to communicate direct with each other.

Towards the end of the first year, responsibilities and relationships were redefined to centralize direction in Atlanta, the Lagos office assuming a support role in contacts with national authorities and undertaking special investigations and assessments. In practice, the revised system worked well: new approaches were identified as experience accrued, and alternative methods and systems found useful in one country were applied with little delay throughout the region.

Surveillance and Containment Activities

It had been thought at first that surveillance and containment activities would be most crucial to interrupting transmission during the concluding phases of each of the national mass campaigns, but experience quickly showed that they could play a vital role from the beginning of a programme, irrespective of smallpox incidence. This was first shown in eastern Nigeria, just as the regional programme began.

The Nigerian programme agreement was signed on 6 October 1966 and field staff soon began to arrive. Operations were, however, initially confined to 2 of Nigeria's 4 regions because special agreements had to be finalized with each of the semi-autonomous regions before work could begin. The Eastern Region was the first to commence operations. In November 1966, Dr Foege with Dr David Thompson and Mr Paul Litchfield, began a programme of staff training while awaiting delivery of vehicles and other commodities. Early in December, they were informed by a missionary of smallpox cases in a small village and decided to use this opportunity to train vaccination teams in containment activities. Using borrowed transport, they vaccinated people in the

village and along nearby roads; an outbreak of 19 cases was stopped in 4 weeks (Foege et al., 1975). Missionaries in the southern part of the Eastern Region, who had their own radio network, were approached for help in notifying other outbreaks. Two further outbreaks were soon identified, one of 14 cases and one of 5 cases. Both were contained within 3 weeks, again simply by vaccinating household and village contacts. With the limited resources available, the programme staff had expected to do little more than control a few of an anticipated large number of outbreaks, but surprisingly no further outbreaks were reported in this area. On investigation, the staff discovered that the last epidemic to be recorded in the area had occurred in 1950, despite the fact that comparatively few persons, except those living near roads, had been vaccinated since then. The first case in the 1966 outbreaks had come from the Northern Region of Nigeria fully 5 months before; subsequently, smallpox had spread slowly southwards with as many as 4 generations of cases occurring in a single compound. The finding of so few outbreaks, all in nearby villages, along with the discovery that they could be rapidly contained even where vaccinial immunity was low, was impressive. A review of data from earlier years suggested that outbreaks normally began along the northern borders of the region and spread progressively towards the south, an observation which suggested that persistent endemic transmission did not occur in most of the Eastern Region.

The programme staff decided to concentrate their resources in areas in which smallpox was known to be present. Accordingly, a new reporting system was devised. In each of the 3 provinces of the Eastern Region, a reporting officer was designated to obtain weekly reports from all government and missionary health establishments and transmit them by radio directly to Enugu, the regional capital. The data quickly revealed that most of the known cases were occurring along the northern boundaries, and a pilot vaccination campaign was therefore begun in the northern urban area of Abakiliki (WHO/SE/68.3, Thompson & Foege). Within a week, 46 500 people were vaccinated and gradually the campaign moved to adjacent areas in the savanna. Numerous unreported cases of smallpox were discovered and, by May 1967, 754 cases with 180 deaths had been documented.

Meanwhile, political turmoil steadily increased throughout the Eastern Region and on 30 May the predominantly Ibo tribal population seceded from Nigeria, proclaiming the independent Republic of Biafra. It became increasingly difficult to continue with the programme; travel was restricted to those with special passes, and petrol became scarce. Nevertheless, during June 1967, a mass vaccination campaign was conducted in and around Enugu — the only remaining endemic focus. By the end of the month, transmission appeared to have ended, after only 6 months of activity, during which only 750 000 of the 12 million inhabitants had been vaccinated (Foege et al., 1971). Programme operations in eastern Nigeria were interrupted almost immediately thereafter but the idea had been planted that it might be desirable to give precedence to the discovery and containment of outbreaks over the execution of the mass vaccination campaign.

By June 1968, vaccination teams were active in 19 countries; some 40 million persons had been vaccinated—about 35% of the estimated population. In each programme, priority was given to vaccination campaigns in the areas reporting the most cases of smallpox, although this strategy was not pursued with the same vigour as in eastern Nigeria. Less than half the countries had independent assessment teams but in most of them documentary or other evidence indicated that the vaccination coverage was high. The impact of the vaccination campaign was already apparent, only 2312 cases being reported by the end of May compared with 4071 during the same period of the preceding year. Although reporting systems were still inadequate, many cases which would not otherwise have been reported were being detected by vaccination teams, and some during outbreak investigations, where these were being undertaken.

In June 1968, Dr Foege, who had joined CDC's Atlanta staff, proposed to participants at the annual CDC Regional Programme Conference a change in strategy to hasten eradication — namely, to give priority to the detection and containment of outbreaks (Foege et al., 1971). Originally, there had been doubt that simple containment measures could be effective because of the common belief that smallpox was comparatively easily and rapidly transmitted through the population (Felsenfeld, 1966; Top, 1968), especially where vaccinial immunity was low. The

experience in eastern Nigeria and a study in Dahomey in 1967 (Henderson & Yekpe, 1969) contradicted this. Moreover, epidemiological studies of smallpox in East and West Pakistan in 1966–1967 (Thomas et al., 1971a,b, 1972; Mack et al., 1972a,b) also showed that smallpox spread slowly, that outbreaks tended to be clustered in an area rather than widely dispersed and that at the low point of seasonal incidence very few villages were infected. These observations were also confirmed in India in a study conducted in a district classified as heavily infected but in which it was found that at no time were more than 1% of all its villages infected with smallpox (India National Institute of Communicable Diseases, 1968).

Dr Foege reasoned, as had the investigators in Pakistan, that intensive efforts to detect and contain outbreaks, if begun at the low point of seasonal incidence (September–October), should readily contain the few outbreaks then present. This would serve to avert major epidemics later in the year, when smallpox spread more rapidly. He proposed that each of 8 countries which then had endemic smallpox should undertake an intensive and continuing programme of surveillance and containment. The programme was given the name E^2, for "eradication–escalation" (Foege et al., 1971). The strategy was formally adopted in July 1968 by all countries except Nigeria, which decided that because of a widening civil war, it would give priority to completion of its mass vaccination campaign. However, in areas of Nigeria in which mass vaccination had been conducted, specially assigned short-term CDC epidemiologists would undertake outbreak investigation and containment.

For the detection of cases, the usual reporting mechanism was augmented by the cooperative efforts of other special health service programmes (e.g., leprosy and malaria control), government personnel, village leaders and non-governmental bodies such as missions. Outbreaks were investigated and vaccination was performed in a "geographically or socially contiguous area around each patient", as determined by epidemiological investigation. The area was not defined more explicitly, as was later done in Asia, nor was an attempt made to enumerate contacts and village populations to ensure that all had been vaccinated.

The increase in surveillance activity led to the discovery of many additional cases, with the result that the number of reported cases rose from 197 in August to 289 in September; from then on, it fell steadily (Table 17.7).

By January 1969, endemic smallpox remained only in Dahomey, Nigeria, Sierra Leone and Togo. The last cases in Sierra Leone and Togo were detected in May of that year, and the last case in Dahomey was found in September; thereafter no further cases were notified for 6 months (Table 17.8). In March 1970, however, a persistent endemic focus was discovered in northern Nigeria, but 2 months later the last known case in Nigeria, the last in western and central Africa, was detected, only 9 months after "eradication–escalation" had begun.

The vaccination campaign continued throughout the "eradication–escalation" operation, 33 million persons being vaccinated during 1969 and 22 million in 1970 (Table 17.9). Contrary to expectations, the pace of the vaccination campaign did not diminish during this period; indeed, more vaccinations

Table 17.7. Western and central Africa: number of cases of smallpox reported and detected in 9 countries,[a] 1968[b]

Period	Total	Number of reported cases	Number of additional cases discovered	Percentage detected through active surveillance

[e] Cases reported in May 1969; the onset of the last case was in April 1969.

were given each week, on average, than before the special programme began. By the end of 1970, the number of vaccinations performed in 12 of the countries was equivalent to, or greater than, the estimated population.

During 1971–1972, the programme was modified in order to give priority to the vaccination of those who had been missed during the initial mass campaign and of those born after it. By the end of 1972, 153 484 000 smallpox vaccinations and 28 163 000 measles vaccinations had been performed. The cost of smallpox eradication in the region was estimated to be US$0.138 per head of population (Foege et al., 1975).

In 1972, as the 5-year programme drew to a close, CDC staff proposed to AID that other types of vaccine and support for other preventive measures should be provided in order to strengthen the health services in the countries of western and central Africa. Although the proposal was endorsed by all the ambassadors of the USA in the region, as well as the respective health ministers, the programme was terminated at the end of 1972. CDC sought to sustain surveillance and a maintenance vaccination programme by assigning epidemiologists to OCCGE and OCEAC, but because of the large number of countries and the lack of supplies and equipment to replenish the programmes, vaccinial immunity steadily declined thereafter as did the quality of surveillance. By 1976, when precertification activities had to be undertaken, special programmes had to be initiated in all the countries of the region to document what had been accomplished and to verify, through pockmark surveys, that no further cases had occurred.

NATIONAL PROGRAMMES

Each of the national programmes had different characteristics and encountered different types of problems, some of which are summarized and discussed below. For ease of presentation, the countries are dealt with in 7 groups (shown in Fig. 17.1): (1) Nigeria—the most populous country, which, between 1967 and 1970, reported 6854 (40%) of the region's 17 106 cases; (2) Dahomey and Togo—2 small adjacent coastal countries, in which smallpox incidence was high, and in which there was resistance to vaccination because of fetish practices; (3) Mali, Niger and Upper Volta—3 inland Sahelian countries, in which

Guinea-Bissau

Throughout the duration of the AID-supported smallpox eradication programme in western and central Africa, the status of smallpox in Guinea-Bissau was uncertain and caused concern. Until 1974, when Guinea-Bissau became independent, the Portuguese colonial administration reported regularly that no smallpox cases had occurred. However, there was widespread civil war, with rebel forces reputed to be in control of two-thirds of the country. The adjacent country of Senegal remained smallpox-free and posed no threat, but extensive epidemics occurred in many parts of Guinea, in which the bases of the rebel forces were located. Officially, nothing could be done to support activities in Guinea-Bissau but, as was the case in the Sudan, which also experienced protracted civil war (see Chapter 18), leaders of the rebel forces evinced concern about smallpox. They sent health workers for training in Guinea, which provided vaccine and bifurcated needles. Health staff in the rebel-held areas also reported periodically on smallpox. So far as could be ascertained at the time, and later during certification surveys, no cases of smallpox occurred in Guinea-Bissau during this period.

there were many nomads and frequent transhumance; (4) Guinea and Sierra Leone—2 highly endemic countries, in which programmes were launched nearly a year later than in the other groups but which succeeded in interrupting transmission within 18 months; (5) Côte d'Ivoire, Ghana and Liberia—3 adjoining countries on the southern coast of western Africa, which experienced few cases of smallpox after 1966; (6) the Gambia, Mauritania and Senegal—all of which were free of smallpox when the programme began, and remained so; and (7) the OCEAC countries—only 2 of which (Cameroon and Chad) detected cases of smallpox after 1966, mostly imported from Nigeria. Guinea-Bissau's status is summarized in the accompanying box; activities in Equatorial Guinea, which remained free of smallpox and in which no special programme was conducted, are not further described.

CENTRE CULTUREL AMERICAIN, COTONOU

Plate 17.9. A vaccination team at work in Dahomey in 1967.

Nigeria

Nigeria (population in 1967, 51.9 million) was the crucial country for the smallpox eradication programme, being centrally located and heavily endemic (Fig. 17.4) and having a population totalling nearly half that of the entire region. The largest number of CDC technical staff were therefore assigned to Nigeria and the CDC regional programme office was located there.

When the programme began, Nigeria was a federal republic consisting of 4 regions and the federal district of Lagos. Because responsibility for health matters was delegated to the

regions, programme policies and plans had to be worked out and agreed on not only at the federal level but with each regional authority as well. Each region, in turn, dealt with traditional tribal authorities, which, in the Northern Region, had substantial powers. The National Council on Health had decided in 1962 that the eradication of smallpox should be an objective of national policy (Foster & Smith, 1970) and plans for such a programme were developed by the Principal Medical Officer of the Ministry of Health of Nigeria, Dr G. A. Ademola. Implementation of the programme, however, had to be delayed until 1967, when resources were made available by AID. Meanwhile, thermolabile lanolinated vaccine, produced in a government laboratory in Lagos, was provided for use in health centres, but because it was rarely kept under refrigeration, many of the vaccinations were unsuccessful. Mobile field teams, which periodically undertook mass vaccination campaigns, undoubtedly improved vaccinial immunity in the Eastern, Western and Mid-Western Regions. However, nowhere was the level of immunity high, and in the Northern Region, vaccination coverage was especially poor.

Pockmark surveys conducted after the AID-supported programme began revealed that smallpox had been widely prevalent throughout Nigeria during the early 1960s, an estimated 100 000 or more cases having occurred annually. Survey data, as well as morbidity data compiled in 1967 (Fig. 17.5), showed the Northern Region to be the most heavily afflicted. In this region, which consisted mainly of savanna and arid scrub, the highest incidence occurred in the dry season, from January to May; in coastal areas, seasonal changes were less marked. The case-fatality rate was probably about 10%, although the only available data pertain to persons admitted to hospital—usually those who were the sickest and among whom deaths would have been more frequent (Table 17.10).

Early in 1967, Nigeria was on the brink of civil war. As major tribal groups vied for power, a military government displaced civilian rule, and an army mutiny occurred in the north, accompanied by extensive riots. The Eastern Region of the country threatened to secede. Despite these serious problems, the government supported the smallpox eradication programme. Pilot activities, each with its own programme unit, began in Lagos and in the Eastern and Western Regions during the spring of 1967 and in the Northern and Mid-Western Regions during the summer. Because of the widespread prevalence of smallpox and concern as to the continuing stability of the country, Dr Ademola and Dr Stanley Foster, the CDC senior adviser, decided to devote all available resources to the mass vaccination campaign, giving first priority to the areas with the highest incidence in each region.

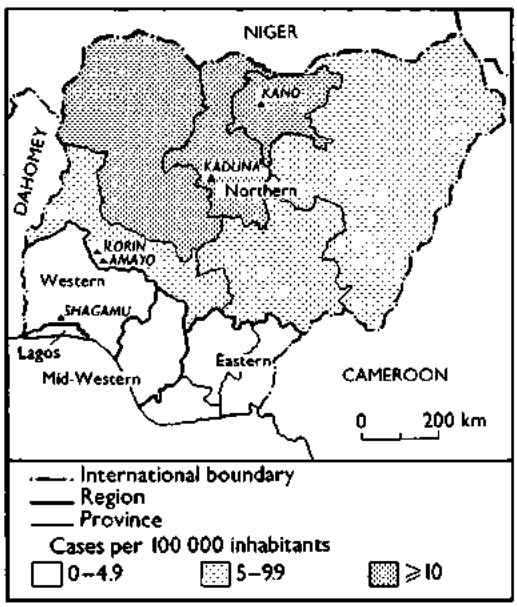

Fig. 17.5. Nigeria: smallpox incidence by administrative region and province, 1967. Early in 1967, Nigeria was made up of 4 regions and the federal capital territory of Lagos. The map also shows the provincial subdivisions in the Northern and Eastern Regions.

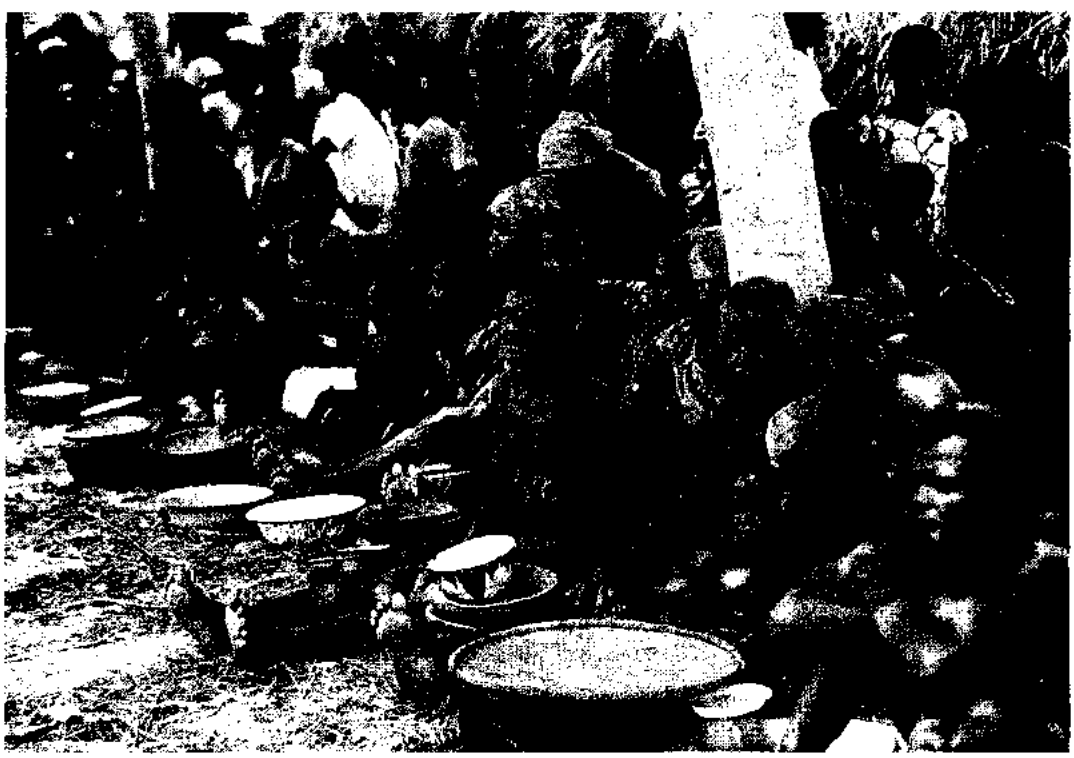
The responsibility for outbreak control was left to local health authorities, to which the government continued to issue lanolinated vaccine despite advice to the contrary by CDC staff.

In the Eastern Region, smallpox was eliminated with surprising rapidity. Mass vaccination in the north of that region, in which cases were concentrated, concluded in June 1967, simultaneously with the occurrence of the last known smallpox cases. In July, the Eastern Region having declared itself the independent Republic of Biafra, fighting between the Nigerian and Biafran armies began along its borders. The vaccination campaign decreased in intensity but did not stop immediately, and for many months vaccine continued to be transferred from Nigerian to Biafran health authorities during cease-fire periods arranged for this purpose. By the end of 1967, however, vaccination had ceased, and in 1968 widespread famine developed in Biafra, accompanied by epidemics of measles with high case-fatality rates. In October, the government of Biafra appealed for help and the International Committee of the Red Cross (ICRC) and the World Council of Churches responded with technical assistance and provided measles and smallpox vaccines, the latter coming from WHO stocks in Geneva. A vaccination campaign began again on 27 December 1968, organized by Dr A. E. Ifekwunigwe, a senior lecturer in paediatrics at the university in Enugu, Dr Nicole Grasset of the Institut Pasteur (Paris) and Dr A. T. C. Bourke, consultant to the ICRC. Despite serious shortages of petrol and staggering problems of transport and communication, 11 teams succeeded during the following year in giving an average of 100 000 smallpox vaccinations and 3500 measles vaccinations each week. Suspected cases of smallpox were investigated and specimens sent to Geneva for examination by WHO reference laboratories, but none contained smallpox virus.



ICRC

Plate 17.10. The secession of the Eastern Region of Nigeria and the civil war that ensued resulted in extensive famine throughout that area. Despite formidable problems and great personal danger, national and international staff undertook extensive smallpox and measles vaccination campaigns, with special attention to refugees in camps.

Meanwhile, by the beginning of May 1967, a pilot project in Lagos had been completed during which 1 million persons were vaccinated against smallpox; in February, the Western Region began its programme and in July more than 750 000 were vaccinated in Ibadan, the capital. Assessment showed that 90.8% of the population had been vaccinated. In the Northern Region, however, problems in reaching agreement about the conduct of the programme delayed its start until July. The vaccination campaign began in the western part of the region, in which the reported smallpox incidence was highest, and moved progressively eastwards, achieving substantially higher levels of coverage than in other parts of the country. The better coverage was achieved as a result of the edict of tribal leaders that people accept vaccination or be fined if they refused. As one programme officer commented: "In the south, a health education programme had to reach all the people to convince them to participate in a health activity, whereas in the north, a health educator only had to convince the emirs."

By the end of 1967, some 9.5 million smallpox vaccinations had been performed in Nigeria. A monthly mimeographed "Nigerian Smallpox Eradication–Measles Control Surveillance Report," which first appeared in April of that year, informed health staff throughout the country about the efforts being made. The number of cases reported in 1967 (4753) differed little from the 1966 figure (4953), most of the cases being reported during the first half of the year, primarily from the Northern Region.

Although the national programme had proceeded at a slower pace than planned, it was remarkable that so much progress had been made in a country engaged in full-scale civil war. There were problems in the delivery of supplies by air and sea, serious impediments to travel, shortages of petrol and other supplies and considerable personal risk to the teams working near the areas bordering on Biafra. Imagination, persistence and courage were required of national staff and CDC advisers alike: Dr Ademola and Dr Emmanuel A. Smith, the national programme director; Dr J. I. Adetosoye, Dr I. S. Mebitaghan and Dr P. O. Adeoye, Nigerian directors of programmes in the west, mid-west and north, respectively; and their CDC counterparts, Dr Margaret Grigsby (succeeded by Mr Lloyd Wade), Mr Warren Jones (succeeded by Mr Paul Bond) and Dr Deane Hutchins (succeeded by Mr Robert Hogan). The age distribution of cases of smallpox for which ages were recorded closely resembled that of the general population (Table 17.11), suggesting that where outbreaks occurred, primarily in rural areas, immunity was low throughout the population.

Problems in northern Nigeria continued to be substantially greater than in other regions, partly because of its size, the lack of roads and the relative paucity of health facilities, and partly because many of the senior administrative and technical staff, including mechanics, had been Ibos from the Eastern Region who had fled with the onset of war. Only 3 CDC technical staff had originally been assigned to assist, but in April 1968 their number was increased to 6 and the CDC regional office equipment specialist was transferred to Kaduna to train new mechanics in the repair and maintenance of some 60 vehicles and jet injectors. Operations were further complicated, however, by the government's decision to divide the region into 6 states, a move which required many modifications in the programme, including the reassignment of supervisors and field personnel, the restructuring of the reporting system, and changes in the budget and payment systems.

As 1968 advanced, the programme in Nigeria became fully established and during the year almost 24 million persons were vaccinated against smallpox by 60 mobile teams. In the Northern Region, assessment teams, visiting areas 7–14 days after the population had been vaccinated, usually found coverage levels of 95% or higher. For assessment elsewhere, the authorities decided to use the less satisfactory method of comparing the number of vaccinations performed with the population census figure. Although the personnel of the Western Region pro-

Vaccine Production in Nigeria

From 1967 onwards, both CDC and WHO provided support to a government vaccine production laboratory at Yaba, near Lagos, in the hope that it might be able to manufacture sufficient high-quality freeze-dried vaccine to meet the needs of Nigeria and perhaps of other countries in western Africa. A CDC virologist, Mr Nathaniel Rothstein, was appointed to the laboratory in 1967 and, later, a WHO expert in vaccine production, Mr Ronald C. Kent, was assigned there and remained until 1976. Nigerian laboratory staff, assisted by WHO fellowships, received training in the United Kingdom, and the necessary laboratory equipment was provided by WHO. Batches of freeze-dried vaccine began to be produced in 1968 but the vaccine did not meet international standards until 1974, and then only briefly. Frequent transfers of technical personnel and management problems hampered work throughout this period. Nevertheless, the vaccine was routinely distributed for use in health centres, the vaccination teams using vaccine supplied by the USA. After 1973, the laboratory supplied all the vaccine required in Nigeria.

gramme regularly estimated the coverage to be 90% or greater, later surveys showed levels of 80% in towns of more than 5000 inhabitants and levels as low as 45–65% in the villages.

In September 1968, with the introduction of the regional "eradication–escalation" programme, efforts were made in Nigeria to improve the reporting system, which was complex and functioning poorly, some reports being delayed for weeks or even months—if they were sent at all. The system required the responsible village heads to report suspected cases to a district superintendent, and although some complied, many did not. The district superintendent, in turn, was expected to inform the superintendent for health, who was supposed to institute control measures and to forward his report to an area medical officer, who in turn reported to the regional government. Such outbreak control measures as were undertaken were largely ineffective, since the lanolinated vaccine continued to be distributed to the local health authorities. In the hope of improving reporting, efforts were made to persuade teachers, missionaries, foreign volunteers and others to report cases by recording the details on stamped addressed postcards, which had been duly supplied. In practice, however, this activity had little effect.

Although the epidemiological observations in eastern Nigeria had generated the "eradication–escalation" strategy, Nigerian staff and their CDC counterparts decided not to divert resources to this undertaking. As they assessed the situation, surveillance in northern Nigeria, in which virtually all cases were then occurring, could be established only with difficulty and over time because health centres were few, experienced personnel were lacking and the population was widely dispersed. In view of the continuing war, it was uncertain whether vaccination teams would have access to many areas in the future. Because the mass vaccination campaign was progressing well, with high levels of coverage, it seemed to the personnel concerned that the most prudent course would be to complete the campaign as rapidly as possible. That being accomplished, resources could be diverted to the investigation and containment of outbreaks. Limited surveillance activities were begun, however, towards the end of 1968, using short-term CDC epidemiologists in areas in which mass vaccination had been completed. At that time cases were found to be occurring in small outbreaks primarily among semi-nomadic Fulani herders. Having no special allegiance to the principal tribal leaders, these groups had largely been missed by the vaccination teams and by assessment teams as well (WHO/SE/68.5, Pifer & Adeoye).

The mass vaccination campaign continued to progress rapidly, concluding in the autumn of 1969. Meanwhile, the number of reported cases of smallpox declined sharply, only 5–16 cases being recorded each month from March to the end of July 1969. After July, no further

Northern Nigeria: the Role of Traditional Leaders

In northern Nigeria, strong traditional tribal leadership both helped and hindered programme implementation. One adviser recalled his surprise when attending the first mass vaccination campaign in a town to find 6000 persons already in a line at 6 o'clock in the morning. As the day progressed, he proposed to the chief that a vaccination team should move to the market area to begin work there. The chief forbade this, indicating that if all vaccinations were performed in front of him, everyone would comply, but if he were not present at the vaccination assembly point, people would report they had been vaccinated when they had not. Vaccination in this and other largely Muslim northern cities continued until long after dark, as women were not allowed to leave their homes until nightfall.

On the negative side were such problems as those encountered during the investigation of the outbreaks in 1970 in and around Amayo. A village chief, when questioned about rumours of smallpox cases, denied all knowledge of them until, during the course of interrogation, his granddaughter emerged from the house with evident smallpox lesions. Because of fear that he would be deposed from his chieftaincy if it were found that he had been hiding cases, he had suppressed information about the outbreaks.

cases were detected that year although an average of 10 rumours were investigated each month (WHO/SE/71.30, Foege). Transmission appeared to have been interrupted and, with the last cases occurring in Dahomey in September 1969, national and CDC staff scheduled a celebration for the end of March 1970 to mark the eradication of smallpox from western and central Africa. On 21 March, just as the staff were preparing to depart for the celebration, a 14-year-old girl was admitted to the infectious diseases hospital in Kaduna (Fig. 17.6) with unmistakable smallpox (*Wkly epidem. rec.*, 1970b). She had fallen ill shortly after arriving from the town of Amayo (population, 1400), Kwara State, some 400 kilometres away. The outbreak was discovered almost simultaneously by a state senior health superintendent. Intensive house-to-house vaccination and search for cases revealed 48 additional cases in the town (WHO/SE/71.30, Foege) and 12 other cases in neighbouring villages, the first cases in the outbreak having occurred in October 1969. Further investigation revealed that smallpox transmission had persisted in the area since early 1969, primarily in communities of up to 300 persons, the cases being hidden by their families from the health authorities. The search was extended to Ilorin, the capital of Kwara State (population, 300 000), only 11 kilometres away. Nine additional cases were found—the last on 22 April 1970.

Vaccination in Kwara State had been conducted between December 1968 and July 1969. However, the reassignment of personnel, which accompanied the division of the Northern Region into states, had left Kwara with fewer resources than other states, and the supervision of the programme had been poor. Teams had concentrated their efforts in the major villages and towns, but even there coverage was poor because villagers resisted vaccination. During assessment, it had been

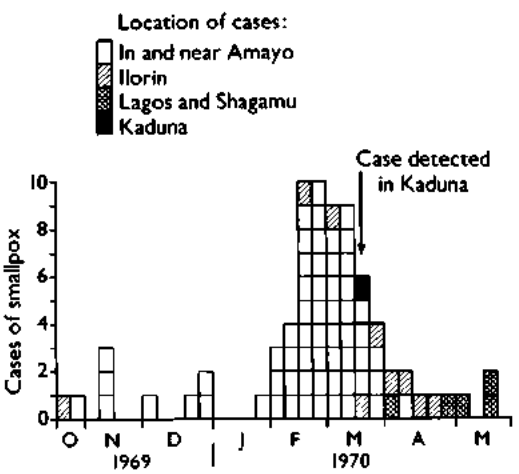

Fig. 17.6. Nigeria: number of reported cases of smallpox, by week of onset and by area, October 1969–May 1970.

found that coverage was only 70% in rural areas and 60% in the town of Ilorin; a repeat campaign had therefore been conducted in the course of which 97 000 additional vaccinations had been performed. Despite this effort, a survey in April 1970 showed that only 77% of the population had vaccination scars; in some peripheral areas of the city, the proportion was only 35%. Following the discovery of the outbreak in April 1970, a repeat house-to-house vaccination campaign was conducted, and road-blocks were established around the city to vaccinate any person who entered or left. Subsequently, special teams conducted village-by-village searches and vaccinated the inhabitants of the surrounding districts; special district search teams continued work during the following 12 months. The last known case in the area, however, occurred during the second week of April, 3 weeks after containment operations had begun.

Just as the outbreaks in the Amayo Ilorin area began to come under control, a more alarming discovery was made: 2 cases had occurred in Lagos, 150 kilometres to the south, the patients having become ill during April. Three further cases, with onset of illness in May, were discovered in Shagamu, a town to the north of Lagos. The source of infection in both outbreaks was suspected to be Ilorin, but this could not be confirmed. Intensive search and vaccination were extended in ever-widening areas around these 2 foci but no further cases were found.

The occurrence of new, widely scattered outbreaks in Nigeria was profoundly disturbing to staff throughout western and central Africa, since the cases were discovered more than 6 months after it had been thought that transmission had been interrupted and more than a year after the intensified surveillance scheme had been launched. Optimism and complacency were quickly replaced by doubt and a redoubled surveillance effort. No celebrations were in fact held until more than a year later. Although the cases in Shagamu proved to be the last, the intensified search that their presence had stimulated gave grounds for confidence that transmission had indeed been interrupted.

Dahomey and Togo

In 1967, Dahomey (population, 2.5 million) and Togo (population, 1.8 million), former colonies of France lying on the Bight of Benin between Nigeria and Ghana, were impoverished and politically unstable. Together, they cover an area between 250 and 500 kilometres from east to west and 650 kilometres from north to south. In both countries, the population was concentrated in the south. Travel from one to the other and to neighbouring countries was unrestricted and frequent because the presence of tribal groups extended across national borders. In contrast to most of the former French colonies in Africa, traditional tribal leadership remained strong and the civil governments were comparatively weak and unstable. Togo experienced 2 *coups d'état* in the 4 years immediately preceding the smallpox eradication–measles control programme; and Dahomey 6 *coups d'état* between 1960 and 1970, its first decade of independence.

Preventive medical services in both countries had all but ceased to function by 1967 because of political upheaval and lack of funds. Dahomey had had a reasonably effective mobile endemic diseases control service, which had functioned like its counterparts in other former French colonies. As recently as 1965, it had had a complement of 237 staff, operating from headquarters posts in the southern, central and northern parts of the country. The number of vaccinations given each year had been equivalent to 20–25% of the population. The activities of the service had, however, gradually diminished, and by 1967 little field work was being done. Togo had also had a mobile endemic diseases control service, which was less well supported and had effectively been disbanded in 1964–1965. The number of vaccinations performed and the type of vaccine used are not recorded.

In both countries, substantial numbers of smallpox cases were reported every year (Table 17.12), primarily from southern areas. There, as in parts of western Nigeria, resistance to vaccination had been widespread, especially in the more rural areas. The resistance was attributed to the cult worship of a smallpox fetish (see Plate 17.11) called Vodu-Sakpate, or Sopona, the major earth god of the Fon tribe. Hereditary fetish priests (*féticheurs*), who were thought by the people to have the power to prevent or to induce the disease, had traditionally performed variolation by the inoculation of pulverized scabs on the forehead, at the base of the nose or on the underside of the wrist (Glokpor, 1970). Customarily, large numbers of persons were

variolated in an affected village some 3–4 weeks after the onset of illness in the first case, in a ceremony which was said to "free the patient" of illness. For the *fétcheurs*, there were economic disincentives to cooperate in vaccination campaigns, since they were customarily given all the possessions of a patient who died of smallpox. Concern about the problem was reinforced by information that a vaccination team in Dahomey had been killed by fetish worshippers in the early 1960s.

Table 17.12. Dahomey and Togo: number of reported cases of smallpox, 1962–1969

Year	Number of cases	
	Dahomey	Togo
1962	132	571
1963	249	285
1964	703	34
1965	168	13
1966	490	201
1967	815	332
1968	367	784
1969	58	83

In Dahomey, personnel from the endemic diseases control service were again employed for a mass vaccination campaign, which commenced simultaneously in April 1967 in the northern, central and southern zones of the country. At the beginning, progress was discouragingly slow, since by government decision smallpox vaccine and measles vaccine were given by separate teams. Ultimately, however, the practice was changed and each team gave both kinds of vaccine, which resulted in a considerable improvement in programme efficiency and a reduction in cost. Better progress was also made when it was realized that tribal chiefs, especially in the southern areas, were more influential than the civil authorities. Accordingly, meetings began to be arranged with tribal authorities to explain the programme's goals and method of operation and to discourage variolation.

In August 1967, soon after the programme had begun, a special study of a small outbreak revealed quite a different epidemiological picture of smallpox in this area from that which had been anticipated (Henderson & Yekpe, 1969), a finding which contributed to

WHO / P. PITTET

Plate 17.11. The practice of variolation and resistance to visits by vaccination teams were both associated with fetish worship. At a celebration in Dahomey, a priestess dances in front of the smallpox fetish until she goes into a trance.

the formulation of the 1968 "eradication-escalation" strategy. The investigation began 10 weeks after the occurrence of the first case, but only 28 cases were found in the village of 300 inhabitants, despite the fact that only 15% of the children and 54% of the total population had vaccination scars. Surprisingly, the outbreak had terminated spontaneously, notwithstanding the many remaining susceptible persons. The study, which was conducted by Dr Ralph Henderson and Dr Maximilien Yekpe, chief of the southern sector of the endemic diseases control service, showed, moreover, that the patients were geographically clustered within the village itself despite the frequent movement of the population throughout the village. These observations reinforced the belief that smallpox in Africa spread slowly and that transmission occurred primarily as a result of intimate personal contact in households and rarely through casual contact in market-places or elsewhere. Given this pattern of spread, outbreak control was clearly more feasible than had been expected.

Assessment of the vaccination programme in Dahomey during 1967 revealed that only 28% of the population were being vaccinated by the teams and that the more remote, less accessible villages and hamlets were being missed; in some of these, smallpox outbreaks occurred after the teams had left the area. To complement the work of mobile teams who vaccinated only at assembly points, a group of 12 young health workers, called "*les douze*," was recruited, trained and given motor cycles. They worked in areas in which coverage was poor, performing house-to-house searches and vaccinating, by means of bifurcated needles, all children under 5 years of age and anybody without a vaccination scar (Yekpe, 1970).

The programme in Togo likewise got off to a slow start in 1967. The vaccination teams consisted of staff from a yaws control programme, who had continued to receive their pay but had not worked for more than 2 years. They were unenthusiastic about performing the requisite field work and made a poor showing until threatened with suspension. For political reasons, the vaccination campaign began in the north but, after a *coup d'état* and a change of government, it shifted to the south, where most cases were being reported and where villagers were both resistant to vaccination and suspicious of the government teams. The problems encountered may be illustrated by the description of an outbreak investigation conducted in November by the CDC advisers, Dr Bernard Challenor and Mr Andrew Agle. On checking a rumour of smallpox cases in a village whose inhabitants had been vaccinated twice, in January 1967 and again in October of that year, they found 8 patients, 7 of whom were hidden in the bush. The director of the medical zone, who was disturbed by these observations, decided to obtain help from the police and to take village chiefs into custody until the inhabitants of their villages had all been vaccinated. As in most areas in which police or military force was used, the result was even less satisfactory than before, since chiefs and villagers fled the area or fought with the police. That approach was soon abandoned.

Despite all the difficulties, 605 000 vaccinations were recorded in Togo in 1967 and 702 000 in Dahomey, which approximated to the projected targets. In that year the number of cases reached 815 in Dahomey and 332 in Togo, an incidence in each country which was among the highest in the world.

During the course of 1968, both countries significantly improved their reporting systems and gradually the proportion of people vaccinated in each area increased. Programme staff in both countries enlisted the help of personnel in health clinics, other health workers, foreign volunteers and tribal authorities to report cases. In south-eastern Togo, 15 health workers, comparable to "*les douze*" in Dahomey, were assigned to visit each house monthly in designated problem areas to vaccinate residents and to detect cases. In both countries, surveillance systems gradually improved and by late 1968 were well established, effective national programme leadership being provided by Dr G. F. Glokpor, Chief of the Division of Epidemiology in the Ministry of Health in Togo, and by Dr Yekpe in Dahomey. The number of vaccinations in 1968 rose to 990 000 in Dahomey but remained almost at the same level as in 1967 in Togo. In 1968, the number of reported cases decreased to 367 in Dahomey but rose to 784 in Togo—mainly owing to more complete notification.

The continuing high incidence of smallpox in Togo and reports that the entire population of villages had fled from the teams led to two studies in January 1969, one to determine what role fetish worship played in resistance to vaccination and what could be done about it, and the other to ascertain overall levels of

Table 17.13. Togo: levels of smallpox immunity by age, January 1969

Age group (years)	Persons examined				
	Total	With vaccination scar	With pockmarks	Total with pockmarks or vaccination scar	Percentage immune
<1	57	18	2	20	35

Total	1 162	919	86	1 005	86

vaccinial immunity. Mr Gordon Robbins, the health education adviser from the CDC regional office in Lagos, conducted the fetishism study (Robbins, 1970). He discovered that the resistance to vaccination had less to do with fetish practices and attitudes than with the concern of villagers about government teams in general, many of which were then engaged in tax collection and military conscription. As he learned, many of the *féticheurs* themselves, as well as their families, had been vaccinated. To measure overall levels of immunity, a national cluster sample survey was conducted. The survey showed that immunity was surprisingly high in all age groups, except among infants under 1 year of age (Table 17.13). From these findings, it seemed unlikely that smallpox transmission could persist for long, especially with the greatly strengthened systems for case detection and containment then operating. Indeed, the last case in Togo occurred in May and the last in Dahomey in September.

Observations made during the surveillance programme in Togo during 1969 are of interest (WHO/SE/70.21, Glokpor & Agle). In that year 45 outbreaks were reported, of which 17 were notified by the routine report-

Number of cases of confirmed smallpox	11	9	2	53	8	0	0	0	0	0	0	0	83

ing centres, comprising 190 dispensaries and polyclinics and 15 hospitals; 9 were found by smallpox teams in the field; and 19 were reported by other sources. The other sources included a radio-club president, village chiefs, a civil administrator, a social worker, an employee of the social welfare bureau, and members of malaria control spraying teams. Twenty-five of the 45 reported outbreaks were confirmed to be smallpox; two-thirds of the outbreaks and more than half the cases were in generally remote and isolated villages of less than 200 inhabitants. In these places vaccination coverage was usually found to be lower than 50%.

The differences between the number of smallpox cases routinely notified and the number actually confirmed are shown in Table 17.14. If routine notification data had been accepted, 21 cases would have been recorded in 1969, the pattern of occurrence suggesting that smallpox had been transmitted continuously throughout the year. During the investigation of these 21 cases, as well as that of 64 other suspected cases reported by other sources, a total of 215 cases of fever with rash were identified, of which only 83 were smallpox. All occurred between January and May.

Of the 61 cases discovered in Togo during April and May 1969, all but 2 were in riverine areas, difficult of access, in the south-east near the border with Dahomey. There, resistance to vaccination had been the greatest and, despite two intensive vaccination campaigns, only 60% of the population had vaccination scars (Table 17.15). Early in April, programme staff were notified of suspected cases by a health centre and, on investigation, they discovered 8 outbreaks with a total of 47 cases. The first of the cases had occurred 2 months before but neither these nor subsequent cases had been reported by the responsible health worker, who, as was later discovered, had vacated his post in January. With transmission apparently close to being interrupted, the President of Togo requested the army to form a *cordon sanitaire* around the areas, and police accompanied teams to lend authority to the effort; markets were closed and public gatherings forbidden. Personnel drawn from other regions vaccinated 45 420 persons in April, a figure which, by September, had grown to 248 854. The last 2 cases in this series of outbreaks occurred towards the end of April, less than 3 weeks after the initial discovery of cases. A survey in September showed that vaccinial immunity had increased from 60% to 93%.

Togo's last 2 outbreaks, numbering 6 cases in all, were discovered in May 1969 in isolated but reasonably well vaccinated fishing villages near the border with Dahomey. These were apparently the last cases of a major epidemic which had occurred throughout the area late in the preceding year.

[a] Details are not available for 308 other cases reported during this period.

Transmission appeared to have been interrupted in Dahomey in January 1969, but in July an infant from Dahomey was diagnosed as a smallpox patient in a dispensary in Togo near the border. Teams from the two countries converged on the area in a coordinated search and vaccination operation on both sides of the border. In all, 55 further cases occurred in Dahomey over the next 2 months but in September 1969 the last case was detected. Until March 1970 (see the section on Nigeria, above) this was thought to have been the last case in western and central Africa.

Programme staff in Togo collected data regarding the age distribution of most smallpox cases occurring between 1967 and 1969; these are presented in Table 17.16. It is of interest that each year 40–50% of all cases occurred among persons aged 15 years and over. This finding reflected the occurrence of the disease in isolated rural villages which experienced smallpox only infrequently and whose inhabitants were poorly vaccinated.

Although programmes in Dahomey and Togo had only limited resources, they began to function reasonably well after little more than a year, and only 18 months later transmission was interrupted. Resistance to vaccination in the southern areas of the countries proved to be a problem, although variolation, associated with fetish practices, was observed only once during the course of the programme.

Mali, Niger and Upper Volta

The third of the 7 groups of countries are 3 inland states, which extend over 2.8 million square kilometres in the central part of western Africa—Mali (population in 1967, 5.3 million), Niger (population, 3.9 million), and Upper Volta (population, 4.8 million). Topographically, the area encompassed by these countries consists of desert in the north, giving way to the semi-desert areas of the Sahel and then to savanna in the south. In Upper Volta the population was evenly dispersed throughout the country, but in Mali and Niger the northern areas were very sparsely populated, virtually all of Mali's population living in the southern half of the country and 90% of Niger's being concentrated along the western and central segments of the Niger river, near the country's southern border, in a belt less than 250 kilometres wide. Thus, although both Mali and Niger were far larger than Upper Volta, the areas with a significant concentration of population in these countries were only slightly greater than in Upper Volta. As in most parts of western and central Africa, roads were few and communications difficult.

The majority of the population were sedentary agriculturalists living in villages of fewer than 1000 inhabitants. Large numbers of pastoral nomads, however, were to be found in all 3 countries, being especially numerous in Mali and Niger. They were predominantly Tuareg and Peuhl tribal people, who moved along well-defined routes seeking pasturage for their animals. During the May–October rainy season, the nomads worked on farms or congregated in pasture areas, but during the October–April dry season, they migrated over great distances. During this period, smallpox spread extensively.

OCCGE had its headquarters in Upper Volta and the country's endemic diseases control service, directed by a French military medical officer, was perhaps the best supported and most effective of such services in western Africa in 1967. In Niger, a similar service existed, but its performance was much less satisfactory. In Mali, which had ceased to receive financial support from France, the multi-purpose teams no longer functioned, having been replaced in 1962 by 2 mobile smallpox vaccination teams.

In these countries, in which health services were traditionally provided by mobile teams, there was both interest in and a structure for a large-scale combined smallpox and measles vaccination campaign. As has been described earlier, Upper Volta had, in fact, completed a national measles vaccination campaign in 1962. However, the assessment of vaccination coverage and surveillance were unknown

practices, and government officials considered them unnecessary. Moreover, views differed within each of the countries as to whether separate teams should conduct the measles and smallpox vaccination campaigns or whether they should, in some manner, be incorporated into the scope of work of multi-purpose teams. Because of these problems, there were delays in the signing of programme agreements, although all the programmes became operational by April 1967. In the end, none provided for ongoing assessment of vaccination coverage; surveillance activities, although originally intended to be conducted by national teams, became, by default, the responsibility of CDC advisers.

In Mali, a special smallpox vaccination campaign had been in progress since December 1962 with 2 teams, each composed of 15 persons, administering freeze-dried smallpox vaccine provided by the USSR and yellow fever vaccine produced in Senegal. Mali was handicapped by a lack of trained personnel, transport and petrol and requested assistance from WHO, which began to be provided in 1964; a WHO medical officer was assigned to the programme in December 1965.

A WHO team which assessed the Mali programme in February 1965 described the prospects for eradication there as "bleak" (World Health Organization, 1965b). In the campaign, vaccinators were expected to average 140 vaccinations a day, but even this modest target was not being met. At that rate of work, the WHO team estimated that it would take at least 8–10 years to complete one round of vaccination. Such vehicles as were available were old and frequently out of order, and refrigerators did not function. The vaccine was stored at ambient temperatures of up to 50 °C, which caused it to deteriorate and the take rates to decline as a result. The vaccination campaign did not improve materially during 1965–1966, but the number of reported cases decreased significantly, reaching, in 1966, the lowest total ever recorded in Mali (Table 17.17).

With the offer of AID assistance, government health officials in Mali decided to reconstitute the multi-purpose mobile teams, 8 such teams being created to administer yellow fever vaccine, as well as smallpox and measles vaccine, and to examine and treat patients for onchocerciasis, trypanosomiasis and leprosy. The problems involved in drawing up plans and in training teams for this more complex set of activities delayed the launching of the programme. Further delays resulted from the government's insistence that each trip the CDC advisers (Dr Pascal Imperato and Mr Jay Friedman) made outside the capital should be authorized weeks in advance. Although this requirement applied to all foreign advisers at the time, it was apparent that this policy would seriously handicap the necessary training of staff and all but preclude the establishment of surveillance and containment measures. The problem was compounded by a lack of collaboration between the smallpox eradication adviser assigned by WHO and the CDC staff, which resulted in the government's receiving contradictory advice. In view of the many constraints and frustrations, senior CDC smallpox eradication staff proposed suspending assistance until the problems could be sorted

Table 17.17. Mali, Niger and Upper Volta: numbers of reported cases of smallpox and vaccinations performed, 1962–1969

Year	Mali (population, 1965: 5 105 000)		Niger (population, 1965: 3 736 000)		Upper Volta (population, 1965: 4 648 000)	
	Number of cases	Number of vaccinations	Number of cases	Number of vaccinations	Number of cases	Number of vaccinations[a]

[a] .. = data not recorded.

out. When confronted with this possibility, the government decided to give the advisers full freedom to travel; a new Chief Medical Officer, Dr Ousmane Sow, was appointed; and the WHO smallpox eradication officer completed his assignment and returned home. The campaign proceeded to gain rapid momentum. The complex logistics and problems of conducting a vaccination campaign in areas such as Mali have been described by Dr Imperato in his book, *A Wind in Africa* (Imperato, 1975).

The teams began work in areas in the eastern part of the country, in which most cases of smallpox were then being reported. The cases were mainly among nomads and in remote rural areas (Imperato et al., 1972), a distribution attributed to the great distances separating the vaccination assembly points established during the 1962–1966 campaign. Early surveys in the more accessible areas revealed that 93% of the farmers, but only 54% of the nomads, had vaccination scars. In some areas, the inhabitants of entire villages, far from the assembly points, remained unvaccinated, as were many young children and elderly persons, who could not easily walk or be carried over long distances. Assembly points continued to be used, as in the earlier campaign, but they were more numerous, requiring the villagers to travel less far.

In April 1967, the CDC advisers began to investigate some of the outbreaks. The first were in east-central Mali, in which mass vaccination had been completed in 1965 but, as was discovered, less than half the population had a vaccination scar. Smallpox transmission, nevertheless, was not rapid, even in the season of highest incidence. In one outbreak, for example, only 71 cases were found to have occurred over a 4-month period (Imperato, 1970). As the programme moved towards the border with Upper Volta, the teams began to encounter a large number of persons who refused vaccination and found that many women and children were hidden when the teams arrived. Vaccination continued throughout the east-central area, 521 000 people being vaccinated over a 2-month period beginning in October 1967. Although programme staff had expected to find epidemic smallpox occurring widely throughout the country, only 293 cases were discovered during 1967, most of which were in areas bordering on Upper Volta, in which a mass vaccination campaign was in progress. Of the

WHO / CHI-VAIPH

total, 145 cases occurred in a cluster of 5 villages whose aggregate population was only 3700. Variolation was responsible for some of the cases—the only occasion on which variolation was observed in Mali.

Following the mass campaign in the endemic border areas, 2 further outbreaks, of 12 and 28 cases, were discovered in March 1968 among unvaccinated children who had been hidden from the teams (Imperato et al., 1973). Repeat vaccination in the respective villages quickly terminated the outbreaks, and for 6 months no further cases were found or notified in the entire country. It appeared that smallpox transmission in Mali had been interrupted by the time the vaccination campaign was little more than a quarter of the way towards completion.

On 6 November 1968, however, programme staff in Mali received a telegram from Upper Volta informing them that the first case in an outbreak near the border had come from a village in Mali. The Upper Volta outbreak—the last in that country—had begun in May 1968 and although 6 months had elapsed since the first case had entered Upper Volta from Mali, programme staff from the two countries agreed that a joint search should be undertaken. This began on 14 November. The village from which the initial case had come was 10 kilometres from a road and could be reached only by a narrow footpath through a mountainous rocky area. On arrival, the teams discovered that the village consisted of 8 widely separated groups of huts with a population of about 1350 people. During the vaccination campaign, which had concluded 1 year previously, the villagers had been directed to visit an assembly point 10 kilometres away, but few had done so. An outbreak had begun in late 1967 and spread progressively from one of these groups of huts to another.

Despite the fact that this was then Mali's only known focus of smallpox, the containment measures were surprisingly incomplete: only 541 villagers (40%) were vaccinated and only 16% of them were found to have vaccination scars. Pockmarks indicative of recent smallpox were observed in 65 of the 541 people examined, the last person to contract the disease having become ill in October 1968, a month before the team's arrival.

Only 1 further case was discovered in Mali, in February 1969; it occurred in a migrant tribal group believed to have been infected in Niger. This was the last of 9 known outbreaks, comprising a total of 370 cases, which had originated among migrant Tuaregs and Peuhl nomads between 1967 and 1968, and accounting for more than three-fourths of all cases recorded in Mali (Sow, 1970).

In Upper Volta, smallpox vaccination had been a routine activity of the mobile multipurpose teams, and the director wanted to continue this practice. He believed, correctly, that smallpox was then substantially under control and saw no reason to mount a special effort, since he did not consider eradication of the disease to be achievable. However, he decided to create special teams to administer measles vaccine, much as had been done in the 1962 campaign.

Smallpox incidence in Upper Volta had diminished greatly after 1962, as it had in Mali. Because there were comparatively few cases and responsibility for the smallpox vaccination campaign had been assumed by the endemic diseases control service, the CDC advisers, Dr Christopher D'Amanda and Mr William White, devoted substantial time to the improvement of reporting and the investigation and containment of outbreaks. In 1967 they discovered 195 cases, mainly along a north–south route used by pastoral nomads. In 1968, however, the epidemiological pattern changed. Only 100 cases were found, all of them in small villages near the border with Mali or Niger (D'Amanda, 1970). One outbreak of 19 cases in a village only 3 kilometres from the border with Niger led to a joint vaccination campaign by teams from Niger and Upper Volta. In October 1968, the last outbreak in Upper Volta was discovered by one of the multi-purpose teams in a village of 650 persons situated in a rocky mountainous area near the border with Mali. Forty cases had occurred between May and October, the first being infected in Mali; only 2 patients remained with active disease. Thorough vaccination in this and neighbouring villages quickly stopped transmission.

The concentration of cases along the frontier areas, in which health dispensaries were the most scarce, led to changes in the programme strategy in 1969. The schedule of the multi-purpose teams was altered to achieve a thorough coverage of the frontier areas, and the 604 mobile and established health units, as well as members of mobile teams giving leprosy treatment, were asked to supply weekly reports. The new system elicited many additional rumours of smallpox cases, but

transmission had ceased by then and no importations were detected.

For Niger, smallpox was a much greater problem than for Mali or Upper Volta. In all, 1023 cases were recorded in Niger in 1966 and 1187 in 1967. Until 1967, the numbers of smallpox vaccinations given by mobile teams, in proportion to population, were comparable to those in Mali, but the campaign in Niger had not achieved effective smallpox control. In part, the failure could be attributed to the high ambient temperature and the inactivation over time of improperly stored freeze-dried vaccine. This was apparent from studies conducted in early 1967 which showed primary take rates of only 20–25%. Another contributory factor was Niger's proximity to northern Nigeria. Most of the population lived within 250 kilometres of the Nigerian border, and many travellers crossed it. Mali and Upper Volta, in contrast, were at a considerable distance from the heavily endemic coastal areas of neighbouring countries.

Of special concern to the CDC advisers, Dr Donald Moore and Mr Anthony Masso, as well as to the national programme staff, were the nomads, estimated to number about 530 000. They travelled widely throughout Niger and to neighbouring countries and were, therefore, considered to constitute a special risk in the spread of smallpox. Moreover, they were said to practise variolation when outbreaks did occur, thereby amplifying the outbreaks and increasing dissemination.

The vaccination campaign, utilizing teams devoted solely to giving smallpox and measles vaccine, began well and, by the end of 1967, 1.61 million people—equivalent to 41% of the population—had been vaccinated. A component of the programme during its first year was a special campaign aimed at vaccinating nomads, some 150 000 of whom gathered annually in a pasturage area 600 kilometres from the capital. Although the strategy was sensible, it proved to be a far more difficult endeavour than had been expected when the rains turned the few dry roads into a quagmire which could scarcely be traversed even with 4-wheel-drive vehicles. A sand storm ripped the tents and scattered the camping equipment, and the nomads sought to evade the

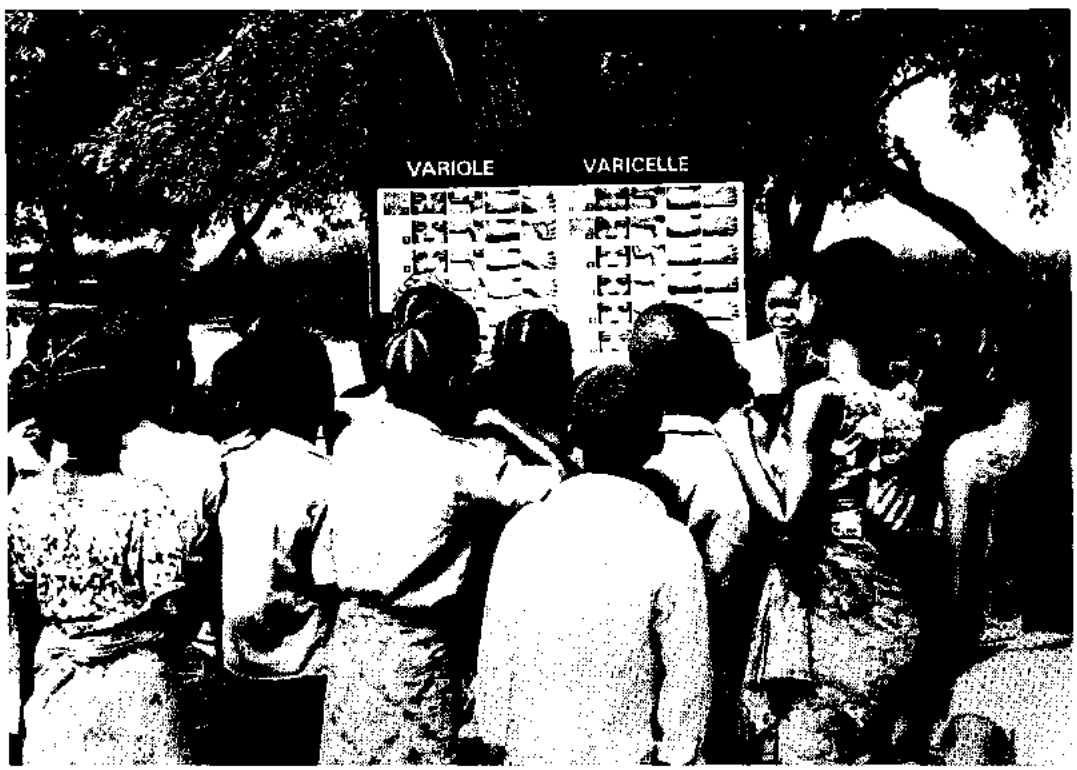

Plate 17.14. In Niger, a health worker uses the WHO diagnostic wall chart to explain the difference between smallpox and chickenpox, an important educational activity in the surveillance phase of the programme.

teams, fearing that they were also engaged in tax collection. Ultimately, as was revealed by assessment, only 45% of the population were vaccinated.

In 1967 and the early months of 1968, some outbreaks in Niger were investigated and containment vaccinations performed, but the principal effort was directed to the difficult logistics of the vaccination campaign. During the first 6 months of 1968, an additional 725 000 persons were vaccinated, following which—and coincidentally with the beginning of the seasonal rains—smallpox incidence declined sharply and did not increase again. Only 24 cases were recorded during the last 6 months of 1968 and another 28 cases in 1969. Although they were not fully documented, all the cases in 1969 are believed to have resulted from importations from Nigeria.

Despite the concern of programme staff, nomads in Niger—unlike those in Mali and Upper Volta—were found to play only a minor role in transmitting smallpox from place to place, even in the more densely populated areas. In the vast but sparsely populated northern regions of Niger, in which an estimated 150 000 nomads lived, only 1 case was discovered. That smallpox did not spread through this area was welcome but unexpected, and was probably partly due to a comparatively high level of immunity induced by vaccination as well as variolation (Masso, 1970). In a survey conducted in 1969, 38% of the nomads examined were found to have vaccination scars, but an additional 29% had the scars of variolation. Evidence of past variolation was frequently observed in different parts of Niger, and although the practice was originally believed by health staff to be important in sustaining transmission, only a single instance of recent variolation was observed—in October 1967 in a village near the Nigerian border.

The transmission of smallpox in Mali, Niger and Upper Volta was interrupted more rapidly than had been foreseen, but the problems of logistics and vaccination proved greater than expected. In Mali and Upper Volta, previous vaccination campaigns had been successful in sharply reducing the incidence of smallpox, and in less than 2 years—in November 1968— transmission was interrupted in both countries. In Niger, smallpox incidence was high at the outset of the programme, but the vaccination campaign progressed rapidly and transmission was interrupted at about the same time as in the other countries.

Guinea and Sierra Leone

The fourth of the 7 groups of countries to be discussed consists of 2 neighbouring coastal countries, Guinea and Sierra Leone. Programmes in both countries began in December 1967, nearly 12 months after the regional programme had started. As has been noted earlier in this chapter, the reason for the delay was that the CDC staff wanted to phase in activities over a 2-year period. When this decision was made, the fact was not recognized that cycles of epidemic smallpox had recurred in these countries at intervals of 10–12 years. Major epidemics had occurred in Sierra Leone in 1956–1958, and in Guinea in 1955–1957, although in the latter country nearly 3000 cases occurred only 5 years later, in 1962. In both countries, epidemic smallpox recurred early in 1967 (Table 17.18). Sierra Leone (population, 2.7 million) recorded 1697 cases and Guinea (population, 3.7 million) 1530 cases, giving incidence rates for that year which were among the highest in the world. In aggregate, the total number of cases represented nearly a 10-fold increase in incidence over 1966.

The launching of both campaigns in December 1967 coincided with the advent of the dry season—the season of highest incidence—and the beginning of the second year of the epidemic. Smallpox being a matter of much concern at the time, Guinea and Sierra Leone gave their full support to the programme and developed plans to complete the mass vaccination campaign within 16 and 24

Table 17.18. Guinea and Sierra Leone: number of reported cases of smallpox, 1960–1969

Year	Number of cases	
	Guinea	Sierra Leone
1960	176	12
1961	96	6
1962	2 948	78
1963	224	14
1964	320	90
1965	70	60
1966	56	293
1967	1 530	1 697
1968	330	1 143
1969	16	80

months, respectively. In the summer of 1968, case detection and outbreak containment were given special emphasis. Smallpox incidence declined rapidly, and the last cases were recorded in January 1969 in Guinea and in May 1969 in Sierra Leone. Benefiting from experience in the other countries of western and central Africa, these programmes were the best executed and the best documented. An account of the programme in Sierra Leone has been given by Dr Evelyn Cummings, the Chief Medical Officer, and Dr Donald Hopkins and Mr James Thornton of CDC, and their colleagues (Hopkins et al., 1971a, b, c). Guinea's programme has been described by Dr A. B. Alécaut, the director of the country's endemic diseases control service, and Dr Joel Breman, the CDC medical epidemiologist, and their colleagues (Alécaut et al., 1970; Breman, 1971; Breman et al., 1977a, b).

The population in both countries consisted primarily of sedentary farmers living in villages of less than 1000 inhabitants, most of which were not readily accessible by motor vehicle. The most densely populated part was the coastal area from Freetown, the capital of Sierra Leone, to Conakry, the capital of Guinea. In the more sparsely populated area comprising north-eastern Guinea and north-eastern Sierra Leone, cattle herders moved freely between the two countries. Work in the diamond mines of eastern Sierra Leone attracted many farmers during the dry season.

In 1967, neither country had a continuing special programme for smallpox vaccination. Vaccinations were performed by the established health units and, in Sierra Leone, by a mobile unit of the endemic diseases control service, which periodically conducted small-scale mass vaccination campaigns. Approximately 700 000 persons were reported to have been vaccinated each year in Guinea and 300 000 in Sierra Leone. In Guinea, freeze-dried vaccine from Switzerland and the USSR began to be used in the early 1960s. Sierra Leone, like Nigeria, employed the thermolabile lanolinated vaccine purchased from the United Kingdom or Nigeria. Surveys in Sierra Leone when the programme began revealed vaccination scars in only 26% of those under 15 years of age and in 60% of older persons. Overall, almost half the population of Sierra Leone was considered to be susceptible to smallpox. Comparable data from Guinea are not available.

Smallpox incidence began to increase in Sierra Leone in 1966 (Table 17.18); in 1967 the disease became endemic throughout the country, the eastern areas being the most affected. In Guinea, the incidence started to increase a year later, the most heavily afflicted areas being the coastal districts bordering on Sierra Leone (Fig. 17.7.). Because of the spreading epidemic, an emergency mass campaign was conducted in Conakry in February and March 1967, during which 180 000 of the city's 250 000 inhabitants were vaccinated.

In Guinea, the AID-supported vaccination campaign began in December 1967, utilizing, as supervisory personnel, senior staff of the former endemic diseases control service, which, by 1967, had ceased to function owing to a lack of vehicles and of funds for petrol and equipment. Vaccination was conducted by 8 mobile teams of 6 persons each: a team leader, 2 vaccinators, a recorder, a driver and an "advance man". The last-named visited leaders of the well-organized political party in each area and village prior to the team's arrival, in order to acquaint them with the programme and to obtain their support. To simplify the logistics of providing supplies, all teams worked together in a given region of the country, vaccinating at assembly points situated so that villagers had to walk no more than 2–3 kilometres. Local costs, which amounted to US$10 000 per annum, were covered by WHO.

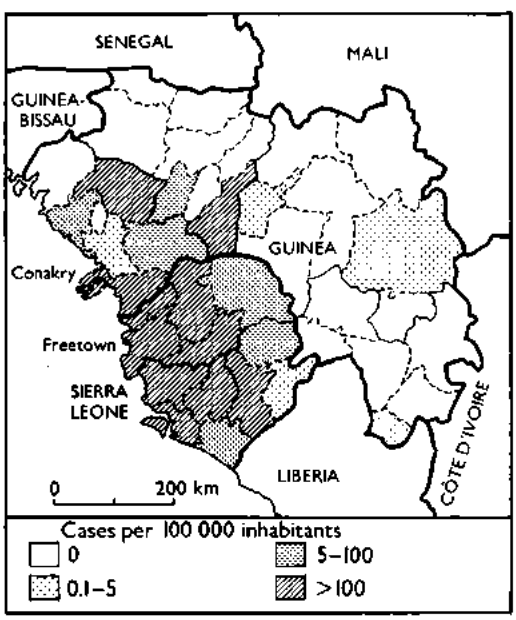

Fig. 17.7. Guinea and Sierra Leone: smallpox incidence, by province, 1967.

From the beginning, vaccination coverage in Guinea was carefully assessed. Two methods were used. The first, performed when the teams were working in the village, consisted simply in comparing the numbers vaccinated with the population census. If the numbers vaccinated seemed to be low, local party officials were asked to search for those who had been missed, and send them for vaccination. Where vaccination coverage was particularly low, a special team was assigned to conduct repeat mass vaccination and vaccine was sometimes left with regional officials, who were asked to vaccinate the people who had been missed.

The second form of assessment, conducted a week later by a senior technical officer of the programme and an assistant, utilized the modified cluster sample technique devised by Dr Ralph Henderson (Henderson et al., 1973); this required the examination of a number of persons sufficient to ensure, with 95% confidence, that the results obtained were within 10% of the true value. Although this was a more sophisticated survey method than that routinely employed in other programmes, it was well executed. As the programme progressed, it was found that the results of the two types of assessment usually corresponded well, due primarily to close supervision of teams and the availability of unusually accurate census data.

With the active cooperation of party leaders, the levels of vaccinial immunity achieved usually exceeded 80% and more often 90%. The teams themselves averaged 2000 smallpox vaccinations a day and, in addition, provided measles vaccination to all children between 6 months and 4 years of age.

From January to October 1968, the end of the rainy season, the residents of Conakry and of all districts bordering on Sierra Leone were systematically vaccinated (Fig. 17.8). These areas included most parts of the country then known to be infected with smallpox.

The investigation and containment of outbreaks began within months of the start of the mass vaccination campaign. In June 1968, a special surveillance team was assigned this responsibility and asked to make a village-by-village search for cases in high-risk areas. By then, owing to the decrease in incidence during the rainy season and the high levels of vaccinial immunity in previously infected areas, smallpox had all but disappeared. From July 1968 to the end of January 1969, only 8 outbreaks, with a total of 75 cases, were

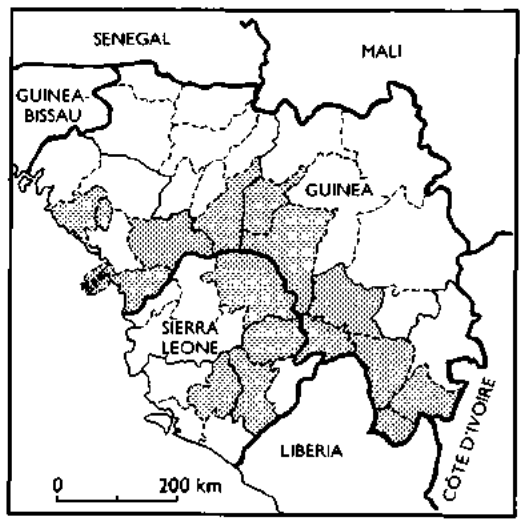

Fig. 17.8. Guinea and Sierra Leone: areas (shaded) in which mass vaccination was completed before the end of the rainy season, October 1968.

discovered, almost all in villages of less than 500 inhabitants. All were in western Guinea, near the border with Sierra Leone, and 5 of the 8 were thought to have originated in that country. In each instance, information regarding the source of infection was cabled promptly to Sierra Leone. The last known case in Guinea was reported and investigated in January 1969, though it actually occurred in December 1968.

The first phase of the systematic vaccination campaign continued until June 1969. In all, 3.1 million smallpox vaccinations were given during the 18-month period, another 2.6 million during a subsequent 2-year cycle, and a further 2 million in a third 2-year vaccination cycle. Meanwhile, weekly reports from each of the 29 regions were being received with increasing regularity. In 1968, 33% of the expected reports were received—a proportion which increased to 60% in 1969, and to 87% in 1970.

The smallpox problem in Sierra Leone differed from that in Guinea in that the disease was widespread throughout the country. The campaign, which began in January 1968, utilized the staff of the endemic diseases control service, which had previously been responsible for 43 treatment centres for yaws and trypanosomiasis. Six teams performed the vaccinations and one the assessment. The composition of the teams and their methods of work were similar to the system operating in Guinea. Priority was given to

eastern Sierra Leone, in which smallpox incidence was the highest, presumably because of a large population turnover associated with diamond mining and the migration of cattle herders. Because of the epidemics, attention was initially concentrated on vaccinating as widely and as rapidly as possible before the end of the rainy season in 1968 and the commencement of the expected seasonal increase early in 1969.

The help of tribal chiefs in the 146 chiefdoms was necessary to obtain the cooperation of villagers. Although the chiefs were generally receptive, they proved to be less effective than Guinea's political party leaders. Efforts were made to achieve a vaccination coverage of 80% or more in all areas, but assessment showed that it was usually no greater than 75%.

A few outbreaks were investigated between January and August 1968, but a concerted effort to investigate and to contain all reported outbreaks did not begin until August, when the regional "eradication escalation" activity commenced. Vaccination teams were assigned in rotation to this duty. As in Guinea and in other countries at this time, outbreak containment consisted primarily of 1–2 days of intensive vaccination in the infected village, in neighbouring villages and in nearby markets. Patients were isolated in their houses, a traditional practice in most of this part of Africa. Nearly all the cases (94.5%) in Sierra Leone occurred in villages of less than 1000 inhabitants and although containment measures were less rigorous than in the later phases of the Intensified Smallpox Eradication Programme, most outbreaks ended quickly. Studies by the programme staff showed that no secondary cases occurred in villages in which coverage was greater than 80%, and 1–9 secondary cases in those in which vaccinial immunity was less than 70%.

An unusual feature of smallpox transmission in Sierra Leone was the occurrence of outbreaks associated with special funeral ceremonies for smallpox victims. In two documented outbreaks (Hopkins et al., 1971c), cases occurred among members of secret societies who washed the corpse of the smallpox victim and among others who attended special funeral services. One of the outbreaks gave rise to 33 cases among contacts at the funeral and an additional 97 cases due to further spread; the other resulted in 10 contact cases and 2 cases due to secondary spread. While secret societies were prevalent throughout western Africa, and other such outbreaks were believed to have occurred in Sierra Leone, these were the only ones which could be documented.

From August 1968 onwards, the number of cases in Sierra Leone decreased steadily and from January to the end of April 1969, only 12 outbreaks, with a total of 80 cases, were found, all but one situated in coastal areas in which mass vaccination had not yet been conducted. On 5 April, the last case occurred, in Freetown; it was not officially reported until May and the source of infection was not discovered.

An important contribution to the success of the programme was the monthly publication of a mimeographed bulletin, *The Eradicator*, which was distributed widely to programme staff, medical officers, dispensers, civil officials, paramount chiefs and other interested persons. It reported on the programme's progress, paid tribute to effective health workers and local officials and announced the schedule of activities for the coming month. When the intensified surveillance programme began in August 1968, the bulletin served to stimulate reporting throughout the country.

Data on the age distribution of cases and case-fatality rates in Guinea and Sierra Leone

1979

Plate 17.15. Donald R. Hopkins (b. 1941), a CDC epidemiologist, served as the senior adviser to the programme in Sierra Leone. Although the incidence of smallpox in Sierra Leone was among the highest in the world in 1967, it was possible to interrupt transmission in only 16 months. Hopkins later wrote a history of smallpox, *Princes and Peasants*.

Table 17.19. Guinea and Sierra Leone: number of cases of and deaths from smallpox and case-fatality rate, by age, 1968–1969

Age group (years)	Guinea[a]			Sierra Leone[a]		
	Number of cases	Number of deaths	Case-fatality rate (%)	Number of cases	Number of deaths	Case-fatality rate (%)
<1	9	5	56	35	7	20
1–4	77	10	13	163	14	9
5–14	94	0	0	270	10	4
15–44	116	7	6	522	70	13
⩾45	9	1	11	105	14	13
Total	305	23	7.5	1 180	131	11

[a] Data are not available for 41 cases in Guinea and 43 cases in Sierra Leone; in addition, the age distribution of 85 cases in Sierra Leone is unknown though their outcome was recorded.

were more complete than in most national programmes, and it is pertinent to include them here, since they are probably representative of the situation in other countries of the region (Table 17.19).

In proportion to population, cases were more numerous among children than adults, but there was, nevertheless, an unusually large percentage of adult cases in what were considered to be endemic countries. Most of the cases, however, occurred in rural areas, in many of which smallpox had not been present for several decades. The low levels of vaccinial immunity in these areas, coupled with the infrequency of variolation, ensured the presence of many susceptible adults when outbreaks occurred. Because of the nature of data collection, the case-fatality rates probably understate the severity of the disease. Since in most of the fatal cases of smallpox, the patients did not die until the second or third week of illness, some who were acutely ill at the time of outbreak investigation may have died later but their deaths were not recorded. An overall case-fatality rate of perhaps 10–15%, depending on the age distribution of cases, would probably be more correct.

The programmes covering the comparatively small populations of Guinea and Sierra Leone, both highly endemic at the start, are of interest because of the rapidity with which they succeeded in interrupting transmission. Guinea's last case occurred only 12 months, and Sierra Leone's only 16 months, after the inception of their respective programmes. This achievement in two countries which were so lacking in health services, transport, and communications greatly encouraged regional and global smallpox eradication programme staff and, to some extent, generated an unwarranted confidence that comparable successes could be achieved as readily in other parts of the world.

Côte d'Ivoire, Ghana and Liberia

In the adjoining countries of Côte d'Ivoire, Ghana and Liberia, smallpox had largely been brought under control by 1967; Côte d'Ivoire, in fact, had succeeded in interrupting transmission (Table 17.20). Each had achieved this status in a different manner: Côte d'Ivoire by mass vaccination, with little external assistance; Liberia through a mass vaccination campaign supported by a private voluntary organization; and Ghana by a remarkably effective programme of surveillance and containment.

Ghana is of special interest, being one of the few countries in which an effective programme of case investigation and outbreak control all but interrupted smallpox transmission despite a comparatively low level of vaccinial immunity in the population

Table 17.20. Côte d'Ivoire, Ghana and Liberia: number of reported cases of smallpox, 1961–1968

Year	Number of cases		
	Côte d'Ivoire	Ghana	Liberia
1961	4 656	70	1 116

and the use of a thermolabile smallpox vaccine. Ghana was the second most heavily populated country in the western and central African region (population in 1967, 8.1 million), and in the 1950s and 1960s had one of the best-organized health services and networks of all-weather roads. A moderately extensive morbidity reporting system had been established, and a compulsory mortality registration scheme covered approximately half the population. Between 500 000 and 1 million persons were vaccinated annually in hospitals, health centres and health posts and by mobile rural health service teams (originally called medical field units). The thermolabile lanolinated vaccine produced in the United Kingdom was used exclusively until 1964, when freeze-dried vaccine began to be purchased from Switzerland. However, on the basis of field observations by a WHO adviser in 1965, and outbreak investigations in 1967, it can be assumed that overall vaccinial immunity was probably not greater than 50% when the programme began. Despite this, no more than 251 cases had been notified in any year since 1953—that is, during a period when many countries in western and central Africa with smaller populations reported 1000 or more cases every year. The explanation can be found in the existence of a corps of well-trained sanitarians who took special care to keep the vaccine refrigerated, investigated all outbreaks, isolated patients in a hospital or in separate quarters, vaccinated those living in the area and recorded the daily temperature of household contacts in order to detect additional cases as early as possible. Only 7 cases of smallpox were notified in 1965 and 13 in 1966.

The mass vaccination campaign began in February 1967 in the capital, Accra, utilizing the mobile health service teams to give both smallpox and measles vaccine. At the same time, senior Ghanaian programme staff, Dr Frank Grant and Dr V. de Sario, with the CDC advisers Dr Challenor, Dr David Melchinger and Mr James Lewis worked with local sanitarians in the investigation and containment of outbreaks. In all, 17 outbreaks, with 114 cases, were found in 1967. Two of these, with a total of 21 cases, were in Accra and affected only 7 households in an area populated by immigrants from Togo; 5 others, with 27 cases, were in southern Ghana, the Accra outbreaks being the source of one of them and Nigeria another; 10 outbreaks, with 66 cases, occurred in a cluster of small villages within a few kilometres of the point where the borders of Ghana, Togo and Upper Volta meet (WHO/SE/69.8, de Sario). The last group of outbreaks occurred in a tribal area in which no cases had been seen for 6 years but in which smallpox was well recognized by its name *naba*, which means "the chief of all the other diseases". A source of infection in Togo or Upper Volta was suspected but not proved. Although the sources of infection could not be traced for all outbreaks, it is apparent that there was little endemic disease and few chains of transmission. During 1968, 24 additional cases in 6 outbreaks were discovered, all of which could be traced to importations from Togo, 2 of the outbreaks occurring very near the border, while the others were at a distance of more than 100 kilometres from it (Grant, 1970).

The mass vaccination campaign progressed steadily but more slowly than in most other countries of the region, being completed in 1970, 4 years after it had begun. Coverage levels, based on concurrent assessment, were consistently over 90%.

In Côte d'Ivoire (population in 1967, 4.9 million), smallpox had been an important problem in the early 1960s, 4656 cases having been reported in 1961. In August of that year, the government decided to embark on a special 3-year mass vaccination campaign using a freeze-dried vaccine produced in France and 5 mobile teams comprising 50 health staff. The responsibility for its execution was entrusted to the Institute of Hygiene in Abidjan and its director, Médecin-Colonel Gaston Binson. During the next 3 years, 3.6 million persons were vaccinated; a repeat 3-year campaign, lasting from 1964 to 1966, succeeded in vaccinating another 3.7 million. Smallpox incidence fell precipitously and by 1965, only 27 cases were notified, followed by 10 cases in 1966.

When assistance was provided by the USA, the government decided to undertake a third national smallpox vaccination campaign under the same leadership as before; other teams from the Ministry of Health, working independently, administered measles vaccine. The smallpox vaccination campaign differed somewhat from those in other countries in that the vaccine was administered by scarification rather than by jet injector. Dr Binson saw little virtue in speeding up the rate of vaccination by using the jet injector, since this was offset by the time-consuming process of preparing for each person vaccinated a signed

Plate 17.16. Headquarters of the national smallpox eradication programme at Abidjan, Côte d'Ivoire.

personal vaccination certificate giving the individual's name, the date of vaccination and the batch number of vaccine used. The preparation of a vaccination certificate was traditional in Côte d'Ivoire, as in many of the other francophone countries and, while most countries soon abandoned the practice or simply distributed certificates without the holder's name inscribed, the traditional approach continued to be used in Côte d'Ivoire. Assessment of coverage was not performed. In November 1969, at the conclusion of the third national mass smallpox vaccination campaign, measles vaccination teams were merged with the smallpox teams, the practice of issuing vaccination certificates was abandoned and jet injectors began to be used for both antigens.

After the regional programme had commenced, only 2 cases of smallpox were discovered in Côte d'Ivoire, in March 1967, both of which were importations from Upper Volta. The cases did not appear in the official records, however, until 2 years later; the director of the programme, proud of its accomplishments, believed that the country's record should not be blemished by 2 cases for which he did not feel responsible.

Liberia (population in 1967, 1.3 million), which abutted on Côte d'Ivoire in the west, reported more than 1000 cases in 1961, and the following year began a smallpox vaccination campaign. It was directed by a religious organization called Brother's Brother, which undertook mass vaccination throughout the accessible, populated areas (Bryant, 1968). Over a 5-month period, some 775 000 vaccinations were reported to have been given, using jet injectors of a different type from those subsequently employed by CDC, and a freeze-dried vaccine, which was diluted approximately 15-fold owing to a lack of supplies. Neither vaccination take rates nor coverage was assessed.

After the 1-year mass campaign, WHO provided an adviser, Arita, and enough freeze-dried vaccine to permit a more systematic programme which utilized undiluted vaccine administered by scarification. That this was needed became apparent when Arita found that only 60–70% of persons had had successful primary vaccinations when vaccinated in accordance with the procedure used by the Brother's Brother group. Progress in the WHO-supported programme was slow, but smallpox incidence continued to fall. Although the number of reported smallpox cases had averaged more than 1000 per annum from 1958 to 1962, only 325 cases were reported after the first mass campaign in 1962. The figure dropped to only 40 cases by 1965, to 32 by 1966 and to 6 by 1967.

The AID-supported campaign, which began early in 1968, progressed little more satisfactorily than had the campaigns in 1962–1967. Even with 7 vaccination teams, nearly 4 years were required to complete the operation. Assessment was seldom conducted and reporting remained almost as unsatisfactory at the conclusion of the programme as at the beginning. Nevertheless, a system which had notified hundreds of cases in previous years reported only 5 cases in 1968, all of which occurred during the first 3 months of that year. Nothing is known of these cases, since no reports of cases were investigated until April 1968. Some—perhaps all—may have been erroneously diagnosed, or they may have been importations. No further cases of smallpox were discovered by vaccination teams as they advanced systematically across the country, but in 1970 they did detect the first cases of human monkeypox outside Zaire (see Chapter 29).

The Gambia, Mauritania and Senegal

The Gambia, Mauritania and Senegal, 3 contiguous countries comprising the westernmost part of the region, recorded no cases of smallpox after 1966 (Table 17.21). The

Table 17.21. Gambia, Mauritania, Senegal: number of reported cases of smallpox, 1961–1967

Year	Number of cases		
	Gambia	Mauritania	Senegal
1961	12	12	201
1962	4	40	232
1963	52	0	231
1964	6	0	2
1965	6	2	2
1966	3	76	0
1967	0	0	0

cessation of reported smallpox that year followed many years of effective control measures, especially in Senegal, which accounted for 70% of the area's population (in 1967) of 5.3 million and which was economically the most developed. The Gambia, a strip of land 16 kilometres wide and 320 kilometres long, entirely surrounded, except for the coastal section, by Senegal, had a population of 438 000, which moved freely back and forth across the border. Not surprisingly, its experience with smallpox reflected that of Senegal. Mauritania, although 6 times larger than Senegal, was mostly desert. Because its predominantly nomadic population of 1.2 million was widely dispersed throughout the country, the transmission of smallpox was not easily sustained. After 1962, Mauritania reported 78 cases of smallpox—2 in 1965 and 76 in 1966. Government reports, however, note that the 1966 cases, all in a confined area, had never been confirmed by a physician and, in retrospect, chickenpox was thought to have been a more probable diagnosis.

In Senegal, the endemic diseases control service had been in operation for many years and had a personnel of 292 in 1967. With a reasonably extensive network of all-weather roads, the multi-purpose mobile teams were able to move comparatively easily throughout the country. Vaccinations, equivalent in number to about 20% of the population, were administered annually. Since the early 1960s, a good-quality freeze-dried vaccine produced in France had been used, a factor which undoubtedly contributed to the interruption of smallpox transmission. No surveys were performed either before or during the programme to assess the level of vaccinial immunity, but it was believed to be reasonably high. For the AID-supported programme, the government decided that the supplies and equipment provided should be utilized by its mobile teams, which endeavoured to visit all villages once every 3 years. During the first 3 years of the programme, 2.6 million smallpox vaccinations were performed. No cases of smallpox were discovered.

In the Gambia, some 50 000–75 000 smallpox vaccinations had been administered annually at health centres and dispensaries, using lanolinated vaccine produced in Nigeria. Few of the health units, however, had refrigeration equipment; supplies of vaccine were distributed monthly and kept in wet cotton until used. Mass vaccination had been conducted only once during the preceding decade—in a localized area in 1963, when an outbreak of 52 cases occurred. The proportion of successful vaccinations is unknown, but it was probably not high, as the method of storage would not have preserved the thermolabile vaccine for more than a few days. Despite the presumably low levels of vaccinial immunity and the fact that 10% of the population was migratory, few cases of smallpox were recorded, the immune barrier provided by Senegal undoubtedly playing an important role in protecting the Gambia.

With assistance provided by the USA for smallpox and measles vaccination, 3 mobile teams were created, each consisting of 2 vaccinators, a tally clerk and a driver; a health superintendent, Mr Kebba A. M. Sanneh, supervised field activities. The mass vaccination campaign began in June 1967 and was completed in 10 months (167 working days), during which 350 000 people were vaccinated against smallpox and 81 000 against measles, an average of 2580 vaccinations a day. This far surpassed the expected average of 1500 vaccinations a day (see box). The continuing programme of maintenance vaccination was no less successful. Concurrent assessment regularly showed coverage rates of more than 90%, which were sufficiently high to interrupt measles transmission for more than 2 years. No cases of smallpox were discovered after the programme had begun.

Mauritania presented a set of problems quite different from those encountered either in the Gambia or in Senegal. Like Senegal and other former French colonies, Mauritania had had an endemic diseases control service, which consisted of 7 mobile teams, each composed of 5 health workers. About 125 000 people were being vaccinated annually against smallpox with a freeze-dried vaccine produced in France. However, in 1962, most senior staff of the service left Mauritania, and thereafter team activities diminished sharply,

Factors in the Success of the Programme in the Gambia

In a detailed paper (unpublished), the Gambian field supervisor, Mr Kebba A. M. Sanneh, enumerated the factors which he considered to be of importance in the success of the programme.

Training: The field supervisor was trained first and actively participated in training the teams, all of whose members (vaccinators, recorders and drivers) were trained together. This created a special team spirit. Included in the training were 5 stand-by vaccinators who could replace any who became ill. After several days of classroom training, a 3-day field exercise was conducted in a large village to work out practical problems.

Publicity and scheduling: Before the programme began, it was given wide publicity through the local press and radio, and through letters to all medical and health personnel, as well as to Divisional Commissioners, and through them to district chiefs. In each district, the field supervisor met each *seyfo* (chief) to discuss the programme and to obtain a list of all villages and hamlets. The *seyfo* was asked to inform each *alkalo* (village head) of the programme and assign a "badge messenger" (a type of policeman) to work with the teams. One day before the teams vaccinated in a village (the population of as many as 20 villages were vaccinated each day), a team member met the *alkalo* and requested him to ask each family head to bring his family to the vaccination assembly point. The field supervisor was given wide latitude in planning the programme, but once a village had been informed that the teams would be present on the following day, every effort was made to reach it even if this meant working for 12 hours or more.

Support of teams: Team morale was enhanced by support given to them by headquarters staff and other government personnel. If transport was sent on a Sunday to obtain vaccine and petrol, these would be supplied, although Sunday was not a normal working day. In addition, teams were paid promptly whenever they returned to the capital. They were given priority at ferries by Marine Department personnel, and priority in vehicle repair by the Public Works Department. The CDC advisers, Dr Thomas Drake and Mr Robert Helmholz, gave help wherever this was required, sharing with the teams the hardships of field living conditions.

Local customs: Public support was actively sought but no compulsion was used and no attempt was made, at any time, to foreshorten the traditional greetings required in the Gambia before any matter could be taken up for discussion. Where teams encountered the initiation ceremonies for circumcision, which necessitated the isolation of the boys and girls concerned from others in the village, the boys were vaccinated "in the bush", and the girls were vaccinated privately in a compound.

With good support from local government and villagers alike, the morale and enthusiasm of the teams remained high, permitting a programme scheduled to last 260 working days to be completed in 167 days, with an independently assessed rate of coverage of more than 90%.

only penicillin and aspirin being distributed during the period 1962–1967.

With the provision of assistance from the USA, it was decided to reconstitute the endemic diseases control service and to add smallpox and measles vaccination to its tasks. For ease of supervision it was decided that the teams would work in two separate groups, progressing from one region to the next, rather than assigning one team to each of 6 regions. However, in 1967, following the outbreak of hostilities between Egypt and Israel, Mauritania severed diplomatic relations with the USA. The United States adviser left the country and field activities ceased after only one week, not to be resumed until 1969.

In March 1968, Dr Mayer, the WHO intercountry smallpox adviser for western Africa, visited Mauritania and, with government officials, developed a plan of operations which provided for the assignment of a WHO medical officer and an operations officer, as well as a vehicle, some items of equipment

and funds to cover local costs. The USA agreed to provide vaccines and other supplies and equipment, using OCCGE as an intermediary. The arrangement was similar to that which was devised to support the programme in the Congo.

At government insistence, two basic changes were made in the original plan: BCG vaccine (provided by UNICEF) would also be administered, and the teams would work simultaneously in 6 rather than 2 regions. In a country of 1.2 million square kilometres with few, poorly maintained roads, the dispersal of teams created difficulties in communication as well as in supervision and supply. Air transport was of little help since scheduled weekly flights served only a few of the larger towns and were frequently cancelled owing to the breakdown of equipment and to sandstorms.

Dr Mayer moved from Liberia to Mauritania in May 1968 and shortly thereafter conducted a scar survey among village children in the north of the country. Vaccinial immunity was found to be poor: among the children up to 14 years old only 45% had vaccination scars and these were almost all in the 5–14-year-olds. After 7 months of preparation, pilot field activities were resumed in January 1969, and full operations commenced in April. The programme progressed slowly, owing to difficulties in supervision and supply and to mechanical problems with vehicles. In 1969, 426 000 smallpox vaccinations were given and about one-fourth this number of measles and BCG vaccinations. In 1970, the number of vaccinations decreased by half and remained at about this level until June 1976, when the programme came to an end. However, no cases of smallpox were detected after 1966.

Although the need for smallpox vaccination in the 3 countries was questionable, since all of them had remained free of smallpox after 1966, the campaigns also provided measles vaccination and the vaccinators, in their systematic travels through the countries, were able to ensure that no foci of smallpox had been missed.

The OCEAC Countries: Cameroon, Central African Republic, Chad, the Congo and Gabon

Of the last group of countries to be dealt with in this chapter, all were members of OCEAC, then directed by Médecin-Colonel Labusquière. The 5 countries (population in 1967, 13.7 million) comprised an area of almost 3 million square kilometres, which, until 1960, had been known as French Equatorial Africa. In the provision of health services, each country relied primarily on the well-established multi-purpose mobile teams of the endemic diseases control service, directed by French medical advisers who were usually military officers. The programmes in these countries all followed the same pattern, which had been agreed on in the meetings of OCEAC.

The method of operation has been described by Dr J. M. Roux, the Chief Medical Officer of Chad (Roux, 1970). A typical team consisted of 12 male nurses, 2 drivers with vehicles and 2 labourers. They administered smallpox, BCG and yellow fever vaccines; examined each person for leprosy and trypanosomiasis as well as other common endemic diseases; conducted simple routine tests on specimens of blood, faeces and urine; and prescribed appropriate treatment. For every individual examined, a special certificate documenting each procedure was prepared and retained by the person concerned. Two or three years were required for the teams to visit all parts of the country.

A freeze-dried smallpox vaccine of good quality, produced in France, began to be used

J. S. FRIEDMAN

Plate 17.17. A health worker in Gabon repairs a jet injector. Jet injectors made it possible to vaccinate large numbers of people very quickly, but they frequently malfunctioned and their daily maintenance was essential.

Table 17.22. OCEAC countries: number of reported cases of smallpox, 1961–1969

Year	Number of cases				
	Cameroon	Central African Republic	Chad	Congo	Gabon
1961	1 145	0	502	23	0
1962	743	57	769	1 254	1
1963	135	3	10	1 476	111
1964	88	0	5	198	49
1965	28	0	73	89	1
1966	2	0	0	0	0
1967	119	0	86	0	0
1968	37	0	5	0	0
1969	3	0	0	0	0

in the early 1960s, and soon thereafter the number of reported cases of smallpox declined sharply, only 2 cases being recorded in the 5 countries in 1966 (Table 17.22).

In the initial planning for the regional programme, CDC staff had not been fully aware of the scope and extent of activities already being carried out in these countries, and had envisaged the need to create special teams for measles and smallpox vaccination such as had been done during the earlier AID-supported measles vaccination campaigns. However, OCEAC and government officials decided to incorporate the new vaccination activities into the work of the multi-purpose mobile teams, and to utilize the vehicles and equipment to strengthen existing efforts. Although this was advantageous to the execution of the vaccination campaign, the prescribed operations provided for neither concurrent assessment of the work by sample surveys nor a surveillance team to investigate suspected cases of smallpox.

OCEAC officials decided that the provision of separate assessment teams would be too costly and that it was basically unnecessary, since assessment in the OCEAC countries was conventionally done by the vaccination teams, who compared the numbers vaccinated with the estimated population in the area served. In most countries, such assessments proved misleading, partly because of inaccurate census data, but the OCEAC programmes were generally well conducted, and independent assessments, when performed, usually revealed that at least 80% and often more than 90% of the population had vaccination scars. By late 1969 and early 1970, the total numbers of smallpox vaccinations administered in each country during the course of the regional programme were almost equivalent to or exceeded the estimated population.

The investigation of suspected cases was generally undertaken by the CDC advisers, with assistance from local officials. After 1966, all smallpox cases in the OCEAC countries were discovered in Cameroon and Chad, in areas bordering on Nigeria. The outbreaks in Chad were traced to importations from Nigeria, as were most of those in Cameroon.

In Cameroon, during 1967–1969, 21 outbreaks, with 159 cases, were detected among tribal peoples who lived in widely scattered settlements in the rugged Mandara mountains adjacent to Nigeria. The villagers frequently crossed into Nigeria and some, in fact, maintained houses in both countries in order to escape taxes. Many villagers resisted vaccination, and because of the difficult terrain, the multi-purpose teams had not vaccinated extensively throughout the region. When surveys showed that 40% of the inhabitants had never been vaccinated, special smallpox vaccination campaigns were conducted in 1967 throughout the area, primarily in the crowded market-places. By March 1968, the last of the large outbreaks had been contained (Delas, 1970). Over the next year, however, 9 additional outbreaks of 1–7 cases occurred among visitors to Nigeria, then still heavily endemic and in which neither vaccination nor surveillance had yet begun.

The outbreaks in Chad occurred among villagers living on thousands of floating islands on Lake Chad, a shallow lake some 250 kilometres long and 25–100 kilometres wide. The islands, inhabited by fishermen, consisted of matted networks of papyrus reeds and other weeds, which often drifted for miles over the surface of the lake. Cases were reported from the area by a missionary physician in June 1967—the first cases known to have occurred in the lake area for more than 2 years. To investigate the outbreak, Dr Bernard Lourie, the CDC adviser, chartered an aeroplane with pontoons, and using a medical service boat and 4-wheel-drive vehicles, he and Chadian staff eventually identified more than 100 cases, not all of which were officially reported. The first had occurred in April among fishermen returning from Nigeria. Smallpox then spread from one small village to another in an area in which only 20–30% of the population bore the scars of vaccination. A special vaccination campaign was conducted in markets and villages

throughout the area. The floating islands presented a special problem, because when pressure was exerted on the pedal of the jet injectors, they tended to sink through the surface. The difficulty was solved by laying mats on the island. In all, some 80 000 people were vaccinated in an area thought to have a population of about 150 000. Transmission was interrupted within a matter of weeks, although importations resulted in 5 further cases in 1968.

Throughout the OCEAC countries, roads were few, the distances were great and communications were limited. Secessionist groups, who were active throughout the central and northern parts of Chad, compounded the problems there and taxed the skills of the able director of the mobile disease control service, Dr Pierre Ziegler. Rebel groups, in fact, ambushed a team, killing a labouret, wounding a driver and setting fire to one of the vehicles. Efforts to contact the secessionists to ensure safe passage proved futile, since the different groups acted independently and assurances provided by one leader did not obligate others. Accordingly, vaccination in these areas had to be restricted to the major towns and cities which had military garrisons. Neither surveillance nor vaccination was possible in rural areas of the north, but the population was sparse there, and smallpox transmission did not persist as it did under similar conditions in the Ethiopian Ogaden in 1975–1976.

CONCLUSIONS

The elimination of smallpox in 1970 – little more than 3 years after the inception of the Intensified Smallpox Eradication Programme—from the vast region of western and central Africa provided enormous encouragement to the remaining endemic countries. The fact that many countries of the region were among the world's poorest, with the least developed infrastructures of health, transport and communication, increased confidence that global eradication could eventually be accomplished. The valuable early insights into the epidemiology of smallpox and the methods for its control were no less important. Subsequently, the experience acquired by both national and CDC staff was to prove invaluable when many of them served with programmes in other parts of the world.

The regional programme was also important in that the USA provided sufficient support to make eradication feasible in this vast region; WHO did not then have resources of this magnitude available for programmes in other endemic areas. The fact that CDC staff assumed full responsibility for technical assistance permitted WHO Headquarters staff to direct their efforts and attention elsewhere. Indeed, in view of the formidable administrative problems that WHO encountered in implementing smallpox eradication programmes in other countries of Africa, it is problematic whether eradication in Africa could have been achieved without this support. At the same time, WHO's own modest but vital contribution to many of the countries by meeting the "local costs" of items such as petrol and vehicle maintenance and repair must be acknowledged.

This programme is identified with the first effort to implement, as national policy, a strategy which accorded priority to the discovery of outbreaks and their containment, even if these activities meant some compromise in the pace of execution of the mass vaccination campaign. An important change of emphasis in the global strategy took place as a result, and, in supporting this change, WHO staff frequently cited the successful experience of the regional programme. In retrospect, however, when the relative contributions made by mass vaccination and surveillance–containment ("eradication–escalation") are weighed, the importance of surveillance–containment to the western and central Africa programme itself is less certain. When such measures were actually implemented late in 1968, the mass vaccination campaign had already reached some 60 million persons, more than half the population of the region, and a much higher proportion of those in the known endemic areas, to which the campaign had given priority. Endemic smallpox then remained in only a few of the countries, and where surveillance teams actively sought to discover and to contain outbreaks—as in Dahomey, Guinea, Sierra Leone and Togo—smallpox transmission had practically ceased, the remaining outbreaks being small and in isolated rural areas. The strategy was not employed in northern Nigeria, then the principal focus of smallpox. There, programme staff undertook to contain outbreaks only in areas in which the mass vaccination campaign had been completed.

Thus although the rapid demise of smallpox in western and central Africa was impressive, and the success of the programme attributed to the new strategy, the well-executed mass vaccination campaign using freeze-dried vaccine probably played the more decisive role.

In this region, as well as in most of Africa south of the Sahara, the interruption of smallpox transmission proved to be more straightforward and less difficult than in Indonesia and the Indian subcontinent. In contrast to the Asian countries, the population density in Africa was lower, population movement was less, vaccination was usually more readily accepted, and many villagers, by tradition, isolated smallpox patients. When the comparatively simple surveillance–containment methods used in Africa were employed in Asia, the results proved disappointing. In Bangladesh, India and Pakistan, in particular, whose populations had generally higher levels of vaccinial immunity than those of African countries, surveillance and containment measures failed to make a significant impact on the disease until the methods were substantially modified and strengthened.

As had been hoped, the programme in western and central Africa served to strengthen the foundation for disease reporting and preventive services in all the countries concerned, but with only 5 years of operational experience the endeavours could not be fully institutionalized. Thus, in 1976, when it became necessary to certify that eradication had been achieved, special programmes had to be organized to permit certification (see Chapter 25).

Subsequent chapters describe eradication programmes in other countries of Africa, which, with some notable exceptions, consisted largely of mass vaccination campaigns but which succeeded in eliminating smallpox with surprising rapidity.

INTRODUCTION

Eradication programmes in a group of contiguous countries of western and west-central Africa began in 1967 and 1968, with support primarily from the USA and technical assistance provided by the United States Communicable Disease Center. East of this area lay two of Africa's largest countries—Zaire and the Sudan (Fig. 18.1). (Zaire was named the Democratic Republic of the Congo from 1960 to 1971, but its present name is used throughout this chapter for convenience.) Their combined population in 1967 amounted to only about 33 million, but their total area (approximately 4.85 million square kilometres) was equivalent to that of the whole of Europe, excluding the European part of the USSR. Transport and communications in both countries were poor and the terrain was difficult. Zaire was in WHO's African Region and the Sudan in its Eastern Mediterranean Region.

In the African Region, Zaire strategically had the highest priority for the allocation of WHO resources. Smallpox was endemic throughout the country; in 1967, it accounted for one-third of the total number of cases reported in the countries of central, eastern and southern Africa. Indeed, of all the African countries, only Ethiopia was to record more cases after the Intensified Smallpox Eradication Programme began. Vaccinial immunity was low throughout the country. Along its lengthy western, northern and southern borders lay 5 countries which had interrupted smallpox transmission or seemed close to doing so—Angola, the Central African Re-

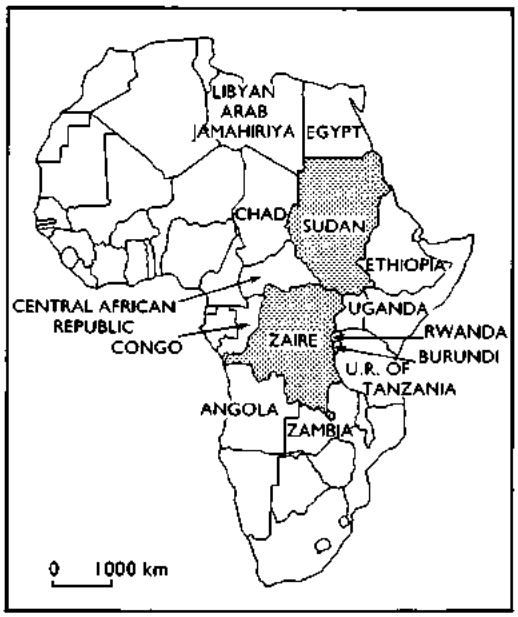

Fig. 18.1. Sudan and Zaire and adjacent countries.

public, the Congo, the Sudan and Zambia. In all, these 5 countries reported 686 cases in 1965 and only 66 in 1966. Because of the frequent movement of travellers across the Zairian border, importations of smallpox were inevitable. When they occurred, the detection and control of the outbreaks, especially in border areas, were problematic owing to the paucity of health services and the difficulties of travel and communication.

The status of smallpox in the Sudan was entirely different. A mass vaccination campaign using freeze-dried vaccine had been conducted throughout the central and northern parts of the country between 1961 and 1963. The Sudan reported no cases at all in 1963, 1964 and 1966; in 1965, 69 cases occurred as a result of importations. However, in the country's 3 southern provinces, which had a population of about 2.5 million, government health services were restricted to the larger towns because of a protracted, devastating civil war. Thus, the status of smallpox in the extensive rural areas of the south could not be known with certainty. Even so, there was hope that the disease might not be present. No cases were being detected in the towns, no imported cases from this area were being found in adjacent countries despite the considerable numbers of migrants and travellers, and reports reaching WHO from revolutionary groups in the south indicated that no known cases of smallpox were occurring. Moreover, the area was sparsely populated, making the sustained transmission of smallpox difficult.

Agreements to undertake eradication programmes were signed by the Zairian government in November 1966 and by the Sudanese government in April 1967. In both countries, the plans called for the administration of BCG (antituberculosis) vaccine to children and adolescents at the same time as the whole population was being vaccinated against smallpox. It was the first time a national programme had been attempted which incorporated the simultaneous administration of the two vaccines. The concept seemed sensible but, logistically, there were problems because the BCG vaccine had to be administered intradermally. In Zaire, inoculation was performed at collecting points, and there it eventually proved feasible to use the jet injectors for both smallpox and BCG vaccination. In the Sudan, however, the jet injectors were not practical because in many areas the population was not accustomed to assembling at collecting points. Smallpox vaccine was therefore administered with the bifurcated needle by vaccinators moving from house to house, but the administration of BCG vaccine by syringe and needle was too cumbersome to permit this procedure. Accordingly, programme staff endeavoured, without great success, to gather the children at assembly points.

In addition to the problems inherent in administering two vaccines rather than one, both programmes faced other difficulties, including those of conducting campaigns in large areas in which civil disorder was prevalent. Moreover, in Zaire, trained manpower in all sectors of government was scarce, communication facilities were few, the network of roads was limited and in poor repair, and travel through dense tropical rain forests was difficult. However, a highly effective vaccination campaign began to take shape there in 1968, and by July 1971 a carefully assessed systematic programme had been completed throughout the country during which smallpox vaccine was given to more than 24 million persons and BCG vaccine to more than 11 million. The last recorded case of smallpox appears to have occurred in June 1971.

Because of the lack of trained staff and the size of the country, organized surveillance was not developed until after the completion

of the vaccination campaign, and thus few outbreaks were investigated. However, an excellent surveillance system subsequently evolved, which served to strengthen the existing health structure and to confirm the absence of smallpox. Between 1970 and 1986, more than 400 cases of monkeypox, a disease clinically resembling smallpox (see Chapter 29), were eventually discovered.

The hope that the Sudan would remain free of smallpox was shattered late in 1968, when increasing numbers of cases began to be detected among persons living in the war-stricken south near the Ethiopian border and among migrant agricultural labourers from that area. Meanwhile, a mass vaccination campaign had been initiated in provinces in the central part of the country, but it was disrupted by the occurrence of cholera in 1970–1971. Although the investigation and containment of all suspected cases in a country believed to be smallpox-free were considered by WHO to be of high priority, no programme for the purpose was developed. Smallpox spread across the country in 1970 and 1971. In only 2 African countries that were free of smallpox in 1967 did endemic smallpox become re-established, and the Sudan was the first of these. Finally, in January 1972, a Sudanese medical officer took the initiative of developing a surveillance–containment programme which interrupted transmission with such unexpected rapidity that WHO consultants recruited to help to strengthen the operation arrived just as the last cases were occurring. Thereafter, Sudanese surveillance teams assisted Ethiopian staff in search activities along the border, as well as in Ethiopia itself.

ZAIRE

Background

Zaire, Africa's third largest country, is mostly low plateau (average altitude, 500 metres), comprising the central basin of the Zaire (formerly Congo) river and its tributaries. Higher plateaux surround the low plateau, rising to mountains in the east. Extending 2300 kilometres from east to west, much of the country is covered by dense tropical rain forest, giving way at higher elevations to wooded savanna and grassland. Throughout central Zaire, temperatures are uniformly high (24–27 °C), as is the humidity. In 1967, almost 90% of the inhabitants were rural dwellers, many living in clusters of 10 20 houses along roads or tracks. Of the 233 000 kilometres of roads, only 3000 kilometres were of the all-weather asphalt type. In extensive riverine tropical rain forest areas, villages could be reached only by boat or on foot. Kinshasa, the capital (then called Léopoldville), was the largest city in tropical Africa (population, about 1 million), but there were 9 other cities in Zaire with populations of 100 000 or more. Telegraphic and postal services were limited and unreliable; communication among the various tribal groups, speaking more than 200 different languages and dialects, posed a problem.

Zaire became independent in June 1960 but within a week, an army mutiny and threatened secession brought in a United Nations peace-keeping force, which remained for 4 years. A large-scale United Nations technical assistance programme was also initiated and continued in operation until 1969. With the departure of the United Nations forces, rebellion recurred throughout the north-eastern provinces and sections of those in west-central Zaire. After the autumn of 1965, the conflict gradually subsided, but security in parts of the country remained a problem for several years. During the long period of fighting, roads and bridges were destroyed or deteriorated, and the structure of the health services was greatly weakened. Not surprisingly, few persons were vaccinated against smallpox during this time.

Trained personnel throughout the country were proportionately far fewer in Zaire than in most African countries. Primary education had been made widely available during the 1950s, but few people had been educated in secondary schools or institutions of higher learning. There were, for example, no national physicians in 1960, only 88 in 1965 and only 221 in 1970.

Because of the dearth of educated national staff, United Nations and bilateral technical assistance programmes provided many of the necessary senior and middle management personnel for the government. In the health sector, there were, in 1965, 427 foreign physicians, of whom 86 were provided by WHO and 75 by Belgian and French assistance; the remainder worked primarily in mission hospitals and clinics or were under contract with the government.

To carry out a national programme with the situation as it was in 1967 represented a formidable undertaking.

Smallpox Before 1967

During the decades preceding the beginning of the programme, several thousand cases of smallpox had been recorded annually in Zaire, but, because reporting was poor, this represented only a minute fraction of the total which had occurred. The disease was prevalent throughout the year, with no seasonal fluctuations. Mass vaccination campaigns had been conducted sporadically in urban areas and in some rural districts, but vaccination, employing locally produced liquid vaccine, was frequently unsuccessful.

It is probable that both variola major and variola minor prevailed in the country at different times. However, from 1962, smallpox with a case-fatality rate of 5–15%, similar to that in western Africa, was most widely prevalent. Official reports from Zaire usually distinguished between variola major and variola minor (Table 18.1). From these data, the inference might be drawn that variola major, similar in severity to that which occurred in Asia, coexisted with variola minor. During the course of the programme, however, it became apparent that health staff usually based their reports simply on the severity of the disease. Milder cases were customarily reported as variola minor and more severe cases as variola major.

Before 1962, overall case-fatality rates were below 5%, but subsequently they ranged from 5% to 15%. Since no changes are known to have occurred in reporting practices, it is presumed that a more serious form of the disease became more widespread about this time. After 1962 there were occasional undocumented anecdotal reports of outbreaks with few or no deaths; conversely, in Kinshasa a 1961–1962 epidemic was reported in which 280 (27%) of 1021 cases died. However, in the Kinshasa outbreak almost all the cases reported (of which 70% were in children under 5 years of age) were of the more severe type, requiring hospitalization.

Whatever the cause of the higher case-fatality rate, the government authorities of the newly independent country, as well as the foreign medical officers working there, were concerned about smallpox. In 1962–1963, they held meetings with the WHO medical officer for smallpox from Geneva to plan a pilot programme in one of the provinces. It was hoped that this would be followed by a national smallpox vaccination campaign. WHO was asked to provide medical officers, vehicles and equipment, but because of civil war, it was not possible to follow up the request. Meanwhile, smallpox vaccination throughout the country all but ceased. In 1965, WHO was again approached with a fully elaborated plan for a 4-year country-wide vaccination campaign, during which smallpox and BCG vaccines would be administered simultaneously. Such a programme had not been attempted before, in part because of the problems inherent in administering BCG vaccine.

Up to 1964, the administration of BCG

vaccine required that each potential vaccinee should be visited twice, with an interval of 2 days between visits. At the first visit, a non-infectious purified protein derivative (PPD) of the mycobacterium was injected intradermally, and 2 days later the site of injection was examined. The presence of a specified amount of induration at the test site indicated that the child had been infected with tuberculosis. Such children would not benefit from vaccination and thus were excluded from the group given BCG vaccine. The possibility of vaccinating all children, irrespective of whether or not they had had tuberculosis, had been considered, in order to eliminate the cumbersome and time-consuming process of prior testing with PPD. However, the occasional occurrence of unusually severe reactions to vaccine in the already infected group had contraindicated this approach. The WHO Expert Committee on Tuberculosis (1964) discussed the question at length and concluded that, as a practical matter, there was little choice in many countries but to eliminate testing with PPD on the premise that the overall benefits conferred by a logistically simplified BCG vaccination campaign outweighed the risk of a few serious reactions. This change in procedure made it more feasible to administer both vaccines at the same time. Moreover, because UNICEF was supporting many national BCG vaccination campaigns, but not those for smallpox, it was hoped that a combined campaign would elicit from UNICEF material assistance in the form of transport and equipment. The plan called for a national staff of 650, supported by 9 medical advisers, an operations officer, a statistician and an administrator made available by WHO. The magnitude of the programme and the proposed substantial commitment of government resources reflected a degree of interest in smallpox eradication in Zaire that was exceptional in African countries.

The Eradication Programme Begins, 1967–1968

Because of the considerable United Nations and WHO commitment to Zaire, an office in WHO Headquarters rather than in the WHO Regional Office for Africa coordinated the Organization's activities in Zaire until 1968, dealing with such matters as the recruitment of staff and the procurement of supplies. In November 1966, a medical officer from the Smallpox Eradication unit at Headquarters held discussions with national and WHO staff in Zaire and finalized a similar although somewhat more modest plan than that originally proposed by Zaire. Most of the support was to be provided by WHO, UNICEF agreeing to supply only the BCG vaccine, as well as the needles and syringes for its administration.

The overall operational strategy for vaccination was not dissimilar to that in other African countries. It called for 4 large vaccination groups, each composed of 6–8 teams. Each group would be directed by a WHO medical officer and, where available, a Zairian counterpart. Every team would have a supervisor; 3 pairs of vaccinators (a "vaccination unit"), one of each pair giving smallpox vaccine and one BCG vaccine; and a "control unit" of 3 vaccinators and a sanitary agent to visit a sample of the villages one week after vaccination to verify coverage and vaccination results. It was expected that each pair of vaccinators would be able to give 140 smallpox vaccinations and about 70 BCG vaccinations a day. Smallpox vaccination would be performed by scarification and BCG vaccination by intradermal inoculation using a syringe and needle. Village chiefs and local authorities would be notified in advance and asked to bring the people together at a convenient collecting point. In view of tribal and linguistic differences from area to area, local recruitment and the secondment of personnel from existing health services were anticipated.

The WHO senior medical officer was to be designated "co-director" of the programme rather than "adviser", in recognition of the more substantial role that the Organization was intended to play. In addition to the 4 medical officers who were to head the vaccination groups, WHO was also to provide an administrator, a public health nurse and a statistician—in all, 8 staff members, plus short-term consultants. The government complement was expected to amount to 363 persons, of whom 260 would be vaccinators. The cost to the government was set at US$353 800 for the 1967 pilot project and at US$677 000 annually for the principal "attack phase", which was scheduled to extend from 1968 to the end of 1970.

At the outset, WHO provided 34 Land Rovers with trailers, 6 trucks, 5 outboard motors, 14 motor cycles, 10 refrigerators plus

camping gear, office equipment, megaphones and other miscellaneous supplies. WHO's support for this programme up to 1974 represented, on average, about 8.5% of all funds earmarked for smallpox eradication in the Organization's regular budget (Table 18.2).

Following completion of the mass vaccination campaign, it was expected that maintenance vaccination would be continued by the established health units, which by 1972 included 302 hospitals, 45 clinics, 2705 dispensaries and 242 maternity wards. Little attention was paid to reporting and surveillance in the 1966 plan of operations, reflecting the minimal interest in this component of the programme before 1967. As was stated in the plan: "Long-term objectives are to maintain smallpox eradication by appropriate surveillance methods as will emerge from experience and evaluation."

The post of WHO co-director was assigned to Dr Vladimír Zikmund, a WHO epidemiologist already working in Zaire; Dr Lekie Botee, a young Zairian medical officer, was appointed the national co-director – he was to serve in this role with great distinction throughout the early phases of the programme and later, to provide invaluable support as Director-General of Health Services.

The plan called for a pilot programme, to be initiated in 1967, in the course of which 2 groups would administer 2.86 million vaccinations; a full-scale programme, employing 4 operational groups, was scheduled to begin in 1968. Completion of the vaccination phase was foreseen by the end of 1970.

Because of difficulties in organizing so extensive a programme in a country only beginning to recover from civil war, progress was slow at first. Equipment began to arrive in July 1967 and most had been received by October. Two WHO medical officers, already assigned for work in Zaire, were transferred to the programme and a part-time finance officer was made available. At this point, efforts to recruit the remaining promised complement of WHO staff all but ceased. WHO's technical assistance programme in Zaire diminished significantly in scope as from 1967–1968, and responsibility for the Organiza-

Plate 18.1. **A:** Lekie Botee (b. 1930), the first Zairian co-director of the smallpox eradication programme in Zaire; when, later, he became Director-General of Health Services of Zaire he continued to play an active role in the programme. **B:** Pierre Ziegler (b. 1925), WHO co-director from 1968, was instrumental in redirecting operations and in establishing a management system.

tion's activities in Zaire was transferred to the Regional Office for Africa, which had only a small staff, a host of countries to serve and a staggering array of problems. Repeated pleas for additional staff were made but more than a year was to elapse before an administrative officer arrived; not until July 1971 was the promised complement of WHO staff made available.

Preparations for the field programmes were handicapped by the need for the medical officers to spend much of their time on administrative matters, including the creation of a central administrative office, the clearance of supplies through an inefficient customs office and their inventory and storage, and the shipment of vehicles and equipment to provincial capitals which were to serve as bases for field operations. Obtaining the release of government funds was yet another problem which persisted throughout the course of the programme, not infrequently requiring special intervention by the Minister of Health when depleted allocations threatened to stop activities. The part-time WHO finance officer, Mr S. O. Axell, wise in his knowledge of government, eventually obtained agreement to have the allotted funds deposited in a special bank account, and, in time, several such accounts were opened. When delays occurred in obtaining the funds allocated, especially at the beginning of a fiscal year, and the principal account was empty, reserves in the auxiliary accounts were used until the crisis could be resolved.

Because of the difficulties in getting the programme started, the pilot project in 1967 was limited to Kinshasa. It was not an auspicious beginning. The WHO co-director, seeking to ensure a thorough vaccination coverage, proposed that a census should be taken at the same time as the vaccinations were performed so that it could be known precisely what proportion of the population had been vaccinated. Thus, the vaccinators were instructed to prepare a separate card for each family, listing all members by name, age and sex and noting the date of vaccination. Later, an assessor visited each house, issued a special vaccination certificate to each individual successfully vaccinated and revaccinated those whose vaccination had not taken or who had been missed. The process was cumbersome and time-consuming. On average, the vaccinators performed only 20–30 vaccinations a day, and the Kinshasa programme concluded with only 220 000 persons having been vaccinated in a target population of 1 million. Although the methodology was obviously faulty, no changes were made as the programme shifted from the pilot project stage to a mass vaccination campaign.

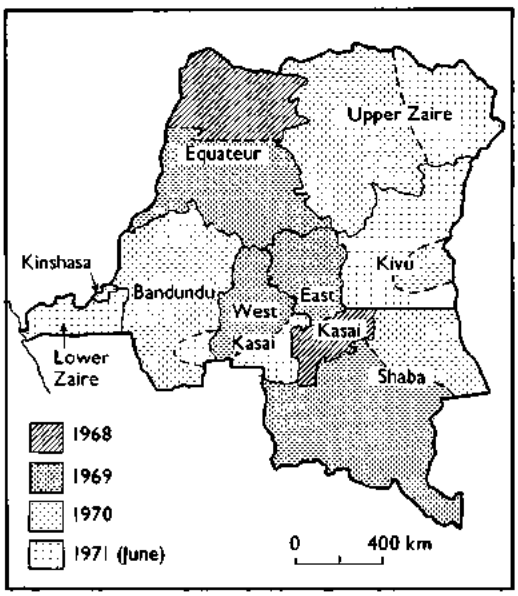

Fig. 18.2. Zaire: areas whose population was vaccinated in the systematic campaign, 1968–1971.

Three vaccination groups had been expected to begin work in 1968, but with only 2 WHO medical officers available to direct them, the programme was launched in only 2 provinces—East Kasai and Equateur (Fig. 18.2). In February, more vaccinators were recruited and trained and, in March, approximately 70 staff began work in East Kasai and 60 in Equateur. On 29 March 1968, a presidential decree gave the programme official status. For smallpox vaccination, most of the staff used the newly available bifurcated needles. In East Kasai, a number of jet injectors, such as were then in use in Brazil and western Africa, were supplied for large-scale vaccination at collecting points.

The jet injectors immediately proved to be widely favoured by the population and permitted the teams to vaccinate many more persons each day. However, the operational problems which characterized the pilot project worsened. The efficiency of the jet injectors was compromised by 3 facets of the programme: (1) the complex enumeration process; (2) the need to distribute vaccination certificates; and (3) the coordination of

smallpox vaccination with the time-consuming intradermal inoculation of BCG using a syringe and needle. Other methods were tried for enumerating the population. Special teams visited each area before vaccination and collected information by house-to-house visits or at collecting points. To simplify the process further, it was decided to record only the names of the heads of households, along with the number of household residents. In addition, efforts were made to persuade village leaders to provide this information. However, it was discovered that the number of people recorded as having been vaccinated in each village was greater than the total enumerated, the discrepancy being accounted for by an inadequate enumeration process and the fact that many individuals from outside the area attended the vaccination sessions. It became apparent that enumeration was a futile exercise. The name of the individual concerned had to be written on each vaccination certificate, after which it was stamped with an official stamp. For each jet injector in operation, on average 6 clerks were required to prepare the certificates. Lastly, the administration of BCG vaccine was an awkward procedure, often requiring, as one observer noted, 2 persons to hold the child and a third to inoculate.

The staffing patterns of the teams were changed to assign more persons to clerical work and to BCG vaccination, but progress remained discouragingly slow. By the end of September, smallpox vaccine had been given to 1 477 000 people and BCG vaccine to 644 000; at this rate the country-wide programme would have taken 8 years to complete.

The Restructuring of the Programme, September 1968

In September 1968, a new WHO co-director—Dr Pierre Ziegler—was appointed. Dr Ziegler had previously served for 16 years in Chad directing a mobile disease prevention and treatment service. During 1967, he worked there with United States Communicable Disease Center staff in the smallpox eradication–measles control programme and understood clearly the practicalities of executing a field programme. Dr Ziegler and Dr Lekie Botee decided to cease the enumeration activities. Instead, a sample survey of 5% of the villages was conducted after 6–8 days to assess the take rates of smallpox vaccination, and again after 2–3 months to assess the take rates of BCG vaccine and overall vaccination coverage. The problem of vaccination certificates proved to be more difficult to deal with because the government insisted on their use and the population was accustomed to receiving them. Procedures for their issuance, however, were greatly facilitated by requiring a member of the team to stamp the certificates and by asking the vaccinee to enter his or her name on the document. Finally, the teams began to use the jet injectors to administer BCG vaccine as well, a recently (albeit incompletely) evaluated technique of BCG vaccination. WHO regional personnel and national tuberculosis advisory staff, in deference to tradition, objected to the adoption of this practice, but eventually acquiesced when Dr Halfdan Mahler, then Chief of the WHO Tuberculosis unit, endorsed it and ordered all to cooperate.

Each vaccination group was reorganized to consist of 5 teams, each with a Land Rover and 5 jet injectors. Every team had 6 members—the team leader, 1 vaccinator for smallpox vaccine and 1 for BCG vaccine, a person to stamp and distribute certificates, another to tally the vaccinees and reconstitute the vaccine, and a driver. One additional team worked with each group to contact the chiefs of all villages 1 or 2 days before the vaccination teams arrived, to explain the programme and to obtain the cooperation of village leaders. An assessment team made up the rest of the field staff.

Each operational group maintained a headquarters in the capital city of the province in which it was working and temporary field camps as it moved through the province. In addition to the field teams, each group had a small administrative unit—a total complement of about 50 persons. Each group was equipped with 10 Land Rovers, 2 trucks, 30 jet injectors and several refrigerators. Each team had specific daily and monthly targets, but was allowed a certain flexibility in its schedule to accommodate the need for frequent long trips by boat and on foot.

The pace of activity began to increase. During the last 3 months of 1968, as many people were vaccinated as during the first 6 months of the programme. By the end of the year, 2 275 000 smallpox vaccinations had been performed over a broad area stretching across the central part of the country. Here, assessment revealed that, except in the most

A Problem Bred by Efficiency

The vaccine standards called for the freeze-dried smallpox vaccine to retain its potency for 30 days when incubated at 37 °C. Thus, in all programmes, provision was made to refrigerate the vaccine at 4 °C at central storage depots and at distribution points in the field to ensure, as far as possible, that vaccine reaching the vaccinee was fully potent. The diluent for the vaccine, however, did not need to be refrigerated. Much of the vaccine provided to WHO came from the USSR, which, like most vaccine manufacturers, packaged both vaccine and diluent in the same box. With this manner of packaging, much more refrigerated storage space was required than if the diluent and vaccine had been packaged separately. Because refrigerated storage facilities were at a premium in all countries, WHO approached the Soviet authorities and proposed that the two should be separately packaged and this was agreed. In 1970, vaccine and diluent began to be distributed in separate boxes, which were clearly marked and had labels of different colours so that there would be no confusion.

Regrettably, the change in the manner of packaging was not at first noted in Zaire until a vaccination team, after 3 weeks' journey into the forest, opened the boxes to begin a vaccination campaign—only to find that they had brought with them nothing but diluent.

isolated districts, more than 90% of the population were being vaccinated. On average, each team was able to administer daily 1200 smallpox vaccinations and 600 BCG vaccinations. In only a few months, Dr Ziegler and Dr Lekie Botee, assisted by 2 WHO group leaders, Dr P. Cartagena and Dr E. Zanotto, had transformed a chaotic operation into a remarkably efficient machine.

In January 1969, the programme began to publish a monthly surveillance bulletin, which was distributed to 943 health units throughout the country. It documented the numbers of cases reported from each province and the progress of the campaign, exhorted all to report cases of smallpox, and urged health units to undertake vaccination.

Until 1969, few of the personnel in the extensive network of health centres, clinics and hospitals had administered vaccines of any type. Those who had done so had been supplied with either liquid smallpox vaccine or a substandard freeze-dried product produced by a laboratory in Lubumbashi. A WHO consultant was recruited to determine whether, with assistance, the laboratory could produce satisfactory vaccine, but the problems were too numerous and the laboratory was closed. In June 1969, it was agreed that only vaccine that met WHO requirements would be used, and thereafter vaccine supplied by WHO, emanating principally from the USSR, replaced the local product. With the continuing encouragement of the smallpox eradication programme staff, the numbers of smallpox vaccinations performed in health centres and clinics increased from 575 000 in 1968 to 3 575 000 in 1969, although some health centre staff, preoccupied with curative medicine, refused to participate in the campaign.

In February 1969, Mr A. Samy, an administrator, was recruited by WHO. A resourceful and experienced person, he soon established a sophisticated vehicle repair and maintenance workshop—a necessity because, as noted in a report: "Despite more than 3000 Land Rovers in service in the country, the after-sales service provided is inadequate as for repair and often nonexistent concerning locally available spare parts." Records of repair and maintenance schedules were established for all vehicles, mechanics were recruited and trained, and trailers were rebuilt to permit them to carry petrol, often unavailable in remote parts of Zaire. A workshop for repair of the jet injectors was also established, along with an inventory of spare parts.

The logistic and operational problems were formidable but programme staff, with ingenuity and persistence, competently dealt with them. The recruitment of the required WHO staff, the placement of orders for equipment and the arrangements for its shipment were, however, beyond their control, these tasks being the responsibility of the WHO regional office. All were greatly delayed. Even the use of BCG vaccine had to be

Plate 18.2. **A:** The protracted fighting in Zaire devastated the road system, and vehicles frequently became mired along bush trails. **B:** Broken chassis were common; without a special repair and maintenance workshop, the programme would have foundered.

interrupted for a period when UNICEF decided to send the vaccine by air but the diluent for reconstituting it by sea. The only supplies which did not present a problem were smallpox vaccine, bifurcated needles and jet injectors. These could be provided promptly, on request, from a reserve stockpile held at WHO Headquarters.

In January 1969, Dr Ziegler and Dr Lekie Botee decided—and the government supported them with an appropriate request to the regional office—that persons with qualifications similar to those of staff employed by the United States Communicable Disease Center in western Africa should be recruited as WHO operations officers. It was expected that they would organize provincial surveillance teams so as to strengthen reporting and investigate outbreaks. WHO agreed to recruit 5 such persons, but more than 2 years were to elapse before 4 of the 5 arrived. Meanwhile, with only 2 WHO medical officers available for field work and no Zairian staff who could independently supervise field activities, Dr Ziegler and Dr Lekie Botee had no option but to pursue the vaccination campaign, postponing surveillance until adequate staff became available.

The vaccination campaign steadily gained momentum: between April and June 1969 an average of about 500 000 smallpox vaccinations were administered each month, compared with only 200 000 a month the year before. In July, a third vaccination group was able to begin work under the supervision of a WHO medical officer recruited from among the foreign medical staff remaining in Zaire. He was replaced later that year by the first of the WHO operations officers, Mr Garry Presthus, who was to provide able assistance first in Zaire and later in Botswana. By the end of 1969, more than 8 million persons had received smallpox vaccine and almost 3.5 million BCG vaccine (Fig. 18.3). The total was less than the optimistic target projected in 1966, but the gap was narrowing. The results of continuing assessment showed a vacci-

nation coverage which frequently exceeded 95% and was never below 80%.

The number of recorded cases decreased from 3800 in 1968 to 2072 in 1969 (Table 18.3; Fig. 18.4), a significant reduction in view of the fact that more medical units, encouraged through the monthly surveillance bulletin, began to report each week the number of cases of smallpox seen. During 1969, an average of 87 medical units out of an estimated 535 provided weekly reports—a far from optimum response but an improvement over 1968. The highest proportion of reports was received from the provinces in which the vaccination groups had worked and the medical units had been most thoroughly briefed about the programme. In East Kasai Province, in which the vaccination campaign was completed in February 1969, the results were dramatic (Fig. 18.5).

The Vaccination Campaign Becomes Fully Established, 1970

Most of the supplies and equipment had been received by 1969 (Table 18.4), sufficient to meet the needs of 4 vaccination groups, but it was not possible to establish a fourth group

until February 1970, when Dr Ziegler succeeded in arranging for the transfer of another locally employed foreign medical officer, Dr A. Hornbanger. In just 8 weeks Dr Hornbanger's group of 7 teams, based in Kinshasa, performed more than 1.6 million smallpox vaccinations and 800 000 BCG vaccinations in the city; during March, each team of 6 persons gave, on average, 5300 smallpox vaccinations and 2800 BCG vaccinations a day.

With 4 groups in the field, the complement of national personnel increased until it reached its highest number—234 persons—a ratio of 1 staff member for about 100 000 inhabitants (Table 18.5). There were 9 international staff. The vaccination campaign progressed rapidly despite the fact that groups were beginning to spend more time in the least accessible regions of the country, where travel by boat and on foot was frequently required. For example, one group, consisting of 50 persons, which had succeeded in vaccinating 915 000 people in one month in an accessible, more populated, area, was able to vaccinate only 54 000 people during the succeeding month.

By the end of 1970, 17 million persons had been vaccinated against smallpox and systematic programmes had been completed throughout the country except in areas in which security had been a problem, and in Lower Zaire, near Kinshasa, in which few cases were being detected and which, accordingly, had lower priority.

The Problem of Surveillance

Dr Ziegler and Dr Lekie Botee continued to worry about reporting and surveillance. The recruitment of operations officers who could lead surveillance–containment teams had been expected but the arrival of only one such officer, late in 1969, was of little help. The creation of a national team was considered but, in a country so large and with travel so difficult, it was decided that this would be unproductive. Moreover, communications were a major problem, so that even when cases were discovered notification was so greatly delayed that it was difficult for a single team to be effective. For example, a telegraphic message sent in April, reporting cases in a province adjacent to Kinshasa, took a month to reach Kinshasa.

Each of the health units throughout the country continued to be encouraged to vaccinate, to report cases and to contain outbreaks. Although the average number of reports received each week increased from 87 in 1969

[a] Two cases of chickenpox incorrectly notified as smallpox.

to 140 in 1970, there were still many units which did not report at all.

During 1970, only 716 cases were reported, the lowest total recorded in Zaire since a national reporting system had been introduced. By September, fewer than 50 cases a month were being discovered, most of them in eastern Kivu Province (Table 18.6), in which the vaccination campaign was still in progress. At least some of the reported cases were thought to be chickenpox, since they were noted as having occurred in young children with a distinctive vaccination scar. In the hope of getting a more accurate assessment of this problem, Dr Ziegler and Dr Lekie Botee decided to distribute collection kits and to ask those who reported cases to submit specimens for examination by WHO reference laboratories. However, the distribution of the kits, as well as their return, proved troublesome because of the poor postal service.

Frustrated by WHO's inaction in recruiting staff, Dr Lekie Botee and Dr Ziegler in Kinshasa and Henderson, on a special trip to Washington, approached the United States government, requesting the assignment of 8 Peace Corps volunteers from the USA. This had to be done unofficially, because at that time it was the policy of WHO that the assignment of national volunteers should be decided on and worked out by agreement between the national governments concerned. WHO staff were to play no role in encouraging their assignment in any country or in supporting their activities. However, the Zaire programme was desperate for personnel to undertake surveillance activities and there appeared to be no other alternative. United States officials were themselves not initially enthusiastic about the proposal because of their policy of assigning Peace Corps volunteers to specific areas in which they would become acquainted with the local people during their tour of duty. The surveillance teams, in contrast, were expected to travel constantly over an extensive area. Moreover, the task of supervising a surveillance team was felt to be unusually demanding. Reluctantly, the USA agreed to select Peace Corps volunteers who had performed especially well during a 2-year assignment and wished to extend their tour of duty for a year or more. Those appointed were to prove invaluable.

The Discovery of a Case of Monkeypox in a Human Being

The imperative need for surveillance was heightened by the identification in October 1970 of the first recognized case of monkeypox in a human being. The WHO reference laboratory in Moscow isolated monkeypox virus from a specimen collected from a child who had become ill on 22 August 1970. The virus had been isolated previously from outbreaks of disease in captive monkeys but never before from a human (see Chapter 29). Nothing was known about the possible clinical manifestations in humans or about the potentialities for spread from human to human. Recalling that yellow fever eradication had been thwarted in the 1930s when a natural reservoir in mammals had been discovered, WHO staff were deeply concerned that monkeypox virus might be analogous to sylvan yellow fever virus, perhaps dooming the objective of global eradication. Concern grew when, within a week, 4 cases in Liberia were confirmed as monkeypox by the WHO reference laboratory in Atlanta, USA.

Ladnyi, at that time the WHO intercountry smallpox adviser in eastern and

Plate 18.3. Kalisa Ruti (b. 1948) examining a patient with monkeypox. He succeeded Lekie Botee as co-director of the smallpox eradication programme in Zaire and subsequently supervised the extensive investigation of monkeypox.

southern Africa, joined Dr Ziegler early in January 1971 to investigate the case in Zaire. The child, a 9-month-old boy, had been admitted on 1 September to a hospital in Basankusu, a small town in the central part of Equateur Province. He had a rash with a distribution like that of smallpox but because the lesions were haemorrhagic, the physician was uncertain of the diagnosis and had taken a specimen. After admission the child developed enlarged cervical glands as well as otitis and mastoiditis. Subsequently, he contracted measles and died on 29 October. Ladnyi and Dr Ziegler searched for other cases with rash in Basankusu town and in the village in which the child had lived until 4 days before becoming ill. No cases could be found, although it was ascertained that the family of the patient occasionally ate monkeys, as did many other people in the area.

The nature of the area and the difficulties of travel and communication in this and many other parts of Zaire is conveyed in the report of Ladnyi and Dr Ziegler. Equateur Province was made up of 4 districts, each district consisting of a number of territories, of which Basankusu Territory was one. To travel from Kinshasa to Mbandaka, the provincial capital, and from there to Basankusu town was difficult. A weekly air flight, often cancelled, connected Kinshasa with the two towns. Travel by road meant crossing no fewer than 20 lakes and rivers, only some of which had a regular ferry service. Twice monthly, a river-boat made a 2-day trip to Mbandaka, where, after a wait of several days, one could transfer to another boat for a further 2-day trip to Basankusu. A cable to Kinshasa often took a month or longer to deliver. Basankusu Territory covered an area of 20 000 square kilometres and had a population of 62 000, mainly primitive farmers living in small villages scattered along paths and tracks in dense tropical rain forest. The distance from the capital of the territory to the most remote villages was 150 kilometres. Only one all-weather road crossed the territory, intersected by several impassable rivers with neither bridges nor regular ferry services. Travel along the tracks and paths was difficult, the so-called rainy season being 10 months long; even in the drier months, rain fell 2 or 3 days a week.

Basankusu Territory was served by a government hospital and 18 dispensaries scattered throughout the area, some operated by government health staff and some by missionaries. Smallpox had been present in the district in 1968 but no cases were known to have occurred in 1969. Two cases had been reported in 1970, one of which was discovered to have been chickenpox; the other was the case of monkeypox.

Vaccination had been performed by the teams in 1969, but no special containment vaccination programme had been conducted after discovery of the monkeypox case. Ladnyi and Dr Ziegler carried out a vaccination scar survey in 6 villages near where the patient lived, 115 kilometres from Basankusu town. The results are indicative of the thoroughness of the vaccination campaign (Table 18.7).

Twenty-one persons had characteristic residual pockmarks of smallpox but their illnesses had all occurred before or during 1968,

Table 18.7. Basankusu Territory: results of vaccination scar survey, by age group, 1970

Age group (years)	Number assessed	Subjects with vaccination scars	
		Number	%
0–4	186	159	85.5

≥ 16	588	567	96.4
Total	1 132	1 065	94.1

when smallpox had been widely prevalent. In this instance, at least, monkeypox appeared not to have spread to other human beings. The results of this and subsequent investigations of cases of monkeypox are described in Chapter 29. Eventually the studies confirmed that cases of monkeypox in humans were rare and that the disease spread only with difficulty from human to human.

The Creation of a Surveillance Programme, 1971

In January 1971, 5 provincial surveillance teams were established with the eventual arrival of 2 additional WHO operations officers and 3 United States Peace Corps volunteers. One of the 2 operations officers, Mr Mark Szczeniowski, was to remain with the programme in Zaire over the following 15 years, continuing the programme of surveillance and supervising special investigations of monkeypox. Each of the teams had a vehicle, a driver, a Zairian counterpart and a vaccinator. Each was equipped with a 100-watt transceiver in order to communicate rapidly with Kinshasa, with their provincial base of operations, and with each other. In their respective areas, they began to visit in a systematic fashion all hospitals, dispensaries and health centres to inquire about possible cases, to request immediate notification of any suspected case, to distribute vaccine and needles and to encourage each establishment to vaccinate everyone who attended it. Each health facility was visited once or twice every 6 months. The teams investigated all suspected cases and obtained specimens. In addition, in different villages they undertook a random scar survey assessment of about 2000 persons each month to assess the status of vaccinial immunity. Each team spent 21 days in constant travel, followed by a week's holiday.

By July 1971, 11 surveillance teams were in operation; 2 were assigned to each of the 3 largest provinces, and 1 each to the smaller ones. With the termination of the vaccination campaign at the end of July, the numbers of national staff were reduced and the medical officers who had served as group leaders each assumed supervisory responsibility for several provinces.

During the vaccination campaign, more than 24.3 million persons were vaccinated against smallpox and 11.4 million received

Plate 18.4. The surveillance programme in Zaire began in January 1971 and continued into the 1980s as teams sought human cases of monkeypox, a disease clinically almost identical to smallpox. Schoolchildren were shown pictures of smallpox in the WHO pictorial guides and asked if they had seen any cases.

Table 18.8. Zaire: population and number of reported smallpox and BCG vaccinations, by province, March 1968–July 1971

Upper Zaire	3 446	3 524 230	1 405 349	Feb. 1970–May 1971
West Kasai	2 499	1 836 095	827 673	July 1969–May 1970
Total	22 219	24 346 418	11 356 928	

[a] Derived from United Nations (1985).

BCG vaccine (Table 18.8). All parts of the country had been reached except for a small area in Kivu Province with a population of 115 000 persons. Even there, where security remained a problem, the staff were able to vaccinate some 50 000 people, although not in the systematic manner in which the rest of the campaign had been conducted.

The number of cases diminished rapidly during 1971. No cases were discovered in July and only 2 in August—the last reported cases in Zaire. The occurrence of these 2 cases, in West Kasai Province, long after any previous notifications there, was most puzzling. Extensive investigation, however, revealed that they were cases of chickenpox. Thus, a case in June in Upper Zaire appears to have been the last in the country, occurring just as the vaccination campaign concluded.

By the time this last case had occurred, Zaire's only infected neighbour was the Sudan, in which cases continued to occur in border areas until December 1972. No importations were detected in Zaire, despite continuing, intensive search by a specially assigned surveillance team headed by one of the WHO medical officers.

Data regarding the age and vaccination status are available for 2124 cases that occurred between 1969 and 1971 (Table 18.9).

The surveillance teams, with a staff of 95, continued to function until eradication was certified in Zaire in 1977, although international staff were gradually replaced by experienced Zairian counterparts. A special programme for the surveillance and investigation of monkeypox continued through 1986 (see Chapter 29).

Between 1971 and July 1976, nearly 700 specimens were collected, of which 3 (in 1971) contained variola virus, 9 contained monkeypox virus, 88 contained viruses of the herpes–varicella group and 6 contained either vaccinia virus or tanapox virus (Table 18.10).

Table 18.9. Zaire: number of reported cases of smallpox, by age group and vaccination status, 1969–1971[a]

Age group (years)	Cases		With vaccination scar	
	Number	% of total	Number	% of cases
<1	360	16.9	—	—

5–14	548	25.8	84	15.3
⩾15	458	21.6	155	33.8
Total	2 124	100.0	317	14.9

[a] Details are not available for 725 other cases of smallpox reported during this period; in addition, 2 incorrectly notified cases of chickenpox have been omitted from consideration.

Eventually, the teams were successful in obtaining the cooperation of all but a few of the 3289 health establishments in performing vaccinations. A surprisingly large number of vaccinations were given (Table 18.11), especially after the surveillance teams began their regular schedule of visits in 1971.

As Dr Ziegler was to observe, many staff working in rural dispensaries had not been

Plate 18.5. A: The roads in Zaire varied widely in character, some consisting only of logs laid along forest paths. **B:** Communication between smallpox eradication headquarters in Kinshasa and the surveillance teams relied on 100-watt transceivers built into trailers. visited by a physician or nurse for 10 years or more. They responded enthusiastically to the visits of the surveillance teams and many conscientiously undertook to sustain high levels of vaccinial immunity, not only among the people coming to their dispensaries but among the inhabitants of nearby villages as well. The results as measured by scar surveys in 1972 and again in 1974 confirm the success of this effort (Table 18.12).

Eventually 238 reporting sites were identified and charged with the responsibility of reporting weekly any suspected cases of smallpox and chickenpox. This network, which included 92 hospitals, 39 health centres, 54 dispensaries and 48 district or provincial health and medical units, ultimately served as a national morbidity reporting system. The response was remarkably good considering the difficulties of communication (Table 18.13).

During the surveillance period, the mobile teams with their transceivers provided a mechanism for the emergency reporting of outbreaks of other diseases, such as plague, yellow fever and cerebrospinal meningitis. Often the teams themselves participated in special programmes to control these outbreaks.

SUDAN

Background

The Sudan, even larger in area than Zaire, was no less important geographically to the strategy of the eradication programme—but for different reasons. Following a mass vaccination campaign conducted during 1961–1963, the Sudan became free of smallpox and is believed to have remained non-endemic until 1968. However, the risk of the disease being imported into the country and becoming re-established was high. Traditional caravan routes between Mecca and the endemic countries of western Africa crossed the north-central area of the Sudan and, historically, many outbreaks had been traced to cases imported by such travellers. To the east lay heavily endemic Ethiopia, whence came some 200 000 seasonal labourers each year for the harvesting of *dura* (sorghum). In addition, because of civil war in northern Ethiopia, thousands of refugees from Eritrea had moved across the Sudan's north-eastern borders, many of them returning periodically to Ethiopia. In the southern part of the Sudan, a civil war had been in progress since 1956 and many refugees frequently travelled between the Sudan and camps in Uganda and Zaire.

In 1967, the Sudan expressed interest in participating in the smallpox eradication programme, the principal component of which would be a campaign during which, as in Zaire, BCG vaccine would be administered at the same time as smallpox vaccine. The programme, however, did not begin until 1969 and proceeded slowly thereafter, the logistics of administering the two vaccines at the same time never being satisfactorily worked out.

Meanwhile, 9 cases of smallpox thought to be importations occurred in 1967, and during the first few months of 1968, 104 cases were detected. Investigation suggested that they were attributable to an importation from Ethiopia. No cases were discovered after June and it was thought that the outbreak had been satisfactorily contained. However, cases were again detected in December 1968 and in the early months of 1969 in many of the same areas. Once more, special investigations were undertaken. In all, 119 cases were documented but it was believed that there were many others which had not been detected. Although the initial outbreaks had occurred near the Ethiopian border, it was clear that many had originated in rural areas of the southern Sudan, unreachable because of civil war. It was suspected that endemic smallpox had become re-established and, in 1970, this became a certainty as the disease spread widely across the country.

Repeated attempts had been made to persuade WHO advisers and senior Sudanese staff that a continuing programme of surveillance and containment was vitally important in a country which was thought to be smallpox-free, but little was done until 1972. A seminar held in December 1971 marked a turning-point. A Sudanese medical officer, Dr Omer Sulieman, rapidly organized a surveillance–containment programme in the north, beginning in January 1972. In April, he moved to the south on conclusion of the civil war. Working with extraordinary energy and skill, he and Sudanese programme staff stopped transmission in December 1972. Subsequently, programme staff conducted a thorough search and vaccination campaign over extensive areas along the Ethiopian border in collaboration with Ethiopian staff, and at times assisted the programme in Ethiopia through search and case investigation far inside the frontiers of that country.

There was some speculation that the Sudan had never been smallpox-free, that transmission had always continued in inaccessible areas of the war-torn southern provinces. In retrospect, however, the epidemiological data strongly support the belief that transmission in the Sudan was interrupted in 1962 and endemic smallpox did not recur until after the importations of 1967–1968.

Population Movements

The Sudan is diverse in character, with extensive desert throughout the north giving way to steppe and grassland in the central part of the country and to large marshes and tropical forest areas in the south-eastern and southern parts of the country. The White Nile extends the length of the country, some 2000 kilometres, providing river transport and irrigation in the east central region. It is joined at Khartoum, the capital, by the Blue Nile, which flows from Ethiopia. Nearly half of the Sudan's 12.9 million population (in 1967) live in the fertile, extensively irrigated areas of Khartoum, Kordofan and Blue Nile Provinces near the confluence of the two rivers (Fig. 18.6).

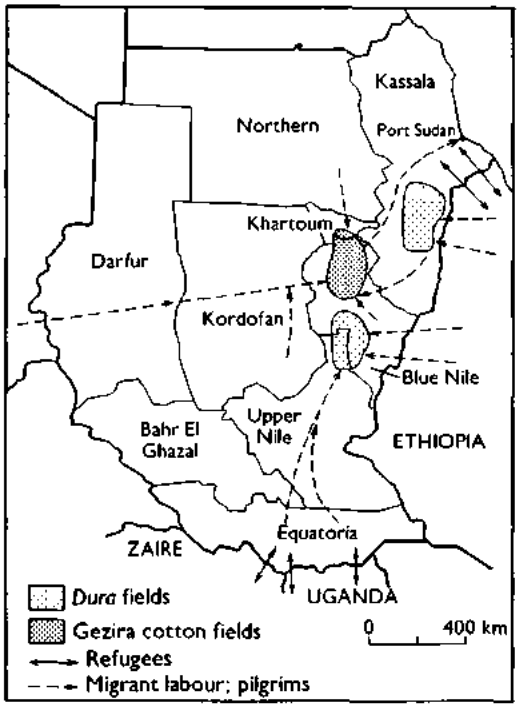

Fig. 18.6 Sudan: movement of refugees and seasonal populations.

The seasonal migration of agricultural workers was a significant factor in the spread of smallpox within the country and in the importation of the disease from Ethiopia. South of Khartoum were the great cotton fields of the Gezira Irrigation Scheme, which employed some 350 000 workers between mid-December and May. The labour force consisted largely of Sudanese workers recruited in various provinces and transported in large groups to and from the area by truck and boat. As important were the *dura* fields in Kassala, Blue Nile and Upper Nile Provinces, which attracted some 400 000 seasonal labourers, most of whom were employed for the harvest during December–February. Half of the workers came from Ethiopia, many of them travelling on foot for as long as 2–3 weeks to reach the area.

Other factors contributed to the movement of population and the spread of smallpox. Some 1.5 million pastoral nomads roamed the central and northern regions of the Sudan. In the north-east, upwards of 100 000 Ethiopian refugees from Eritrea camped near border areas but moved in and out of the country. Additionally, each year 30 000–40 000 pilgrims to Mecca from western Africa travelled across the country, through Khartoum. Population movements, overall, were far more extensive than in other Saharan and sub-Saharan African countries.

Civil war in the 3 southernmost provinces, which began at the time of independence in 1956, when tribal populations revolted against traditional leadership, was another serious problem. An estimated 50 000–100 000 Sudanese refugees from Equatoria Province lived in northern Uganda and Zaire but regularly moved in and out of the Sudan. Until March 1972, when a peace treaty was signed, much of the rural area in these southern provinces could be penetrated only by military convoy; health activities, including smallpox vaccination, were few; roads and bridges were destroyed or deteriorated.

Health facilities were reasonably numerous in the Sudan, although in a country so large they were widely dispersed. A tabulation drawn up in 1976 listed 127 hospitals, 159 health centres, 590 dispensaries and 1214 dressing stations.

Smallpox in the Sudan before 1968

Records of cases of and deaths from smallpox have been available since 1925. Up to the end of 1958, these show case-fatality rates in most years of 10–20%, with between 12 and almost 6500 cases reported each year. Major outbreaks occurred sporadically, the last being recorded during the period 1952–1955 in Darfur Province and the 3 southern provinces. Mass vaccination campaigns were conducted whenever outbreaks developed. Each year, 500 000–2 000 000 persons were vaccinated with liquid vaccine produced at a laboratory in Khartoum. Routine vaccination was rarely performed by the health units but enough persons were being vaccinated in mass campaigns to discourage the practice of variolation, which had once been widely prevalent.

In 1959 case-fatality rates abruptly declined (Table 18.14), falling to levels typical of those of variola minor. Since most of the cases during that year and the 3 subsequent years were recorded in Blue Nile Province, adjacent to Ethiopia, it is probable that the virus strain originated in that country.

Following the decision of the Twelfth World Health Assembly, in May 1959, to carry out global smallpox eradication, the Sudanese government requested assistance

from WHO to undertake a national vaccination campaign. WHO provided US$12 000 for vehicles and refrigerators and the USSR contributed freeze-dried vaccine. Except for this support, the programme was entirely a national effort, utilizing temporary staff who vaccinated by house-to-house visits and, in some areas, at collecting points. The transport provided by WHO was supplemented by rented vehicles and some provided by the military. During a 3-year period (1962–1964) 8 840 152 vaccinations were performed, a number equivalent to about 75% of the total population. The central and northern provinces were much better vaccinated than the 3 war-ridden southern provinces: in Upper Nile and Bar el Ghazal Provinces the coverage was very limited and in Equatoria Province it was nonexistent.

Although many persons remained unvaccinated, the campaign was successful in controlling smallpox. Except for an outbreak of 69 cases in Darfur Province in 1965 and 9 cases in 1967, no cases were reported in the Sudan during the years 1963–1967. Following the mass campaign, the numbers of vaccinations again fell off, averaging just 500 000 per year from 1964 to 1967, and because liquid vaccine was again employed, it is probable that only a small proportion were successful.

The Decision to Undertake an Eradication Programme, 1967

Because so few people were vaccinated after 1964, it was assumed in 1967 that few of those under the age of 5 years had ever been successfully vaccinated and that large numbers throughout rural areas of the southern provinces remained susceptible. No cases were being detected by staff of the comparatively extensive infrastructure of health services but concern was expressed that smallpox, if imported, might recur in epidemic form. Accordingly, it was decided in June 1967 to undertake another 3-year national vaccination campaign, and Dr Abdel Hamid El Sayed Osman was placed in charge. The inhabitants of provinces in the central region (Table 18.15) would be vaccinated first, followed in the second year by those of the

provinces in the northern region. By that time it was hoped that the civil war in the southern provinces would have ceased, permitting operations to be conducted there. This initial vaccination of the population of the central provinces could help to ensure high levels of immunity in the agricultural areas, which received large numbers of migrant labourers, and thus serve to prevent the possible spread of smallpox to the northern provinces. However, little attention was given to the development of a reporting system or of a mechanism for the investigation of suspected cases.

WHO support was greater than during the earlier campaigns (Table 18.16) and this time included the services of a WHO adviser. Commitments of the Sudanese government were substantial and included a staff of 539 persons.

It was expected that transport and supplies would arrive in the autumn of 1967, thus permitting the programme to begin towards the end of the year. In 1967, however, war between Egypt and Israel closed the Suez Canal, and supplies and equipment had to be rerouted around the Cape of Good Hope. What with the longer journey and the chaos in shipping, the supplies did not arrive until early 1969. Meanwhile, freeze-dried vaccine was supplied by WHO for use by health service units. However, as in other countries, very few vaccinations were performed.

Smallpox is Reintroduced into the Sudan

The first of what were thought to be imported outbreaks occurred in Khartoum in July 1967, when 4 cases of smallpox were discovered whose source of infection was not identified. Because of the outbreak, a mass vaccination campaign was conducted in and near the city over a 3-week period, during which 717 904 persons were vaccinated. As expected, it was found that few children under 5 years (17%) had been vaccinated previously. In December, another outbreak of 5 cases occurred in Khartoum among Ethiopians from Eritrea, but smallpox did not spread among the now well-vaccinated population.

Beginning in February 1968, more outbreaks began to occur but little is known about their source or true magnitude. The importance of surveillance and containment measures was not then appreciated in the Sudan. In February, a patient from Kordofan Province developed smallpox in Khartoum, the probable source being vaguely identified as a market in Darfur Province. Smallpox was not known to be present in Darfur but no investigation was conducted. However, a mass vaccination campaign was organized in Kordofan during which 801 778 persons were vaccinated. In March, another case was recorded in Khartoum but its origins were not investigated.

WHO staff both in Geneva and in the Regional Office for the Eastern Mediterranean were alarmed by the occurrence of smallpox in a country which was thought to be free of the disease and anxiously sought additional information from the government and from the WHO smallpox adviser assigned to the Sudanese programme, but to no avail. In April 1968, cases began to be reported in Upper Nile Province as well. Dr Ehsan Shafa, the WHO Regional Adviser on Smallpox Eradication, was concerned about the situation and spent 2 months investigating outbreaks in this area and organizing mass vaccination campaigns. The first case was thought to have developed in December 1967, shortly after the infected person had arrived from Ethiopia. From there smallpox appeared to have spread to 10 other localities in Upper Nile Province. Subsequently, cases occurred in 3 areas which were 600 kilometres to the north, 1 area in Kassala Province and 2 in Blue Nile Province (Fig. 18.7), but their sources of infection were not identified. In all, 76 cases were detected in Upper Nile Province, the last on 16 May 1968. The discovery that the first known outbreak originated in Ethiopia, and that other outbreaks followed

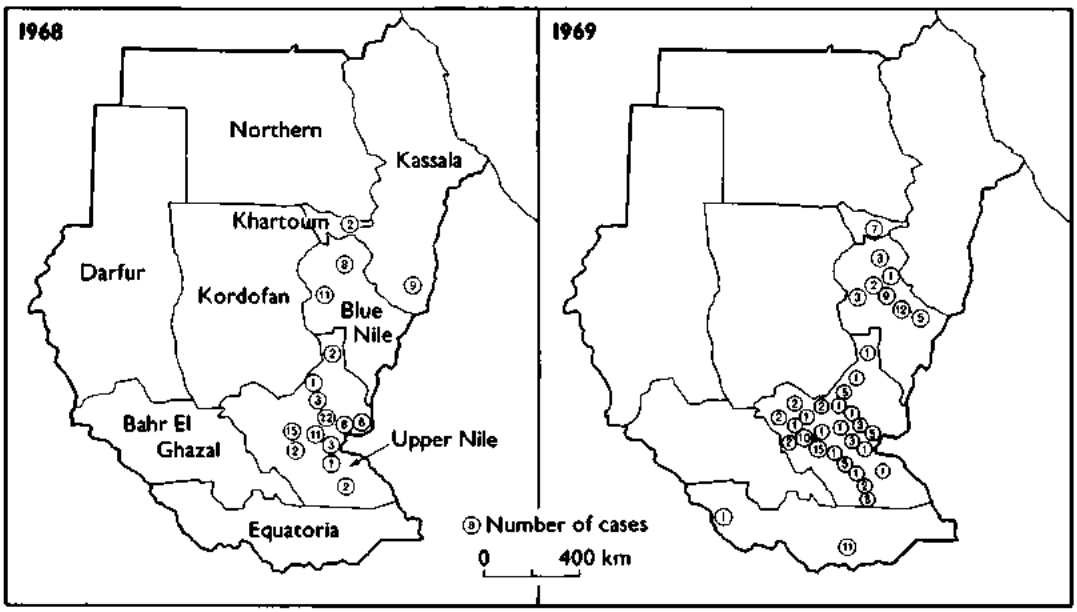

Fig. 18.7. Sudan: geographical distribution of reported cases of smallpox, 1968–1969.

in a temporal sequence moving from south to north, suggested that the series of outbreaks had originated from an importation with subsequent spread in a country otherwise free of smallpox.

To control the early 1968 outbreaks, mass vaccination campaigns were conducted in April and May: 452 256 persons were vaccinated in a single month in Upper Nile Province, 23 005 in Kassala Province, and 638 015 in Blue Nile Province—in all, more than a million people. Few vaccinations had been performed in Upper Nile Province during the 1961–1963 campaign, and the 1968 campaign reflected this. Of those aged 1–4 years, 72% received primary vaccination, as did 61% of the whole population. Primary vaccinees accounted for only 24% of the total in Kassala Province and for only 18% in Blue Nile Province. The last cases in these outbreaks were detected in June. Over the next 5 months, no further cases were reported (see Fig. 18.8).

The National Mass Vaccination Campaign is Launched, 1969

Considering the size of the country and the extensive movement of population in the Sudan, it was recognized that an effective mass vaccination campaign would be a challenge. Favouring its success, however, was the fact that the country's infrastructure of health services was among the best developed in Africa; maps and demographic data were available for most districts and council areas; and health units were widely dispersed. Moreover, a national vaccination campaign had been completed less than 5 years earlier. However, from its inception, the campaign experienced an array of problems. In mid-1968, 190 vaccinators were appointed, trained and posted to the central provinces. Within a short period, most resigned and returned to Khartoum, having found it difficult to cope with field conditions and having encountered resentment by the villagers, who were accustomed to locally recruited vaccinators. New staff were recruited and trained, of whom a greater proportion were from the provinces to be vaccinated, and in January 1969 field operations began.

The staff of 539 was substantially greater, in proportion to population, than in other African countries, in part because of the government's decision to provide BCG vaccine at the same time as the smallpox vaccine. Superficially, this appeared logical, but in practice it presented special problems. Smallpox vaccination in the Sudan was customarily performed by vaccinators proceeding from

house to house, the assembly of large numbers of people at collecting points not being well accepted in most areas. Because of this, jet injectors were not useful. Although smallpox vaccination, administered with the bifurcated needle, was well suited to house-to-house vaccination, BCG vaccination, which required the use of a needle and syringe, was not. Among the problems was that the needles had to be flamed after each inoculation and the syringes repeatedly refilled from the vaccine vial. Accordingly, BCG vaccine was customarily administered at assembly points. To the smallpox staff, it appeared impracticable to try to combine a house-to-house vaccination campaign with one which called for the gathering of children at a collecting point, but the government, supported by the WHO Regional Adviser for Tuberculosis, decided on the combined programme. Unfortunately, the operational problems were never resolved.

For the campaign, 30 vaccination units were constituted, approximately 10 for each of 3 provinces (Blue Nile, Darfur and Kordofan), each unit comprising 6 smallpox and 3 BCG vaccinators plus supervisors. The units moved systematically through the province. The smallpox vaccinators went from house to house; the BCG vaccinators worked at a collecting point, vaccinating those up to 20 years of age. Each group prepared a separate set of records listing the name of the head of each household, the number of residents by age group and the number of vaccinations performed. Thus, two sets of forms were prepared in each village; no effort was made to reconcile them and, in fact, the records were not subsequently used either in assessment or in follow-up vaccination.

The plan for assessment of vaccination coverage and take rates was likewise inefficient. It called for a separate assessment team to examine one-quarter of those residing in 50% of the villages after 1 week. This involved much more travel and manpower than the standard plan proposed in the 1967 WHO *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1), which suggested that 5–10% of the villages should be assessed.

Progress was slow. Smallpox vaccinators averaged only 25–35 vaccinations a day in 1969 and 40 a day in 1970. Those performing BCG vaccinations averaged somewhat less than half this number. Overall, productivity was one-tenth to one-third that of other programmes in Africa.

Recurrent Epidemic Smallpox, December 1968

While national and WHO staff struggled with the logistics of initiating the vaccination campaign, cases of smallpox once again began to be reported in late December 1968 in Upper Nile Province. A surveillance team had not yet been constituted and so 2 WHO staff members were again sent temporarily to the Sudan to investigate. From their observations, it was apparent that smallpox had reestablished itself in the country. The initially reported cases had occurred in villages near the Ethiopian border. The outbreak had spread westwards and northwards just as had happened earlier in 1968. However, careful epidemiological investigations suggested that this was not an importation from Ethiopia followed by localized spread, but rather the spread of smallpox from a number of endemic areas within the Sudan itself (*Wkly epidem. rec.*, 1969b). By the end of April 1969, the team had documented 119 cases in 4 provinces—Upper Nile, Blue Nile, Equatoria, and Khartoum. The beginning of the outbreak coincided with the beginning of the harvest season, when large numbers of seasonal workers began to travel from Upper Nile and Equatoria by boat, truck, train and on foot. Most of the cases were detected in special camps established for seasonal workers and at check-points for those in transit. It was clear that there were many more cases in villages, some in the southern areas afflicted by civil war, but in the absence of an organized reporting system, they were not being notified. The cases were of the mild variola minor type, only 3 deaths occurring among 119 patients. (These deaths are not recorded in the official figures given in Table 18.14.) Many patients were able to travel even when ill and thus readily disseminated the disease. The fact that half of all the cases were in persons over 15 years of age and that more men than women were affected (Table 18.17) reflected the spread of smallpox primarily among migrant labourers.

The investigators recommended that a surveillance programme should be established and a special campaign mounted to vaccinate seasonal workers in and *en route* to their camps. They believed that little could be done to vaccinate those in the southern provinces, but they reasoned that if the seasonal workers were well immunized, vaccinial immunity in sparsely settled rural areas of the south would

Table 18.17. Sudan: number of reported cases of smallpox, by age group and sex, January–April 1969

Total	66	49	115	100

be increased and, conceivably, the disease might die out.

The recommendations were not implemented but, as during the preceding year, the number of reported cases diminished; between the beginning of June and the end of November 1969, only 2 cases were notified (see Fig. 18.8).

Major Epidemics Begin, 1970

In Upper Nile Province 2 cases were reported in December 1969, 3 cases in January 1970, and 124 in February. Smallpox was also introduced into the northern Sudan from Ethiopia. Steadily the disease spread across the country to infect all but Darfur Province. In June 1970, a central surveillance team was appointed under the direction of Dr Sulieman, and by the end of the year, 1051 cases had been documented; most were detected by the surveillance team. Interestingly, adult cases continued to predominate, 55% being in persons over 15 years of age.

The vaccination campaign continued to progress slowly, its pattern of operation unchanged, as neither Sudanese nor WHO staff seemed able to devise an alternative operational approach. Continuing assessment showed that when vaccination had been completed in an area, consistently more than 85% and usually more than 95% of those under 5 years of age had a smallpox vaccination scar. Among older children and adults, the proportions were even higher, reflecting past vaccination efforts. BCG vaccination coverage, however, was usually in the range of 60–75% and sometimes lower. WHO regional smallpox eradication staff urged that BCG vaccination should be suspended until smallpox transmission had been interrupted, but, to the government, the policy of providing two vaccines simultaneously remained an attractive one. The smallpox eradication staff turned for advice to the WHO Regional Adviser for Tuberculosis, who had originally advocated the plan. Unhelpfully, he concluded in his report: "Certainly, the least attractive approach would be to continue the *status quo*, that is smallpox vaccination from house to house and BCG vaccination at collecting points." He offered no alternative plan, concluding only with the advice: "Whatever the final solution, one should test-run the various approaches as envisaged ... and select the most promising one."

By June 1970, 18 months after the programme had begun, only 5.3 million persons had been vaccinated, an estimated 68% of the population in the 3 provinces in which operations had been expected to be completed during the first year of the programme. Outside of these 3 provinces, the number of vaccinations recorded was equivalent to 5% or less of the population.

At the end of August, the programme stopped altogether when cholera cases were detected in the Sudan and the Ministry of Health decided to assign the teams to conduct a mass cholera vaccination campaign. Cholera vaccine offered little protection but was widely used nevertheless in many countries at that time. During November, no smallpox or BCG vaccinations were performed and, for many months thereafter a considerable number of teams and vehicles continued to be used for the administration of cholera vaccine. During December 1970, the smallpox–BCG vaccination campaign was gradually resumed but, as was noted in the populous Blue Nile Province, many villagers had left by that time to pick cotton. Entire villages were found empty or with very few residents. Vehicles were in critically short supply, some having been irreparably damaged by the bad roads, some remaining with cholera vaccination teams and some having been diverted to other uses by the Ministry of Health. In March 1971, the mass campaign finally concluded in the central provinces, more than 2 years after it had begun. The number of vaccinations reported to have been performed during 1969–1970 was greater than in 1968 (Table 18.18), but not commensurate with that expected of a staff of more than 500.

The vaccination campaign shifted to the northern provinces in 1971 and coincidentally the surveillance programme—such as it

Table 18.18. Sudan: number of reported vaccinations, 1968–1975

Year	Number of vaccinations
1968	1 967 450
1969	3 404 587
1970	4 871 573
1971	2 376 038
1972	2 268 142
1973	1 944 700
1974	1 121 693
1975	942 068

was—ceased when Dr Sulieman was reassigned to organize the vaccination campaign in Kassala Province. The WHO regional office replaced the WHO smallpox adviser by another adviser who, like his predecessor, was an ardent proponent of mass vaccination, with no understanding of the importance of the surveillance–containment strategy despite intense efforts at persuasion by the WHO regional office and Headquarters staff. The contributions of these advisers to the field programme were further compromised by the fact that neither travelled frequently out of Khartoum.

By the autumn of 1971, smallpox transmission in Africa had been interrupted in all but 3 countries: Ethiopia, in which the programme had only just begun; Botswana, which had become reinfected that summer following an importation from South Africa; and the Sudan, whose programme was then in its fifth year. Cases in the Sudan were being reported from all provinces, although of greatest concern were the 3 in the south, in which no formal smallpox programme activities were being conducted and from which 55% of all cases were then being reported. Some cases in Uganda were also traced to this area.

To assess what, if anything, could be done, Dr Shafa, then assigned to the WHO Smallpox Eradication unit in Geneva, visited the southern provinces in late October. He determined that movement out of the main towns was restricted but convoys regularly travelled to various areas, including the health establishments, which, for a population of 2.5 million, were quite numerous (Table 18.19). None held stocks of smallpox vaccine. None reported smallpox cases regularly, but all stated they could readily do so by utilizing police and army radio. It was apparent that vaccination and the investigation of outbreaks were impossible in rural areas, but

much could be done in the main towns and in districts adjacent to health units. Learning that a year earlier cholera vaccine had been successfully administered throughout the area with the help of police and army personnel, Dr Shafa proposed that vehicles, vaccine and other necessary supplies should be sent to the south, and that personnel from the southern provinces, then working in the mass vaccination campaign in the north, should be transferred to staff surveillance teams. Vaccine was sent to the south but the smallpox eradication programme leadership remained preoccupied with the mass vaccination campaign in the north and little else was done.

D. P. FRANCIS

Plate 18.8. Omer Sulieman (b. 1940) organized a central surveillance team in the Sudan in June 1970 which was disbanded in March 1971, when mass vaccination began in the northern provinces. He re-established a surveillance programme in January 1972 and transmission ceased by the end of the year. Subsequently, he was recruited by WHO and served as smallpox eradication adviser in Pakistan.

The Initiation of an Effective Surveillance–Containment Programme, 1971

As viewed by WHO Headquarters staff, the critical problem for the Sudan lay in establishing an effective surveillance and containment programme. For this to be done without the support of senior programme staff or the WHO adviser seemed unlikely. Nevertheless, more in despair than in hope, it was agreed that a special seminar on surveillance would be conducted in December 1971 for physicians and senior sanitary inspectors in each province. Hope was expressed that some way might be found for Dr Sulieman again to be given responsibility for supervising surveillance activities. Replacement of the WHO adviser was proposed but the WHO regional office disagreed. However, the addition of a

Vaccination Conducted by the Anyanya Resistance Movement

In 1970, WHO staff in Geneva were asked for vaccine by representatives of the Anyanya Resistance Movement, the rebel forces in the southern Sudan. They denied that smallpox was present in the area but were concerned that epidemics might occur. When asked how they could transport the vaccine, they indicated that they regularly took supplies north by road from Kampala, the capital of Uganda, and from there travelled on foot for 7–10 days into forest areas of the southern Sudan. Government staff could not reach these areas but, officially, WHO could provide vaccine only to Member governments. It was a quandary because, clearly, it was in everyone's best interest for this area to be better protected.

The dilemma was resolved by transferring vaccine to leaders of the resistance movement and recording the amount as "lost from inventory". Whether or not it was used properly was unknown until after March 1972, when the civil war ended. Sudanese staff found on investigation of outbreaks that the Anyanya had conducted quite extensive vaccination campaigns although, as they pointed out, many persons remained unvaccinated.

Plate 18.9. Migrants crossing the White Nile River at Juba in the southern Sudan. Civil war in the southern provinces resulted in a flow of refugees into Uganda and Zaire, who nevertheless frequently returned to trade or to visit relatives. They were the source of many importations of smallpox into Uganda between 1969 and 1972.

second WHO adviser was accepted provided that WHO Headquarters could find the necessary funds.

To the surprise of all concerned, the December seminar proved to be the turning-point. As Dr Sulieman later observed, he appreciated for the first time how important surveillance and containment really were. Following the seminar, and over the objections of the WHO adviser, he resumed responsibility for the surveillance programme. With a remarkably imaginative and energetic group of public health officers serving as directors of provincial surveillance teams, he began to strengthen reporting, to search for cases and to investigate outbreaks throughout the central and northern provinces. Many outbreaks were discovered and contained. Where resistance to vaccination was encountered, vigorous measures were taken. For example, cooperation was poor in one village in Kordofan; the police surrounded it before sunrise, and vaccinators moved from house to house and room to room, searching and vaccinating. By April, virtually all cases were occurring among travellers from the south, and in June the last cases were detected in the central and northern provinces.

At the end of March 1972, the government and the southern rebel forces—the Anyanya Resistance Movement—signed a treaty of reconciliation. In May, Dr Sulieman transferred his headquarters, including personnel and vehicles, to Bahr El Ghazal to begin work in the south. The rainy season was under way and travel in rural areas was difficult; in some it was impossible until October. In the latter areas, this period was used to construct detailed maps of the routes followed by migratory workers. An order was issued requiring all health units to report cases weekly; all chiefs, subchiefs, police stations, schools, forest and road workers were contacted and asked to report cases to these centres. Work was begun with 44 health staff who undertook a rapid house-to-house search throughout accessible areas.

Vaccination was performed only where outbreaks were encountered. By means of a scar survey, staff discovered that in most towns and villages along the way, 90% or

more of the population had been vaccinated. The cases found in these areas were generally on the periphery of towns and were quickly contained. However, many persons had moved deep into the jungle during the war. There, vaccinial immunity was far lower and rumours of outbreaks were difficult to trace. Accordingly, former Anyanya military personnel were recruited and given bicycles to search for cases in remote areas - -areas well known to them. Returning refugees were vaccinated at resettlement camps; health units throughout the 3 provinces were given supplies of vaccine and instructed to vaccinate both those attending centres and others living nearby. In June 1972, the programme was extended to Equatoria and Upper Nile Provinces. By the end of September 1972, 17 outbreaks had been discovered in Bahr El Ghazal, 10 in Equatoria and 1 in Upper Nile. Surprisingly, the largest of these consisted of only 25 cases. The cooperation of those living in the area was illustrated by the fact that in Equatoria, the last 2 outbreaks were reported by a villager and a chief who, respectively, walked 45 and 70 kilometres to report cases. In October, the rains stopped and the systematic search was extended throughout the rural areas. Teams travelled on northward-bound river steamers to search for cases and to vaccinate embarking passengers, and other check-points were established. Fifty medical students from the School of Medicine in Khartoum joined the programme, working in teams with vaccinators to search for outbreaks and to contain them. Only 5 additional outbreaks were discovered in Bahr El Ghazal Province and 1 in Upper Nile Province, although numerous patients were found who had experienced the onset of illness many weeks previously. Fig. 18.8 shows the number of cases of smallpox by week of report and by week of onset. Interestingly, the last case was discovered on 17 December 1972 in a village called "Malek", which is the local name for smallpox. One additional patient who had been infected in Ethiopia developed smallpox on 23 December in northern Kassala Province but he was the last.

On Dr Shafa's recommendation, a former operations officer from the Ethiopian programme, Mr James Lepkowski, and a former medical officer from the western Africa programme, Dr Donald Francis, were assigned by WHO to Juba in Equatoria Province in November 1972 and January 1973 respectively. A thorough systematic search for cases was organized throughout the southern provinces and subsequently in areas bordering on Ethiopia. It seemed inconceivable that transmission had been stopped throughout such a vast area, in which, less than a year before, smallpox had been reported from all provinces. However, no cases could be found (WHO/SE/73.60, Lepkowski et al.; WHO/SE/74.67, Bassett et al.). During the course of a single year, Dr Sulieman had brought order out of chaos and had succeeded in stopping transmission before additional manpower from WHO had had time to arrive on the scene. In September 1973, a village-by-village search was conducted throughout the country, but again no cases were found.

Smallpox remained widely prevalent in Ethiopia, however, and, as previously noted, many people travelled between the Sudan and Ethiopia. Special surveillance units were posted to migrant labour and refugee camps,

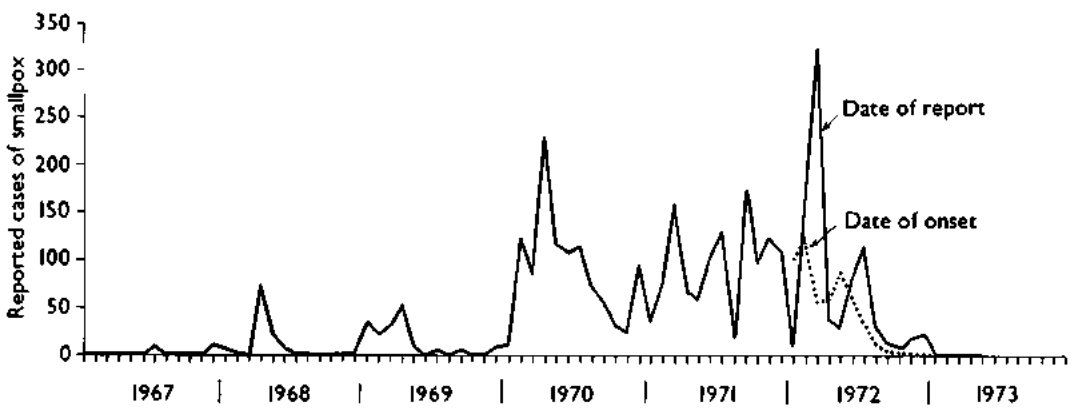

Fig. 18.8. Sudan: number of reported cases of smallpox, by month, 1967–1973, with cases plotted according to week of report and week of onset for 1972.

Plate 18.10. Donald P. Francis (b. 1942), an epidemiologist, was the WHO smallpox eradication adviser in the Sudan from January 1973, arriving just after the occurrence of the last known case in the country. With the Sudanese staff, he helped to organize a national surveillance system to protect against the effect of importations of smallpox from Ethiopia.

search workers were assigned to travel on the river steamers and special search teams covered the border areas. Many rumours of cases were received, but none proved to be smallpox. In September 1972, during a seminar in Addis Abeba, it was proposed that Sudanese and Ethiopian teams should be granted permission to cross the border without hindrance when undertaking search operations. Both governments agreed and, thereafter, Sudanese teams investigating rumours of cases, sometimes at the request of Ethiopian programme officers, travelled far into Ethiopia. In November 1973 and in March 1974, the teams undertook special search and vaccination programmes over extensive areas, difficult of access, in Ethiopia.

Table 18.20. Sudan: results of vaccination scar survey, by age group and province, 1975–1976

Region and province	Number examined	Percentage with vaccination scars			
		<1 year	1–4 years	5–14 years	⩾15 years

Equatoria	2 930	77	88	82	98
Bahr El Ghazal	6 438	15	25	75	71

The level of vaccinial immunity attained in the Sudan had been assessed in the central and northern provinces and found to be uniformly high, although doubt was expressed whether the surveys had been properly conducted. Not until 1975-1976 was a reliable cluster sample survey performed. It was found that coverage, in general, was high except in Bahr El Ghazal, in which systematic mass vaccination had not been conducted (Table 18.20).

The age and sex distribution of cases in the Sudan in 1970 was most unusual in that nearly half of all cases for which data are available were in adults, of whom 60% were male (Table 18.21). A large proportion of the recorded cases that year occurred among adult migrants coming from endemic areas in the south and in labour camps. As the disease continued to spread in the north, larger proportions of children were affected. Finally, in 1972, as cases in southern endemic areas were investigated, more cases were found in children, and the age distribution more nearly approximated to that found in other endemic areas: 15% of patients were under 5 years of age, and 48% were aged 5–14 years.

Table 18.21. Sudan: number of reported cases of smallpox, by age group and sex, 1970–1972[a]

Investigation of a Suspected Case

The problems of travel are well illustrated by extracts from a report of the investigation of a case by Dr Satnam Singh, a WHO epidemiologist in the Sudan. On 10 September 1975, the smallpox programme office was notified of a suspicious rash in a 40-year-old woman seen at a dispensary in the village of Geissan, on the border of the Ethiopian region of Gojam, where many cases of smallpox had been occurring. Because of drought in their own country, many Ethiopians had begun to visit Geissan to obtain sorghum. The report stated that the patient had been isolated and 12 family members vaccinated as well as 980 residents and visitors in the village. The report had been delivered to the nearest telegraph station, Damazien, 156 kilometres away, after a 5-day journey on foot. The telegraph line being out of order, it was not until 9 September that the provincial medical officer received the message. He then telephoned in the report.

A sanitarian, Mr Abdul Gadir El Sid, joined Dr Singh on the first available flight to Damazien on 13 September. There the Assistant Commissioner provided them with a 4-wheel-drive all-terrain vehicle (a UNIMOG) and a 4-wheel-drive army vehicle for a trip expected to take 10–15 hours. They were accompanied by smallpox eradication workers and a few army personnel. As Dr Singh wrote: "From the moment we left Damazien, we realized it would be difficult to traverse the water-logged muddy track overgrown with 12-foot-high grass. Regularly, the army vehicle, despite its more powerful engine, got stuck in the sticky mud and had to be pulled out manually, aided by cables attached to the UNIMOG. The multiple running streams (*khors*) that criss-crossed the track along the west bank of the Blue Nile caused additional delays. Some required reconnaissance on foot above and below the track to find a suitable crossing and the same was done when the regular track was waterlogged for long stretches. Detours were made through the tall grass fields and bushes. After one and one-half days' travel and a one-night halt, we had only covered a quarter of the distance and found ourselves with only the UNIMOG operational—the other vehicle having been irreparably damaged. It was decided that a few should return to Damazien to mount another expedition including a tractor.

"The return journey to Damazien was worse for it had rained in the meantime. After a one-night halt in a village, we reached Damazien at 9:00 p.m. on 16 September . . . and on the 18th we started for Geissan with one tractor, the same UNIMOG and a relatively new army vehicle with a mechanic and spare parts.

"To have a tractor was a boon. The vehicles when stuck were pulled out quickly. In the meantime, however, more rain fell and in consequence more swollen rivulets and *khors* had to be crossed. On the 19th, we had to abandon the army vehicle and pushed ahead with the UNIMOG and the tractor. In spite of the rainstorm, the river was only waist deep but with a fast current. Our vehicles forged through with manual help from the villagers. The rest of the journey was uneventful except that the terrain near Geissan is so hilly that in a few places there was a real danger of the vehicles turning over into the valley. We got a rousing welcome from the residents of Geissan, a community of 1500 persons, when we reached there at 8:30 p.m. on the 21st.

"The patient's rash had healed, but clinical and epidemiological examination clearly indicated that it was a case of chickenpox.

"We began our return journey on 24 September. The return trip was even slower as more rain had fallen. On 25 September, we reached a *khor* so heavily flooded that several days' wait would be required for the waters to recede. The writer and Abdul Gadir decided to complete the trip by boat. We obtained a small leaky fishing canoe and paddled down the flooded Blue Nile endeavoring to avoid the larger, frequent whirlpools. After 4 hours, we pulled ashore at a village to camp for the night and there were able to get a wooden boat with motor which took us to Damazien. On the following day, 27 September, 14 days after arrival, we took the once-weekly air flight back to Khartoum."

During most years and in most age groups cases were more frequent in males than in females. For adults, this was to be expected because the migrants were more often males. For younger age groups, there is no ready explanation for the sex differential. However, the data must be interpreted with caution because outbreaks were not thoroughly investigated until 1972 and, even then, investigation in the tropical forest areas was by no means complete and, in some areas, cases remained undetected because they were hidden from the investigators.

CONCLUSION

The smallpox eradication programmes in the Sudan and Zaire, two of Africa's largest countries, present a study in contrasts. When the programme began in Zaire, smallpox was highly endemic. The population was poorly vaccinated, and its professional staff and health infrastructure were at an early phase of development. Conversely, the Sudan in 1967 was free of smallpox, vaccinial immunity in the central and northern provinces was high and the country's health structure was comparatively advanced.

Both countries endeavoured to execute nation-wide vaccination campaigns employing both BCG and smallpox vaccines, the first programmes to administer the two antigens simultaneously. It was expected that there might be operational difficulties in conducting a time-limited mass campaign which required field activities to accommodate the administration of smallpox vaccine to the entire population and the administration of BCG vaccine to children and adolescents. WHO smallpox staff argued that it would be preferable to begin field operations using only one antigen, and to add the second after the programme had become established. Those responsible for tuberculosis control were anxious that BCG vaccination should be incorporated in the programme from the outset, arguing that to administer two vaccines entailed little more in cost or effort than to administer one. This view prevailed.

As was foreseen, both programmes did experience substantial problems in administering the two antigens simultaneously. Zaire, however, was soon able to resolve the difficulties by using jet injectors for both vaccines and to administer them to groups assembled at collecting points. In little more than 3 years, a country-wide programme had been completed with a staff which, at its maximum, numbered 234 persons. In the Sudan, the assembling of the general population at collecting points was not well accepted, thus precluding the effective use of jet injectors. Smallpox vaccination was therefore conducted from house to house with the bifurcated needle, while BCG vaccine was administered by needle and syringe to children at collecting points—a system that never worked well. Despite a staff of more than 500 persons, the programme proceeded slowly and, in fact, was terminated before vaccination had been completed throughout the country.

Acceptance and understanding of the concept of a national programme for the surveillance and containment of outbreaks likewise differed in the two countries. In the Sudan, as was the practice in other countries with a comparatively well developed infrastructure of health services, provincial and district health officers had primary responsibility for disease control. These medical officers differed greatly in their abilities, their understanding of epidemiology and their perception of priorities and, with no national surveillance unit to provide support and guidance, most controlled such smallpox outbreaks as were discovered in the traditional manner—by mass vaccination. Efforts to improve reporting and to investigate outbreaks to ascertain the sources of infection were uncommon. The belief that no special national surveillance programme was required was reinforced by the fact that the Sudan had succeeded in interrupting smallpox transmission in 1963. In the absence of a national surveillance programme, the disease, following its reintroduction in 1970, spread to almost all parts of the country. When a surveillance programme commenced in 1972, transmission was stopped within 12 months.

By contrast, in Zaire, in which the health structure was less sophisticated and not so well established, the concept of a national surveillance programme was more readily accepted. This proved to be the experience in many of the less well developed countries. Although the establishment of an effective surveillance programme was greatly delayed, owing to the lack of experienced personnel, the programme in Zaire succeeded in interrupting transmission some 18 months before that in the Sudan.

The contributions of WHO and other international agencies were critical to the success of both programmes, but in neither country were they as effective as they might have been. In Zaire, transmission might have been interrupted far sooner had the promised WHO resources been provided in a timely manner; in the Sudan, the assignment of effective advisers might well have helped to prevent the re-establishment of smallpox.

Whatever the problems, the attainment of eradication was a notable achievement in both countries, given their size, the formidable difficulties of transport and communication and the persistence of civil disorder.

INTRODUCTION

This chapter describes the development of smallpox eradication programmes in 5 contiguous countries of eastern Africa—Burundi, Kenya, Rwanda, Uganda and the United Republic of Tanzania[1] (Fig. 19.1). In 1970 their combined population amounted to 42 million and their total land area to 1 818 000 square kilometres. In comparison, adjacent Zaire to the west had half as large a population in 1970 but an area 25% greater.

The infrastructure of transport and communication services was better developed than in the countries of western and central Africa; moreover, government and private health centres, clinics, dispensaries and hospitals were more numerous. Vaccination, with liquid vaccine, had been practised more or less extensively throughout most parts of these countries for more than 50 years, most vaccinations being given when outbreaks of smallpox occurred. Some health facilities offered vaccination to any patients attending them, but the vaccine was generally stored at room temperature and its potency was therefore presumably low or nil.

Among the many health problems in these countries, smallpox in the early 1960s had not been of high priority except in Tanzania. Epidemics of variola major had occurred in previous decades but, more recently, in all countries except Tanzania, variola minor with a low case-fatality rate prevailed. For example, during the period 1961–1965, 1182 cases with only 6 deaths were reported from Kenya, and between 1961 and 1964 Uganda recorded 1960 cases and 4 deaths. However, Uganda in 1965 and Kenya in 1966 began to

[1] The United Republic of Tanzania was formed in 1964 by the union of Tanganyika, Zanzibar and Pemba. Although its official name is used elsewhere in this book, it is, for brevity, referred to as "Tanzania" in the text and tables of this chapter. The islands of Zanzibar and Pemba experienced no smallpox and conducted no special eradication programme.

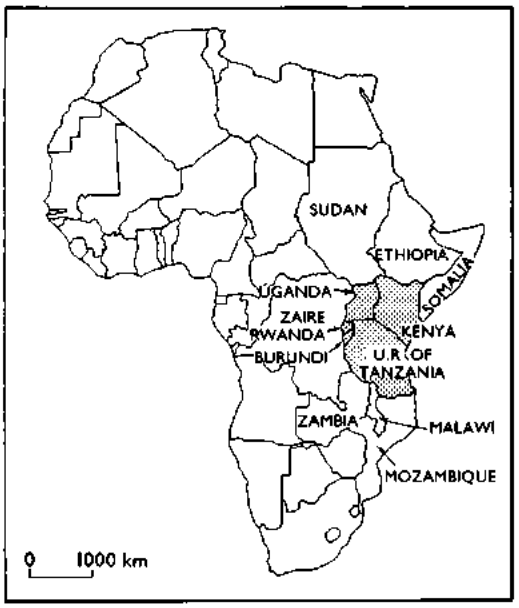

Fig. 19.1. Eastern Africa and adjacent countries.

experience an increasing number of deaths due to smallpox and consequently took a greater interest in controlling the disease. In Tanzania, a more severe form of smallpox had been prevalent, with recorded case-fatality rates of 5–7%. Even so, the problem was not large when viewed against the greater threats posed by malaria, tuberculosis and several other infectious diseases. Vaccination campaigns, however, were an integral part of public health activities because of the fear of recurrence of epidemics of the virulent variola major. With substantial commerce and travel between eastern Africa and Asia and the generally held belief that severe variola major prevailed elsewhere in Africa, there was reason to maintain adequate levels of vaccinial immunity.

After 1967, when the Intensified Programme began, all 5 countries agreed to undertake eradication programmes which would include systematic national vaccination campaigns employing, for the first time, freeze-dried vaccine of acceptable quality. WHO provided each country with advisers, all the requisite transport, equipment and supplies (including vaccine) and reimbursed the governments for the costs of petrol and vehicle maintenance. The countries made available a small cadre of national personnel, but little else. Each conducted effective national smallpox vaccination campaigns, which, in Kenya, Rwanda and Tanzania, were carried out in conjunction with the administration of BCG (antituberculosis) vaccine to children under 15 years of age.

Smallpox vanished quickly, transmission being interrupted by the end of 1970, well before the systematic vaccination campaigns reached most areas and, indeed, before effective programmes of surveillance and containment had been developed. After 1970, importations from the Sudan occurred along Uganda's northern border, and importations from Ethiopia and Somalia along Kenya's north-eastern borders. The outbreaks were all in sparsely populated areas; none resulted in large numbers of cases or persisted for long periods.

The mass vaccination campaigns differed somewhat in character from one country to the next, as each was adapted to the nature of the health services and the political structure of the country concerned. Information about the epidemiological characteristics of smallpox in eastern Africa is scarce, however, because little was done to improve the national reporting systems or systematically to investigate suspected cases until after 1970, when transmission had been interrupted.

The rapidity and ease with which smallpox transmission was interrupted in these countries, as well as many others in Africa, were surprising. At the time, the situation served to engender an unwarranted confidence that smallpox eradication could be readily achieved with only a modest incremental investment of resources, even in programmes in which performance was marginal. In Africa itself--notably in Ethiopia, Somalia and the Sudan—this belief later proved to be unfounded.

SMALLPOX CONTROL ACTIVITIES BEFORE 1969

In 1967, when the Intensified Smallpox Eradication Programme began, the countries of eastern Africa reported a total of only 2221 cases (Table 19.1). In a population which then numbered almost 38 million, this figure was not large. Moreover, the number of recorded cases was diminishing rapidly, from 5607 in 1965 to 4163 cases in 1966. Of the 5 countries, only Rwanda reported no cases whatsoever during the period 1966–1968 but it was provisionally categorized as an endemic country, since it was difficult to believe that a

[a] No cases officially recognized.
[b] Imported cases.
[c] Including 23 cases resulting from importations.

country completely surrounded by heavily infected areas could be free of smallpox. Not until 1969 was it learned that it was government policy to report only cases that were confirmed by laboratory examination. Because no specimens were examined, no cases were reported.

Vaccination was provided routinely in all countries, the number performed annually being equivalent to about 10–20% of the population (Table 19.2). Undoubtedly many of the vaccinations were unsuccessful because of the use of vaccine that was subpotent at the time of administration. Kenya, Tanzania and Uganda used liquid vaccine produced at the Medical Research Laboratory in Nairobi or at the Lister Institute, England. Although usually stored under refrigeration in the capital city, the vaccine was exposed to ambient temperatures during shipment and rarely refrigerated at any of the intermediate distribution points or in health centres. This was a problem, because liquid vaccine becomes inactive within 3 days or less at ambient temperatures when it is not refrigerated. No data are available regarding the proportion of successful vaccinations because vaccinees were not examined to determine whether their vaccinations had taken. Until 1965, Rwanda and Burundi also used liquid vaccine, produced at a laboratory in Rwanda or imported from Belgium. In 1965, the Rwanda laboratory began producing a reasonably satisfactory freeze-dried vaccine, but the vials in which it was distributed were so large that the amount of vaccine each contained was sufficient, after reconstitution, for 600 doses or more. This was not much of an improvement, because freeze-dried vaccine, after reconstitution, loses its potency within 24 hours unless it is refrigerated, and few health centres had refrigerators which functioned properly. Rarely did any health unit have cause to vaccinate more than a few persons a day but the staff continued to use the reconstituted vaccine until each vial was empty. In 1968, for example, a WHO smallpox eradication adviser observed at a hospital in Rwanda that a vial containing vaccine reconstituted 3 months earlier was still in use.

In each of the countries, mass campaigns were conducted from time to time in specific areas when epidemics occurred. For such campaigns, vaccine was shipped to the field direct from the laboratories and was more likely to have been of adequate potency at the time of administration than vaccine which had been kept for weeks or even months at health centres. Only one country-wide mass vaccination campaign—in Uganda—had been carried out since the 1950s. In 1965, the number of reported smallpox cases and deaths in Uganda increased. The Ministry of Health, fearing epidemic variola major, launched a national campaign. Between August 1965 and February 1966, 7.5 million persons were vaccinated, a total equivalent to more than 90% of the country's population at the time. The cost of vaccine alone, most of which was purchased from the United Kingdom, amounted to more than US$200 000. A survey conducted by Ladnyi in 1966 revealed vaccination scars in 88% of children in primary

schools, but in only 61% of people attending clinics at 6 hospitals. The examination of 33 patients with smallpox revealed that 8 had been unsuccessfully vaccinated 1–3 months before. It was apparent that the campaign had been far less successful than the coverage might suggest.

The impression that a more severe form of smallpox had appeared in Uganda is borne out by the available records. Up to 1965, deaths from smallpox had been infrequent in Uganda, but in 1965 the case-fatality rate increased to nearly 5% and remained high until transmission was interrupted (Table 19.3). During the following year, the case-fatality rate in Kenya also increased, with both cases and deaths occurring primarily in areas adjacent to Uganda. Kenya, too, undertook a mass campaign—in Nyanza Province, which borders on Uganda. Between March and April 1966, 670 000 persons were vaccinated. In the same year, 500 000 people in Burundi and 6 million in Tanzania were vaccinated during mass campaigns.

From 1966 onwards, the case-fatality rates in Uganda and Kenya were characteristic of those observed with the African strain of variola major. This strain had been prevalent in neighbouring Tanzania and Zaire, from which it had presumably been introduced. Nothing can be said of the status of Rwanda or Burundi at this time, because no cases were officially recognized by Rwanda and deaths were not registered in Burundi.

AGREEMENTS TO UNDERTAKE ERADICATION PROGRAMMES

In October 1965, Ladnyi was assigned by WHO to Nairobi as an intercountry smallpox adviser in the eastern portion of Africa. He was responsible for providing advice on the development of smallpox eradication programmes to the 19 countries of eastern, central and southern Africa in WHO's African Region that lay to the south of the Sudan, Ethiopia and Somalia (which at that time all formed part of the Organization's Eastern Mediterranean Region). An epidemiologist based in Liberia was assigned similar functions in the western portion of Africa. The initiative by the Regional Office for Africa to provide regional smallpox eradication programme advisers antedated the decision of the Nineteenth World Health Assembly in May 1966 to allocate special

WHO

Plate 19.1. In Rwanda and throughout eastern Africa, mass vaccination had traditionally been used to control the spread of smallpox. Villagers willingly assembled at collecting points to be vaccinated.

funds for eradication; they were, in fact, the first WHO regional smallpox eradication staff to be appointed. Ladnyi immediately embarked on a series of visits to each of the countries, beginning in 1966, with Burundi, Kenya, Malawi, Tanzania, Uganda and Zambia.

At the start, he could do little except offer advice, since the resources allocated to the smallpox eradication programme by WHO were so limited. Moreover, because most countries did not consider smallpox an important problem, few were interested in developing programmes, or, indeed, were able to do so without special assistance.

The above-mentioned decision of the Nineteenth World Health Assembly to allocate funds for smallpox eradication from the Organization's 1967 regular budget made it possible to launch many national programmes. Surprisingly, however, except for those from Zaire and Zambia, no requests for assistance were received by WHO from any of the countries in central, eastern or southern Africa. Meanwhile, during 1966 and 1967, programmes throughout western

Africa began to develop with assistance provided by the USA (see Chapter 17). Smallpox eradication staff from WHO Headquarters asked the regional office to contact the eastern and southern African countries to ascertain their interest in developing eradication programmes. However, the regional office pointed out that, as a matter of policy, it responded only to requests for assistance initiated by the countries themselves. In part, this policy derived from the views of the Director-General of WHO. In meetings with his regional directors in 1966, he had urged extreme caution about imposing another mass programme on Member states, after the experience with malaria eradication. The regional directors, in turn, had conveyed this to the WHO representatives in the countries themselves. Because the Director-General regarded smallpox eradication as improbable, he believed that such a programme would only divert national resources from more important activities (see Chapter 10). The WHO smallpox eradication staff in Geneva, on the other hand, maintained that the decision to undertake global smallpox eradication had received the unanimous approval of the World Health Assembly; funds had been appropriated for this purpose and thus it seemed only reasonable to contact the endemic countries to assess their intentions and needs. To expect the African countries themselves to respond spontaneously to new programme directions seemed unrealistic. All were newly independent, beset with problems and struggling to bring order into chaotic bureaucracies. These arguments were, however, of no avail.

Ladnyi, as a member of the regional office staff, had his hands tied; there was little he could do to overcome the apparent impasse in the initiation of eradication programmes in central, eastern and southern Africa, without directly flouting the policy of the regional office. The problem of how to approach the countries was resolved when the regional office agreed that a medical officer from Headquarters, Dr Stephen Falkland, accompanied by Ladnyi, could visit a number of African countries early in 1967 so that the Director-General could report to the World Health Assembly in May of that year on each country's smallpox status and intended activities, if any, in accordance with the Assembly's request of 1966. Dr Falkland was specifically directed that under no circumstances should he propose to any country that it should undertake a programme. In the event of a display of interest, however, he carried with him a draft letter requesting assistance, prepared for the signature of the minister of health, as well as a draft plan of operations which could be readily adapted to the specific conditions of each country. He made brief visits to Burundi, Kenya, Rwanda, Tanzania and Uganda, all of which expressed interest in initiating smallpox eradication programmes and which forthwith sent formal requests to WHO for assistance.

Of the 5 countries dealt with in the present chapter, only Tanzania viewed smallpox as an important problem. However, to undertake eradication programmes, it was unnecessary for the governments concerned to commit substantial national resources. For each programme WHO agreed to provide an adviser, vehicles (including in some instances, motor cycles and bicycles), refrigerators, camping equipment, vaccine and bifurcated needles, as well as a sum of money to cover the costs of petrol and vehicle maintenance. The country's obligation was primarily to provide a small cadre of national staff. To offset the

additional expenditures necessary for salaries of these workers, WHO made available vaccine and transport, which hitherto had been at the charge of the government. In all, the Organization provided US$1 450 839 in support of programmes in eastern Africa, a sum equivalent to US$0.01–0.07 per head of population (Table 19.4). The individual governments disbursed no more—and in most cases less—to eradicate smallpox than they had spent on controlling the disease.

PROVISION OF FREEZE-DRIED VACCINE

The acquisition of adequate supplies of freeze-dried vaccine and their distribution presented a problem to WHO throughout most of the global eradication programme (see Chapter 11). In the countries of eastern Africa, as well as many of those in central and southern Africa, there were unique difficulties which required special solutions.

Attempts were made in all endemic areas to promote the local production of vaccine, but it was not practicable for every country to do so because of the considerable cost and effort needed to establish and maintain a laboratory. For some 50 years, the Kenyan Medical Research Laboratory had been producing liquid vaccine, which it sold to Tanzania and Uganda. Thus, it seemed logical to supply this laboratory with equipment and consultant assistance so that it might serve as a regional resource for the production of freeze-dried vaccine. UNICEF provided US$20 000 for the necessary equipment and in January 1967 WHO made available the services of a consultant. By April 1967, the laboratory, directed by Dr Geoffrey Timms, had succeeded in producing 4 experimental batches of freeze-dried vaccine and by October 1968 was producing sufficient vaccine of a consistently high quality to meet all Kenya's needs. As production increased, it became possible to supply neighbouring countries, but herein lay a quandary. Kenya needed to charge for the vaccine to recover production expenses. WHO's stock of vaccine, however, was being provided through voluntary contributions and then distributed free of charge to all endemic countries to encourage its use. Unless this had been done, many governments, lacking reserves of convertible currency, would have continued to use locally produced liquid vaccine. The purchase of vaccine from Kenya by WHO was not feasible, because several producers in Europe were anxious to sell vaccine and such a move might have endangered the donation programme (see Chapter 11); thus, WHO had adopted the policy of purchasing no vaccine whatsoever. The problem was ultimately solved by supplying Kenya with almost all the materials needed for vaccine production, thus enabling it to produce additional vaccine which could be donated to WHO for use in other African countries. In all, WHO provided some 31 million doses of vaccine for use in the countries of eastern Africa (Table 19.5), of which 15 million doses were produced in Kenya.

The distribution of vaccine in a timely manner to the numerous African countries was a factor that had to be taken into account. Vaccine was in short supply throughout most of the eradication programme, and it was therefore not possible to stockpile large reserves in the endemic countries. With the uncertain schedule of vaccination campaigns, the shipment of vaccine had to be planned in advance. Vaccine donated to WHO during the early years came primarily from Europe or North America and was maintained in a cold-storage warehouse in Geneva. With the extensive air transport network centred in Geneva, it was not difficult to deliver vaccine anywhere in the world at 48 hours' notice. Vaccine donated by Kenya, however, was shipped direct to neighbouring countries to minimize transport costs. Distribution systems were thus in place for national programmes to be sustained without large stockpiles.

A problem which had to be tackled was that of communication through the official channels of WHO. For an African country to obtain vaccine, the standard procedure called for a request to be directed to the WHO

Regional Office for Africa in Brazzaville, which would forward it to Geneva. Communication between African countries, however, was often much slower than communication between Africa and Europe, and inevitably there were delays in processing the request within the regional office. A telegraphic request through official channels sometimes took 4–8 weeks before being received in Geneva. Meanwhile, field programmes came to a halt. The difficulty was resolved simply by sending 2 telegraphic messages—an official one to the regional office in Brazzaville and an unofficial one to Geneva, on which action was promptly taken.

Freeze-dried vaccine which had been contributed to WHO was made available to several of the countries for use in their health services even before their formal mass vaccination campaigns began (Table 19.5). This vaccine was first used by Burundi and Tanzania at the end of 1967 and by Uganda early in 1968. Kenya began using locally produced freeze-dried vaccine in October 1968. Tanzania reverted briefly to the distribution of liquid vaccine during November 1968, when it received a bilateral donation of 300000 doses, but fortunately no further contributions of this type were received. Rwanda continued to use its own locally produced freeze-dried vaccine until early 1969, when the government was persuaded to stop production and to destroy all existing stocks.

THE VACCINATION CAMPAIGNS

Except for a pilot programme in Tanzania in 1968, during which 350 000 persons were vaccinated, none of the vaccination campaigns began until 1969. Meanwhile, the number of reported cases of smallpox in Kenya, Tanzania and Uganda fell sharply (see Table 19.1), from 3800 in 1966 to 2147 in 1967 and to only 597 in 1968. Rwanda, during this period, did not officially recognize cases of smallpox; and little can be said about trends in Burundi, whose reporting system was less adequate than the others. During these years, little had been done to change the reporting systems and there was no organized surveillance–containment activity. However, the trend in incidence was steadily downward and systems which had detected many cases in prior years were now reporting very few. The mass campaigns in Uganda, Burundi, parts of Tanzania, and in Nyanza Province, Kenya, in 1965–1966 were undoubtedly responsible in part for the decrease in the number of reported cases. Perhaps of greater importance was the provision of freeze-dried vaccine for use by the health services in the control of outbreaks and in the limited routine vaccination programmes in which some health centres were engaged.

However, as we shall see, the vaccination campaigns in Kenya and Uganda began *after* transmission had apparently been interrupted; in Tanzania, only 88 additional cases

occurred after the beginning of the campaign, of which 23 are known to have resulted from an importation from Zaire (Table 19.6). The endemic spread of smallpox stopped only 13 months after the programme had begun in Rwanda and after 17 months in the case of Burundi.

The most heavily infected regions in 1967–1968 lay on the shores and in the vicinity of Lake Victoria (Fig. 19.2) and in the south-eastern area of Tanzania near the border with Mozambique. The region around Lake Victoria was also one of the most densely populated. As programmes began in 1969, Kenya

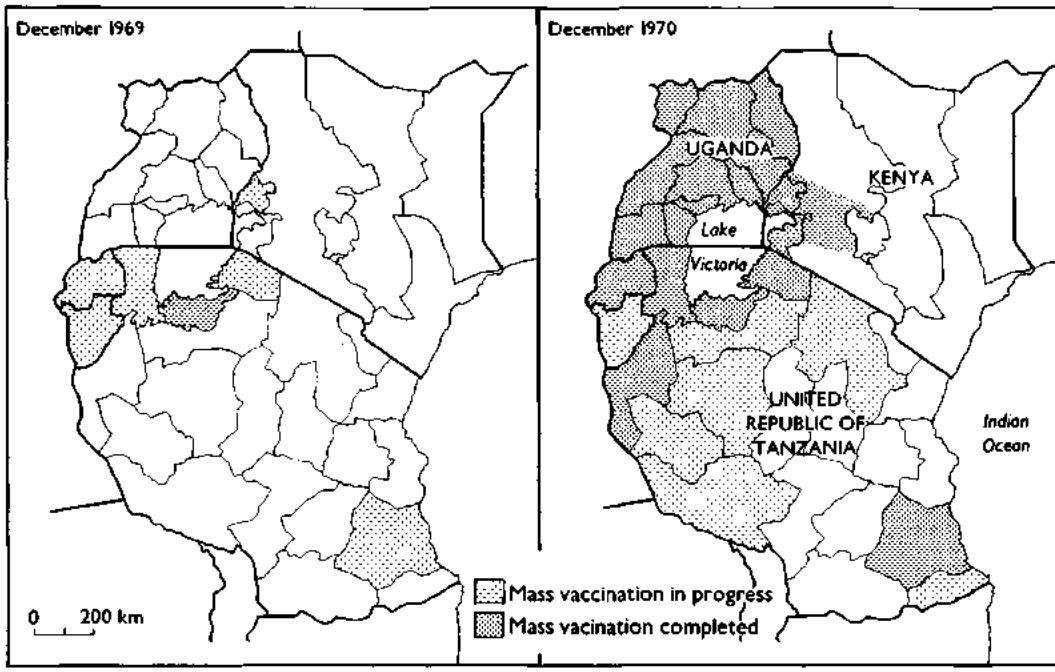

Fig. 19.3. Eastern Africa: status of vaccination campaigns, by administrative area, December 1969 and December 1970.

and Tanzania concentrated their efforts specifically in these areas (Fig. 19.3).

Kenya

A WHO technical officer from Belize, Mr Henry Smith, was recruited to assist in the development of the Kenya programme. He arrived in September 1968 and continued with the programme until February 1974. From October 1968 to the end of May 1969, Mr Smith visited all provincial and district headquarters, beginning with those in the west, whence cases were being reported, to demonstrate the use of the new bifurcated needle and the freeze-dried vaccine. At the time of his visit, stocks of liquid vaccine were replaced with freeze-dried vaccine. Staff in the districts were then given responsibility for training those in peripheral units. In Kenya at that time there were 163 health centres and 350 dispensary clinics; their staff reported having vaccinated 1.5 million persons in 1968 and 948 000 in 1969—about 25% of the population in all.

The beginning of the mass vaccination campaign had to await the delivery of vehicles, which usually arrived 12–18 months after they were ordered. The vehicles were delivered in the spring of 1969 and the programme began in October in Western Province, one of two small but densely populated south-western provinces inhabited by 40% (4.5 million) of Kenya's population. Kenya's last known case of endemic smallpox

Plate 19.2. Henry C. Smith (b. 1935) served as a WHO technical officer for smallpox eradication in Kenya, 1968–1974, before joining the programme in India.

occurred 4 months before the programme began.

Initially, the staff consisted of 2 supervisors assigned from the health services and 18 Kenyan National Youth Service Volunteers, who had completed elementary school and had undergone a 1-month training course. The team progressed from district to district. Three weeks before it was to begin work, Mr Smith, or sometimes the national programme director, met the district medical officer and health inspector to plan the campaign. Within the district, vaccinations were given to the inhabitants of one sublocation after another—a sublocation being a unit ranging in population size from a few hundred to 4000 and administered by a subchief. An assistant health inspector who worked in the area contacted each subchief to explain the purpose of the programme and to select a place of assembly for each sector at which approximately 300 persons would be expected to forgather. In the interests of economy of operation, the entire team worked in only one sublocation or a few adjacent sublocations each day. Assembly points included hospitals, health centres, dispensaries, schools, markets, chiefs' houses, shops, bus stops and wellheads. A few days before vaccinations were to be carried out, the subchief informed people of the schedule and the location of assembly points. Teachers were asked to pass on the details to parents and pupils. On the appointed day, 2 vaccinators (or more, if attendance was expected to be sizeable) were dispatched to the selected locations by Land Rover. One performed vaccinations while the other kept a simple tally by age group of the vaccinees. The vaccination centres were kept open throughout the entire day in order to give people sufficient time to attend, some being obliged to walk as far as 5 kilometres.

Because of the small number of staff, the vaccination campaign progressed so slowly that, by the spring of 1970, it was estimated that 10 years would be required to complete it. Accordingly, it was agreed that more National Youth Service Volunteers should be recruited and more supervisors assigned. By the end of 1970, the staff complement had grown to 50 vaccinators, 18 drivers and 8 health inspectors. In addition, it was agreed that when a team was in an area, local health staff who could be spared would work with it. The resources provided to the programme are shown in Table 19.7. With the increased complement of personnel, it was eventually possible to work in 10 districts simultaneously.

In May 1970, it was decided to administer BCG vaccine concurrently with smallpox vaccine to children under 15 years of age, and from then on the vaccinators worked as 2-man units. One vaccinator administered smallpox vaccine in one arm, using the bifurcated needle, and one administered BCG vaccine in the other arm, using a needle and syringe, and tabulated the numbers vaccinated. With this staff, between 400 000 and 500 000 smallpox vaccinations were performed monthly. By the end of 1970, the vaccination schedule had been completed in Nyanza and Western Provinces as well as in portions of the neighbouring Rift Valley Province (see Fig. 19.3). In other parts of Kenya the population was vaccinated during 1971 and, finally, the coverage was extended to the numerous inhabitants of Nairobi and its surroundings in 1972. In all, 10.5 million vaccinations were performed by the mobile teams and 5.6 million by the established health units during this period.

The only departure from the routine occurred in March and April 1971, when 2 outbreaks, one of 45 cases and one of a single case, occurred in the north-eastern part of Kenya as a result of importations from Ethiopia (see Fig. 19.4). The mass vaccination

[a] During one period of 6 months.

campaign in this area had been scheduled to begin in April and last throughout June 1971, but its date of commencement was advanced to March. Subsequently, 6 vaccination/case-search rounds were conducted in this and 5 other northern districts that bordered on Ethiopia and the Sudan and were considered to be at high risk.

Except for Rwanda, none of the 5 countries followed the programme for assessment recommended in the WHO *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1). The handbook called for an assessment team to visit a 10% random sample of villages 1–2 weeks after vaccination to determine coverage and the proportion of people successfully vaccinated. As was the case in a number of countries, health officials resisted the diversion of personnel and vehicles from the vaccination campaign itself. To determine coverage in Kenya, the number vaccinated was simply compared with the estimated population in the area—an unsatisfactory procedure in a country where census data were so imprecise. Approximately 100 children were examined one week after vaccination to determine whether a sufficient proportion had been successfully vaccinated. Definitive information about the degree of success of the vaccination campaign did not become available until the conclusion of the programme, when, in 1972, 2 WHO staff from the WHO Epidemiological Surveillance Centre in Nairobi undertook a carefully designed cluster sample survey. Approximately 2000 persons were examined in each of 5 different provinces. The results are shown in Table 19.8.

The vaccination coverage of individuals aged 5 years and over was satisfactory in the Central, Eastern and Coast Provinces but not in Western and Nyanza Provinces, in which the programme had first been launched and had been completed in 1970. In these latter two provinces, the vaccination coverage of children under 5 years of age was substantially below expected levels; this was partly accounted for by the fact that health centres were vaccinating only about 25–30% of those born subsequent to the 1970 campaign.

At the conclusion of the campaign, in July 1972, 22 sectors were identified, to each of which a team with a vehicle was assigned. The teams were to proceed from one sublocation to the next, vaccinating those eligible for vaccination and inquiring at schools, markets and health units about possible cases that might have occurred during the preceding 3 months. Each team was expected to complete a tour of its sector once a year; in high-risk areas, the schedule was intensified to once every 3–6 months. The teams were called surveillance teams, but in fact their principal responsibility was to provide maintenance vaccination. The system remained in operation for little more than a year.

Uganda

Like Kenya, Uganda had a reasonably extensive network of health centres and clinics and a complex of roads reputed to be the best in eastern Africa. A mass vaccination campaign using liquid vaccine was completed in 1966, following which the number of cases of smallpox diminished to only 365 in 1967 and 55 in 1968. Between 600 000 and 900 000 persons were being vaccinated annually in the various health establishments, and in 1969 freeze-dried vaccine supplied by WHO was introduced for use throughout the country. Because liquid vaccine had been employed in the previous vaccination campaign and because it was known that many of the vaccinations had not been successful, Uganda agreed in mid-1968 to undertake a special 3-year national vaccination campaign. WHO provided the necessary vehicles and equipment. However, the government later decided to abandon this schedule in order to conduct, in 1970, a national mass vaccination cam-

paign to be completed in just 6 months. To help to prepare the work, Dr Georgij Nikolaevskij, of the WHO Headquarters Smallpox Eradication unit, was detailed to Uganda for a 5-month period. He assisted Dr Yurij Rikushin, a WHO medical officer originally assigned to Uganda for BCG vaccination. District health inspectors in each district organized the programme, which required the population to assemble for vaccination at collecting points. Vaccination staff were divided into groups of 3 or 4 persons who moved from subcounty to subcounty. In all, some 700 public health staff were engaged in the campaign. Between March and August 1970, 8.5 million vaccinations were performed in a population then estimated to be 9.8 million. There was no special assessment of the campaign to measure the prevalence of vaccination scars after it had been completed, but most believed that it had been generally well executed. Like the programme in Kenya, however, it was begun many months after smallpox transmission had been interrupted.

Following the campaign, vaccination continued to be performed by the various health centres in the country but only 100 000–200 000 persons were vaccinated annually, a figure equivalent to perhaps half the number of children born each year. In addition, sporadic campaigns which involved the vaccination of about 100 000 persons were conducted in areas bordering on the Sudan following the importation of cases from that country.

Such knowledge as was available regarding the level of vaccinial immunity at the time was provided by 2 surveys carried out in different parts of northern Uganda (Table 19.9).

Both surveys were conducted in areas convenient of access by road, immediately after special area-wide mass campaigns had taken place. One must assume that vaccinial immunity in more remote areas of these districts and in other parts of Uganda was substantially below the levels shown in Table 19.9.

I.D. LADNYI, c. 1969

Plate 19.3. Yurij P. Rikushin (b. 1923), a WHO medical officer working in tuberculosis control in Uganda, 1965–1971, also acted as the smallpox eradication adviser there and was instrumental in organizing Uganda's 6-month intensive mass vaccination campaign.

Tanzania

Of the 5 countries, Tanzania was the only one which had expressed genuine enthusiasm about undertaking a programme. A thousand or more cases of smallpox had been reported almost every year since the 1950s, and in many outbreaks case-fatality rates of 5–10% had been recorded. Vaccination with liquid vaccine had been provided in health centres throughout the country, but no special programme had been conducted until 1965–1966, when the number of reported cases increased to 2762 in 1965 and to 3027 in 1966. During these 2 years, a mass campaign was conducted in which 6 million vaccinations were given and, subsequently, some 2–2.5 million vaccinations, with the low-potency liquid vaccine, were perfotmed annually in health units, which then consisted of 105 hospitals, 54 rural health centres and 1442 dispensaries. However, 1629 cases were reported in 1967—and reporting in Tanzania was considered to be less complete than in Kenya or Uganda.

In August 1967, WHO and the government agreed on a plan of operations which provided for transport, equipment and sup-

plies of freeze-dried vaccine, as well as the assignment of a WHO medical officer, Dr Roger Lyonnet, and a technical officer, Mr D. G. Michalatos. The WHO staff arrived in the late spring of 1968, and in July 1968 a pilot project was begun in Geita District (population, 385 000) in northern Tanzania. This district had reported the highest incidence of smallpox of any in the country in 1966–1967 and was considered to be one of the most difficult in which to work because of poor roads and extensive swamps. During a 5-month period, a team of 24 vaccinators, a supervisor and 4 drivers performed vaccinations equal in number to more than 90% of the population.

Lack of government funds then resulted in the suspension of the campaign for 7 months, until July 1969, when it was resumed in the endemic north-western districts (see Fig. 19.2) and at the end of the year in 2 endemic south-eastern districts. Three mobile teams, each consisting of 23 persons, conducted the campaign under the direction of each area's district health inspector. The teams were subdivided into 4 units, each comprising a supervisor and 4 or 5 vaccinators and equipped with a motor vehicle, 2 bicycles and a kerosene-operated refrigerator. Political leaders, called "ten-cell chairmen," played an important role. Each was contacted one or two weeks before the team was due to arrive and was asked to prepare a list of all residents in the area for which he was responsible. When the team arrived, the residents were assembled and each was summoned by name for vaccination. The system might appear cumbersome and time-consuming, but in fact the vaccinators consistently averaged more than 500 vaccinations a day. They continued to achieve this norm even when, in 1970, they undertook the additional task of administering BCG vaccine to children under 15 years of age. The system was an unusual one but it worked well in Tanzania, in which the political structure was highly organized. An independent cluster sample survey conducted in Geita District by a team from the WHO Epidemiological Surveillance Centre in Nairobi revealed that 94% of the persons examined had vaccination scars at the conclusion of the programme (Table 19.10).

Later surveys, conducted during 1970 at the conclusion of campaigns in 6 regions, revealed comparable results (Table 19.11).

Although by the end of 1969 the vaccination campaign had been completed in only 1 district and had just begun in 3 others, the number of reported cases of smallpox that year decreased to 117. Reporting was still inadequate, since little had been done to improve the national reporting system; however, this was the lowest total of cases ever recorded. Even if the reporting system had not improved, it certainly did not appear to have deteriorated. Finally, in 1970, the investigation of some cases began. Of 3 outbreaks examined, 1 (in April) had resulted from an importation from neighbouring Zaire. Cases were reported from only 4 regions (Fig. 19.2), and in September the last case was found.

The programme continued, region by region and district by district, at length concluding with the vaccination of the population of the then capital, Dar es Salaam, in August 1973. While in most countries the residents of the capital city were the first to be vaccinated, they were left until last in Tanzania, since Dar es Salaam, situated on the coast, was far away from the known endemic areas. In all, 19.8 million persons were vaccinated against smallpox between 1967 and 1973 and 3.7 million under 15 years of age received BCG vaccine. After September 1970, vaccinators during their visits reported 23

suspected cases but none proved to be smallpox.

On completion of the programme, mobile teams continued to vaccinate and to search for cases in remote and border areas; the health services vaccinated about a million persons each year thereafter but, as in Kenya and Uganda, interest in the programme diminished sharply.

Rwanda and Burundi

The programmes in these densely populated countries, each with some 3.5 million inhabitants, were a study in contrasts. In both, the responsibility for operating the programme was largely delegated to their respective WHO smallpox advisers. One of these, Dr Celal Algan, was an energetic worker, well acquainted with conditions in the field, who, with the help of Rwandese staff, conducted one of the most effective programmes in Africa. The other, who was assigned to Burundi, rarely travelled to the field and had little apparent capacity for organization; the programme in Burundi reflected these shortcomings.

In both countries, the population lived in small hamlets and hillside villages scattered over a tropical and subtropical upland plateau. Roads were few and often impassable during the February–May rainy season. Hospitals, health centres and dispensaries, some operated by the government and some by missionaries or other private voluntary organizations, were comparatively numerous. In 1971 there were 157 hospitals, health centres and dispensaries in Rwanda and 104 hospitals and dispensaries in Burundi. Vaccination was offered at all these health units; about 10–15% of the population were vaccinated each year. The vaccine used was a liquid product which had been manufactured by a laboratory in Butare (Rwanda) since 1953. Beginning in 1965, this laboratory also produced some freeze-dried vaccine which, as has been mentioned earlier, was prepared in 600-dose vials. These vials contained such a large quantity of vaccine that it was often kept, unrefrigerated, for many days or even weeks, with a consequent loss of potency after the first day.

Rwanda

Vaccination in Rwanda had been performed primarily by 2 teams, each consisting of 3 persons, who shared a vehicle and travelled regularly to 400 vaccination points established at health facilities and schools. A sample scar survey conducted in 1968 of 10 404 persons in 3 different prefectures showed a generally low level of vaccinial immunity, especially among children (Table 19.12).

An agreement was signed with WHO in April 1968 which provided for the assignment of a WHO medical officer and the supply of vehicles and equipment, vaccine and needles, as well as for the costs of petrol and vehicle maintenance to be met by WHO. However, at the end of 1968, the Ministry of

Health and WHO staff working in the country re-evaluated the plan and decided to combine the field activities with those of a BCG vaccination campaign then under way. Dr Algan, at that time the WHO adviser for tuberculosis control in the country, volunteered to assume responsibility for both activities.

In mid-April 1969, the programme began operations with a supervisor and 10 vaccinators who worked in pairs, one administering BCG vaccine and the other smallpox vaccine. Only a single vehicle was available, and so the team moved as a group to the various administrative units (prefectures), where vaccination was performed at collecting points. Areas from which cases were reported were attended to first. Hospitals and health clinics were supplied with vaccine and encouraged to participate in giving vaccinations.

As was the practice in other countries, Dr Algan and his Rwandan counterpart held meetings with local authorities beforehand to

Plate 19.5. **A:** Celal Algan (b. 1926), previously the WHO medical officer assigned to Rwanda for tuberculosis control, assumed responsibility in 1968 for organizing the smallpox eradication work in a campaign combining the administration of smallpox and BCG vaccines. The well-planned, rigorously supervised operation completed its 36-month work plan in half that time, while simultaneously developing an effective surveillance programme. Subsequently, as the WHO regional adviser on smallpox eradication in Africa (1975–1980), Algan organized the extensive activities required for the certification of eradication. **B:** Land Rovers move out for field work towing trailers with camping equipment. **C:** Rwandan vaccination team

explain the programme and to identify the most suitable collecting points and work out the best schedule. Local political leaders were given the responsibility for convening the people on the appropriate day and, later, for the reporting of smallpox cases. Concurrent assessment of the campaign was by random sample evaluation to ascertain take rates.

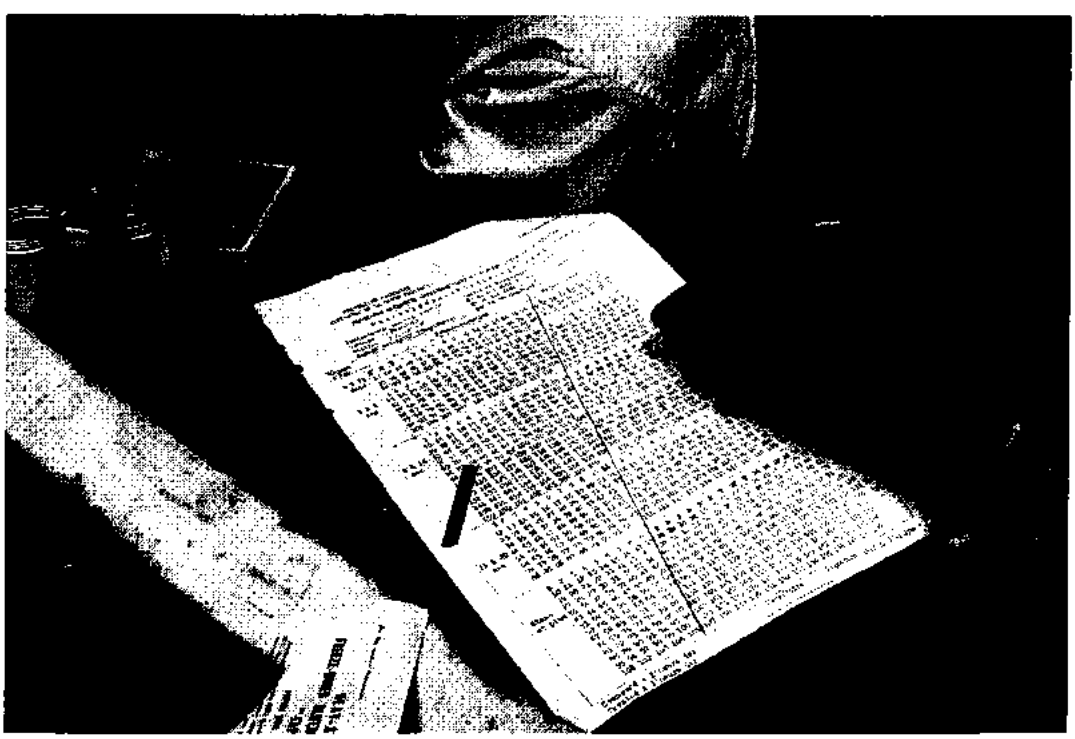
From the beginning, the team worked conscientiously and well, initially averaging 750 vaccinations per vaccinator per day and later as many as 1500 vaccinations per vaccinator per day. The productivity reported was in fact so high that the figures were viewed with scepticism by Ladnyi and WHO Headquarters staff. Ladnyi, however, confirmed the validity of the data during a special visit, noting in passing that the vaccinators complained only of sore fingers and wondered whether thimbles could be provided.

In October 1969, the vehicles intended for the programme were delivered and, with additional transport available, the complement of staff was increased to 27 (2 supervisors and 25 vaccinators, 5 of whom served as drivers); the personnel were divided into 3 teams, of which 2 were occupied with vaccination and the third, headed by Dr Algan, with surveillance–containment. By the end of 1969, 989000 persons had been vaccinated against smallpox by the mobile teams and 54 000 children had been given BCG vaccine.

During 1970, the investigation of 18 reported cases led to the discovery of 235 additional cases. After April, only 3 outbreaks, consisting of 3, 5 and 8 cases respectively, were discovered; each had resulted from importations from Zaire.

By the end of October 1970, only 18 months after the vaccination campaign began, the programme had been completed. During this period, the teams had vaccinated more than 3 million persons. A scar survey conducted in 1971 showed that, of those examined, 87% of children aged 0–4 years had vaccination scars, as did 97% of those aged 5–14 years and 93% of persons aged 15 years and over.

After the programme had been completed, hospitals and clinics continued to administer smallpox and BCG vaccines, while 8 teams, each consisting of 3 vaccinators, travelled throughout the more remote areas, especially those bordering Zaire, to search for cases and to vaccinate.



C. ALGAN

Burundi

Vaccination in Burundi had traditionally been performed by health units. In 1966, however, 500 000 persons were vaccinated during a special mass vaccination campaign undertaken after the occurrence of 1213 reported cases of what was said to have been variola minor. Sample surveys carried out by Ladnyi in 3 prefectures of Burundi in June 1968 revealed a remarkably high level of vaccinial immunity in all age groups in 2 of the areas in which the campaign had been conducted, and satisfactory levels in individuals aged 5 years and over in the third area (Table 19.13).

A plan of operations for an eradication programme was agreed on and signed in December 1967 by WHO and the government. How much smallpox might be present was unknown, since reporting was very incomplete. Only 74 cases were recorded in 1967, but the number rose to 301 in 1968.

In December 1968, a WHO medical officer arrived on assignment, along with supplies and equipment. Field activities began in May 1969 with 2 (later 4) mobile vaccination teams, each consisting of a supervisor, 4 vaccinators, an enumerator and a driver. The number of staff increased to 31 by mid-1969 and to 50 by 1971. The method of work was similar to that in Rwanda although never characterized by the same degree of careful planning and diligence. During 1969, only 415 705 vaccinations were performed, a number far lower than in Rwanda. Ladnyi, who visited the programme in February 1970, discovered that none of the vaccine was being kept under refrigeration, that vaccinators were issuing each vaccinee with a signed and officially stamped certificate of vaccination and that vehicle maintenance was virtually nil. The existing stocks of vaccine were destroyed and new supplies were flown in; the time-consuming practice of issuing individual certificates of vaccination was stopped; but a proposal to replace the WHO smallpox adviser was rejected. Fortunately, a new WHO country representative, Dr Christos Karamustakis, arrived at this juncture. An intelligent, industrious person who had worked previously in Zaire and knew the smallpox programme there, he assumed on a part-time basis an overall supervisory role and, thereafter, the programme proceeded better. However, despite a far greater complement of personnel than in Rwanda, and despite the absence of the requirement for simultaneous administration of BCG vaccine, the mass vaccination campaign in Burundi took more than 2 years to complete and did not conclude until June 1971.

Table 19.14. Burundi: results of vaccination scar survey, by age group, 1973

5–14	103 815	69.8
⩾15	90 118	70.0
Total	200 716	67.7

In all, 2 997 500 vaccinations were performed between 1969 and 1971. No concurrent assessment of coverage was performed, nor were vaccinations checked to find out whether they were successful. Following the campaign, vaccinial immunity was not high, as was revealed in a 1973 sample survey conducted by a team from the WHO Epidemiological Surveillance Centre in Nairobi (Table 19.14).

The local health services were expected to continue the vaccination campaign but little had been done to obtain their cooperation and thus the number of vaccinations performed in 1972 dropped to only 30 000. Other WHO staff were brought in to help to organize an effective reporting and maintenance vaccination programme, and by 1973 reporting had begun to improve and the number of vaccinations to increase.

SMALLPOX OCCURRENCE, 1969–1970

Only 355 cases were reported from the 5 countries in 1969 and 484 cases in 1970. How accurately this reflects the true incidence of

smallpox is difficult to assess. The eradication programmes consisted essentially of the traditional mass vaccination campaigns of the past, few of which incorporated either concurrent assessment of coverage or a special surveillance–containment element.

A national surveillance programme which served to ensure that all suspected cases were investigated and the outbreaks contained was a difficult concept for the countries to grasp and to implement. This was especially true of the former colonies of the United Kingdom, since their health services tended to be much more decentralized, the primary responsibility for health programmes being vested in district medical officers. This policy of decentralization of authority and responsibility offered many advantages in implementing a variety of programmes but not for the development of a national surveillance programme. District medical officers considered the control of smallpox to be specifically their own responsibility and resented the intrusion of a national presence. Where district medical officers were competent and diligent, this was not a problem; but many were not, and for all of them smallpox was but one of an array of problems and not always of high priority. A report of the occurrence of smallpox evoked the typical response that cases occurred in the province from time to time.

Ladnyi struggled to try to improve reporting and surveillance but, with responsibility for 19 countries, could devote little time to any single country. Moreover, he had been instructed by the regional office that he was not to undertake travel unless a visit was specifically approved in advance by the country and by the regional office, a process which he found to require at least 6 months. He ultimately decided to sidestep this restriction by sending a telex to the regional office informing it of his proposed travel plans and indicating that he would proceed unless instructed otherwise within the next 2–3 weeks. Rarely did the regional office reply in less than 4–8 weeks to any communication. A pattern therefore evolved in which Ladnyi proposed a trip and, receiving no reply, went ahead with his travel plans and eventually returned to Nairobi. After his return, he often received a telex advising him not to undertake the proposed trip.

In 1969, with so few cases being reported in eastern and southern Africa, it seemed that transmission would be interrupted quickly whatever the status of the vaccination campaigns. Accordingly, on 4 June 1969, Henderson wrote to the regional office and to Ladnyi in the following terms:

> "I believe that it is absolutely, vitally and unequivocally essential that provision be made for a responsible person, preferably a medical officer, to investigate personally each and every case to verify the diagnosis and to assist with or carry out himself the necessary investigations and containment activities. Any plan not incorporating this particular feature is doomed to failure . . . Experience throughout the world both in endemic and in non-endemic areas has clearly shown that when full responsibility is entrusted to the district health authorities, the results obtained are highly irregular and frequently unsatisfactory."

Interestingly, eastern Africa in particular was to disprove Henderson's sweeping prediction of failure. The status of smallpox in 1969 was anything but clear. Kenya ceased to detect cases that year. Burundi recorded 108 cases and Tanzania 117 cases, but in neither country was there an adequate surveillance programme. In Rwanda, on the other hand, efforts were made to improve reporting and to investigate outbreaks. There, Dr Algan sought to obtain reports from the health units and, when outbreaks were found, redirected the programme to conduct mass vaccination in the infected areas. Virtually all cases in Rwanda were those detected by the special teams. It is probable that reporting was also somewhat more complete in 1969 in Burundi and Tanzania because vaccination teams worked in infected areas and detected cases in the process. However, it is likewise probable that some of the reported cases were misdiagnosed cases of chickenpox. Uganda, for example, originally reported 19 cases in 1969, but when these were investigated by a WHO consultant, only 9 were found to have been smallpox.

In 1970, Kenya reported no cases and Uganda only 2; the latter, when investigated by a WHO consultant, were found to have been infected in the Sudan and Rwanda respectively. Tanzania detected only 32 cases, the last in September. Twenty-three of the cases occurred following an importation from Zaire; the others were not investigated. In Burundi vaccination teams found 197 cases, about which nothing more is known; the last of them occurred in October. Rwanda reported 253 cases in 1970, of which 18 were notified by the health services and the rest detected by the surveillance team. Transmis-

sion in Rwanda was interrupted in April 1970, although 3 outbreaks resulting from importations from Zaire occurred between August and October. Data regarding the age distribution of cases throughout 1969–1970 are available only from Rwanda (Table 19.15). Virtually all the cases were in children under 15 years of age, almost half of them under 5 years old.

Increased confidence that reporting was reasonably complete in 1970 was provided by the expanding vaccination campaigns, which served both to improve vaccinial immunity and to detect any cases that were present. In October 1970, the last cases were reported from these 5 countries, but not until nearly a year later could it be stated with confidence that transmission had actually been interrupted.

The rapid disappearance of smallpox from this area was surprising considering the perfunctory surveillance and containment activities. Levels of vaccinial immunity varied widely from place to place but, except where the systematic vaccination campaigns had been conducted, they were not generally high. Indeed, smallpox had disappeared from all but the densely populated areas of Burundi, Rwanda and Tanzania before the campaigns began. In retrospect, a combination of factors was probably responsible: (1) a generally scattered population with few large urban centres; (2) limited travel by most of the population, many of whom respected the numerous tribal boundaries; (3) prevalent, although not universal, tribal traditions which called for patients to be isolated in a separate hut and cared for by someone who had had smallpox; (4) a comparatively extensive network of health centres which, when freeze-dried vaccine was made available, successfully immunized a large proportion of people; and (5) the presence of a form of smallpox which spread less readily than did variola major in Asia and against which successful vaccination provided a longer-term immunity.

After 1970, outbreaks were reported only in Kenya and Uganda, in the former following importations from Ethiopia and Somalia, and in the latter from the Sudan.

IMPORTATIONS INTO UGANDA

It is probable that transmission in Uganda was interrupted in 1968. Only 9 cases were detected in 1969, and although the sources of these outbreaks were not clearly traced, 6 occurred in Sudanese refugee camps in its northern districts and the other 3 in the south among refugees from Rwanda. In 1970, 1 case occurred in the north in a refugee infected in the Sudan and 1 case in a person infected in Rwanda. During 1971–1972, Uganda recorded 35 cases, all in its northern districts among Sudanese refugees and members of the local population who were in contact with them. These are shown as imported cases in Table 19.1.

Juba Province in the southern Sudan lay just across Uganda's northern border and there a protracted civil war had been in progress. Tens of thousands of Sudanese refugees had taken up residence in northern Uganda and many continued to move back and forth between the two countries. The health services in Juba had been devastated by the war, vaccinial immunity was low, and, throughout 1972, smallpox was widely prevalent.

In October 1970, when Uganda had completed its mass vaccination campaign, it reverted to its previous pattern of operations, whereby vaccination was performed at clinics and health centres; district health inspectors assumed responsibility for surveillance activities and the containment of any outbreaks that were found. WHO recommended that a national surveillance team should be constituted to improve reporting and to participate in the investigation of any reported outbreaks, but this advice was not followed.

In 1971, 19 cases were reported from the northern districts of Acholi and Madi, 15 of which occurred in Sudanese immigrants; 4 local residents were infected by them. In 1972, 16 further cases were detected in this same area, primarily among Sudanese nationals. WHO staff who visited the area discovered that containment measures were not

promptly taken, the investigation of outbreaks was perfunctory, containment was poorly executed and a number of cases reported locally were not notified to the national authorities. Fortunately, in this sparsely settled, reasonably well vaccinated area, the spread of smallpox was even less efficient than the performance of the staff.

In early 1973, a special training programme in surveillance–containment was conducted for the staff in northern Uganda, and in April a central surveillance team was constituted to investigate all suspected cases. A number of suspected cases were competently investigated and specimens obtained, but none proved to be smallpox. Meanwhile, Uganda's only remaining endemic neighbours, Zaire and the Sudan, succeeded in interrupting transmission—Zaire in June 1971 and the Sudan in December 1972. Thus, the surveillance team began work in Uganda after the risk of importations had all but ceased, ironically paralleling the execution of its national vaccination campaign, which began after smallpox transmission had been interrupted.

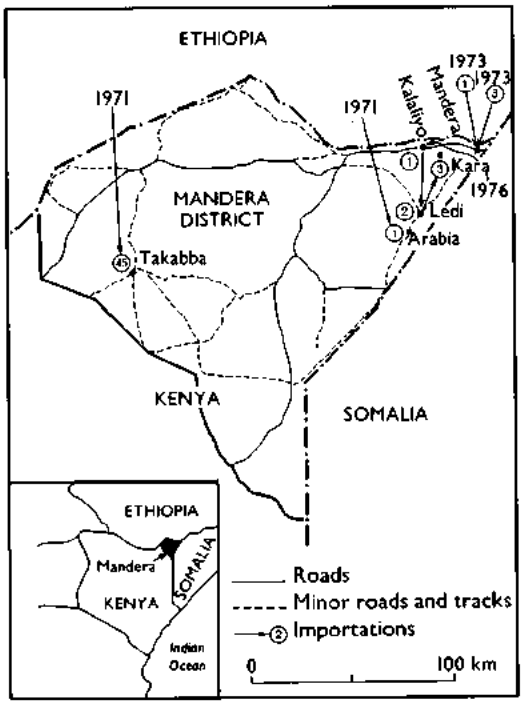

Fig. 19.4. Kenya: sources of importations of smallpox, 1971–1976.

IMPORTATIONS INTO KENYA

Kenya, in contrast to Uganda, initially took more vigorous steps to improve reporting and established a national surveillance team in 1970. Six suspected cases were investigated in that year, all of which proved to be chickenpox. In March 1971, a nomadic herdsman from Ethiopia, travelling while ill, crossed the border and infected residents in a village some 70 kilometres south of the border. Subsequently 44 more cases occurred in 3 generations of transmission, 5 of the cases being fatal. The large proportion of deaths was unusual for outbreaks in the Kenya–Ethiopia area at this time, but whether the outbreak was due to variola major rather than variola minor is unknown. Mass vaccination had not yet been conducted in this area but, because of the outbreak, teams were quickly transferred to the district. Six thousand persons were vaccinated in and around the village, and the teams subsequently searched and vaccinated the entire district. No further cases were discovered.

In April 1971, another case was reported from a village 150 kilometres east of the first (Fig. 19.4). The patient was an Ethiopian adult visitor who resided just 14 kilometres north of the border. More than 95% of the village people had already been vaccinated and no further cases occurred.

The national mass vaccination campaign concluded in June 1972 and, at that time, the country was divided into 22 sectors, each with a mobile surveillance team which was supposed to be responsible for surveillance and for the vaccination of nomadic and other groups considered likely to import smallpox. By then, Ethiopia was Kenya's only neighbour with endemic smallpox.

In Kenya the surveillance programme proved to be little better than in the other countries. In part, this can be ascribed to the fact that no surveillance teams had been established before transmission was interrupted, and thus they had no experience either in the investigation or in the containment of outbreaks. Moreover, the absence of cases understandably led to complacency. Sustaining interest in smallpox eradication after transmission had apparently been interrupted was difficult in all countries and especially difficult in Kenya. Following the outbreaks in March and April 1971, no further cases were detected for more than 2½ years.

On 30 December 1973, a 25-year-old man with smallpox was found in Mandera in north-east Kenya at the border with Ethiopia and Somalia. He had travelled 150 kilometres from an area in Ethiopia in which smallpox was known to be occurring. Containment vaccination was begun, and during the campaign a second case was discovered. The patient was a 23-year-old woman, who developed rash on 27 January and subsequently infected 2 other people. She had arrived in Mandera only 2 days before becoming ill and thus represented a second importation. The source was said to be a Kenyan village near the Ethiopian border, some 80 kilometres to the west. The fact that no investigation of this area was undertaken (although no further cases were reported) is indicative of the quality of the surveillance.

Again, 2 years were to elapse without cases. Meanwhile, Ethiopia reported its last cases in August 1976. In late September, however, Somalia reported its first cases for almost 2 years, in the capital, Mogadishu, supposedly resulting from importations from Ethiopia. As at the end of December, 39 cases had been reported, all in Mogadishu (see Chapter 22). When the report of cases in Somalia was received, a Kenyan team was sent to the border area to undertake an active search for cases. This team then represented virtually the only surveillance unit within 150 kilometres or more, since because of fighting in the area, Ethiopian teams had to remain at least that distance from the Kenyan border. Somali staff, if they were finding cases outside Mogadishu, were not reporting them.

That smallpox did not spread into Kenya must be attributed more to good fortune and to a sparse population than to the work of the inexperienced surveillance team. In December 1976, smallpox was again introduced into Mandera District (see Fig. 19.4). From the available, and somewhat conflicting, reports, it appears that a 40-year-old Kenyan man, who had been studying in an Islamic school near Mogadishu, became ill with smallpox on 26 December. He was then staying with his brother in a village, Kalaliyo, 29 kilometres west of Mandera town; 3 days later, he travelled some 35 kilometres south to a village, Ledi, to stay with his sister, and soon thereafter he returned to Somalia. The health officer in Mandera, informed that a case resembling smallpox had been seen in Ledi, sent a health inspector and a vaccinator. On arrival, they were told that the patient had left; they returned without vaccinating anyone. On 13 January 1977, a subchief reported that the patient's sister had developed a rash. This time, the surveillance team went to Ledi, obtained a specimen and departed. Eleven days later, a report was received from a Nairobi laboratory that the specimen contained smallpox virus. On 26 January, the team again went to Ledi and found that the family had departed for a village (Kara) some 50 kilometres to the north-east. Another day elapsed before they could be found. Vaccination was then begun but 2 daughters became ill with smallpox on 22 and 27 January and another daughter (still unvaccinated) on 7 February. The patients were advised to stay in the house, but it was learned later that the mother regularly left the house to obtain water from a nearby waterhole frequented by a number of people.

Additional staff were sent from Nairobi to assist, and on 17 February 1977 WHO epidemiologists well acquainted with surveillance and outbreak investigation arrived. Mass vaccination carried out by 6 teams with vehicles in villages and towns accessible by road had commenced on 28 January. By mid-February, the proportion of the population vaccinated reached 80% in the main villages, but only 30% in more remote villages. In fact, the 16 inhabitants of a village located just 2 kilometres from the outbreak were found, in early March, not to have been vaccinated at all. Meanwhile, because of heavy rains in the area, many nomads began moving through the area from Ethiopia as well as Somalia. At the end of April, a survey of 2256 persons in a nearby division revealed that only 527 (23%) had vaccination scars. By the end of February, a search had been organized throughout the eastern part of Mandera District which, by assessment, was reasonably effective. A reward of 200 Kenya shillings (US$24) was offered to anyone reporting a case. Gradually, monthly searches were extended to other districts bordering on Ethiopia and Somalia, but because of mud, vehicle breakdowns and scarcity of staff, probably not more than a half to two-thirds of the districts were satisfactorily searched. The searches continued until March 1978, some 6 months after the last known case occurred in Somalia.

It was feared that more cases would be found, but only 1 additional case was discovered by the search teams, in a 25-year-old man who had become ill on 16 December 1976. The source of infection was not

Plate 19.7. The strategy for search activities in Kenya during 1977 was worked out by Jean-Paul Ryst (b. 1939), a WHO consultant, Ziaul Islam (b. 1931), a WHO medical officer for epidemiological surveillance in Africa, 1971–1982, and Wilfred Koinange (b. 1939), Director of Health Services of Kenya.

determined although it was considered to be unrelated to this outbreak. Meanwhile, efforts were made to find the original case in Somalia but it was never discovered.

CONCLUSION

The circumstances attendant on the eradication of smallpox from these 5 countries were wholly unlike those encountered in Asia or South America. In Asia, levels of vaccinial immunity comparable with, and in many instances better than, the levels observed in eastern Africa failed to stop transmission. Only when a fully effective surveillance–containment programme was introduced could transmission be interrupted. In Brazil, surveillance and containment played a notably less important role in eradication, but there the vaccination campaign was carefully executed with specially trained assessment teams evaluating the performance of the vaccination teams on a daily basis. In Kenya, Uganda, and Tanzania, smallpox incidence was diminishing rapidly by the time the Intensified Programme began. In all but limited areas of Tanzania, and in Rwanda and Burundi, the introduction of freeze-dried vaccine of good quality was all that was required to interrupt transmission; the extensive infrastructure of health services did the rest. Mass vaccination campaigns, with neither assessment nor surveillance (except in Rwanda), served to eliminate smallpox in the other areas.

Whatever the deficiencies of the programmes, smallpox transmission was rapidly interrupted at little cost, with the addition of only a few experienced health staff, a small cadre of minimally trained vaccinators and encouragement and support from WHO. In retrospect, many factors account for this success: the substitution of freeze-dried for liquid vaccine; the ready, even enthusiastic, acceptance of vaccination by most of the population; the good cooperation of village leaders, missionaries, teachers and others; the presence of milder strains of variola virus which spread less easily; the generally sparse population and the infrequency with which they travelled over long distances; and an extensive network of health centres and clinics, many of which undertook to control outbreaks when these were discovered.

Of particular note in these countries was the extraordinarily high productivity of the staff compared, for example, with that of their counterparts in the Indian subcontinent. Whereas in the latter group of countries, the performance of 25 vaccinations by a vaccinator in one day was considered to be a worthy accomplishment, African vaccinators regularly vaccinated on average 500 or more individuals a day, the record being achieved in Rwanda, where during a particular month,

the vaccinators, using bifurcated needles, averaged 1508 vaccinations per vaccinator per day. In the Indian subcontinent, it was considered necessary to have at least 1 smallpox vaccinator for every 5000–8000 or 20 000 persons, according to circumstances. In the countries of eastern Africa, on the other hand, the total smallpox eradication staff, at maximum strength, numbered only 1 per 148 000 persons in Kenya, 1 per 180 000 in Tanzania and 1 per 136 000 in Rwanda.

The rapidity with which success was achieved in these and other African countries, at such little cost and with minimum effort, provided enormous encouragement to the global eradication programme. To have interrupted transmission in countries in which health services were considered to be less effective and extensive than in Asia was an important factor in motivating Asian governments to make a more concerted attack on the problem.

INTRODUCTION

In southern Africa, 10 countries or political jurisdictions lie south of Zaire and the United Republic of Tanzania, occupying an area of 6 million square kilometres (Fig. 20.1). This land mass consists principally of a great central plateau, primarily temperate to subtropical in climate; in 1970 its estimated population amounted to 54 million. The vast deserts of the Namib and Kalahari in the west encompass much of Namibia and Botswana, giving way to undulating plains and savanna to the east and eventually to detached groups of hills and mountains which extend from Malawi through western Mozambique and eastern Zimbabwe (called Southern Rhodesia prior to 1980).

In 1967, when the Intensified Smallpox Eradication Programme began, smallpox throughout southern Africa did not appear to be a major problem. Four areas—Angola, Botswana, Lesotho and Namibia—were believed to be non-endemic; 6 other areas recorded a total of only 534 cases in 1966 and 262 in 1967. Health services in most parts of southern Africa were generally more extensive than elsewhere in the continent and all had some type of organized programme of smallpox vaccination. Although smallpox was undoubtedly a greater problem than official data conveyed, it was thought to be not as widespread or of such high incidence as in neighbouring Zaire or the United Republic of Tanzania, for example.

Given the status of smallpox and the national resources available in many of the countries, prospects for the early interruption of smallpox transmission throughout this vast area might have appeared hopeful. However, political problems made it difficult for WHO to cooperate with the authorities in large parts of southern Africa, and these constraints inhibited the programme. Only 4 countries, with a total population of 10.4 million (in 1970), were Member States of WHO with full voting rights (Table 20.1). A fifth, Swaziland, became independent in 1968 and joined WHO a few years later. Official contact between the Organization and the health authorities of the other 5 political jurisdictions, which had a total population (in 1970) of 42.8 million, was difficult at best and in certain cases practically nonexistent. Angola and Mozambique, both Overseas Provinces of Portugal until 1975, were preoccupied with a

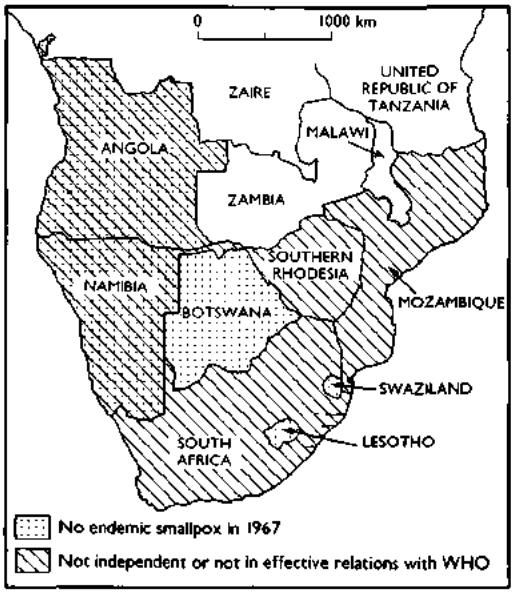

Fig. 20.1. Southern Africa: countries and territories, smallpox endemicity, and relationship with WHO, 1967. The endemicity shown reflects the situation in 1967 as determined later.

protracted and costly civil war. Contact with their health authorities had to be made through the government in Lisbon, for which smallpox eradication was an issue of little significance compared with other problems. Namibia (South West Africa) was administered by South Africa, which, though still a WHO Member State, had been deprived of voting privileges and services by the Seventeenth World Health Assembly in 1964 and which had subsequently ceased to pay its annual contribution or to attend the World Health Assembly. Communications between WHO and South Africa all but ceased at this time, along with South Africa's participation in the Organization's activities. Until 1965, Southern Rhodesia had been an Associate Member of WHO, being represented by the United Kingdom in its international relations. When the government unilaterally declared independence, its rights were suspended on the initiative of the United Kingdom. Communications between WHO and Southern Rhodesia had officially to be conducted through the government in London, but there was little or no official contact between the United Kingdom and the new government of Southern Rhodesia.

The only permissible contact between WHO and the 5 above-mentioned political jurisdictions was embodied in the provisions of the International Health Regulations, which required each to report weekly to WHO Headquarters the number of cases of smallpox, as well as other stipulated "quarantinable diseases", and the areas that were affected. WHO Headquarters, in turn, could query reports and transmit information deemed to be of importance in the control of these diseases. Although many of the authorities concerned, like those of some other countries, were neither prompt nor comprehensive in their reporting, this contact, tenuous as it was, proved to be an important one.

A further difficulty lay in the fact that smallpox eradication held little interest for South Africa, in which an especially mild form of variola minor was prevalent, the severity of which was comparable to that of chickenpox.

In the circumstances, WHO could freely communicate with and provide assistance only to its "active" Member States, which together accounted for just 20% of the population of southern Africa. It was hoped that in the other endemic areas, programmes would eventually be conducted, if for no other reason than to avoid opprobrium in the eyes of independent African governments which had succeeded in eradicating smallpox.

It was therefore difficult to assess the extent of endemic smallpox in most countries of southern Africa between 1967 and 1971, not only because of problems of communication

Table 20.1. Status of political jurisdictions in southern Africa, 1967–1975

	Population in 1970 (thousands)	Area (km^2)

[a] Deprived of voting privileges and services in 1964.

but also because the completeness of notification improved only slowly during this period. Few outbreaks in any country were investigated by appropriately trained staff or were confirmed by laboratory diagnosis. As a consequence, the extent of underreporting, the numbers of reported cases and outbreaks that represented importations from other countries, and the numbers of cases of chickenpox that might have been misdiagnosed as smallpox were, and remain, a matter of conjecture.

Mass vaccination campaigns, assisted by WHO, were conducted in Botswana, Malawi and Zambia; similar campaigns, assisted by WHO and UNICEF, were carried out in Lesotho and Swaziland. None, except the Botswana campaign, was particularly well executed. Nevertheless, transmission was interrupted in Zambia in 1968 and in Swaziland in 1966 or 1969, as is discussed later in this chapter. In Malawi, the disease disappeared in 1971. Lesotho's last cases had occurred in 1962, 5 years before the beginning of the Intensified Programme.

Of the 5 political jurisdictions in southern Africa referred to earlier, Angola and Namibia remained smallpox-free, but endemic smallpox was present in 1967 in the other 3—Mozambique, South Africa and Southern Rhodesia. Because of political constraints, they received no help from WHO in their programmes. Mozambique conducted an extensive vaccination campaign in areas accessible to the health authorities, and in February 1969 the last cases were detected. Southern Rhodesia recorded small numbers of cases throughout 1970, all of them along its eastern border with Mozambique. The last known case occurred in December 1970, but whether it was the last in a continuing chain of endemic transmission or a result of importations from remote areas of Mozambique or Malawi remains unknown. South Africa began active eradication measures in 1970, conducting extensive systematic vaccination campaigns in northern parts of Transvaal Province, its only known endemic area. In 1971, it recorded its last indigenous case.

From February to August 1971, no cases of smallpox were reported to WHO from any country in southern Africa. Just when hope was growing that smallpox had been eliminated from this large area, cases began to be reported from Botswana, a hitherto smallpox-free country, adjacent to South Africa's Transvaal Province. During the preceding 6 years, only a single imported case had been detected in Botswana. Vaccinial immunity throughout the country was low and smallpox began to spread. This was alarming. Not only might smallpox again become established in a country that had been free from it, but it was feared that it might spread through the populated areas in north-western Botswana into areas of Angola which were inaccessible because of civil war. If smallpox were to become re-established there, the prospects for eradication would be significantly diminished. Effective measures to control the disease were greatly delayed but, by good fortune, it remained confined to Botswana, in which more than 1000 cases were recorded during 1972 and transmission persisted until November 1973.

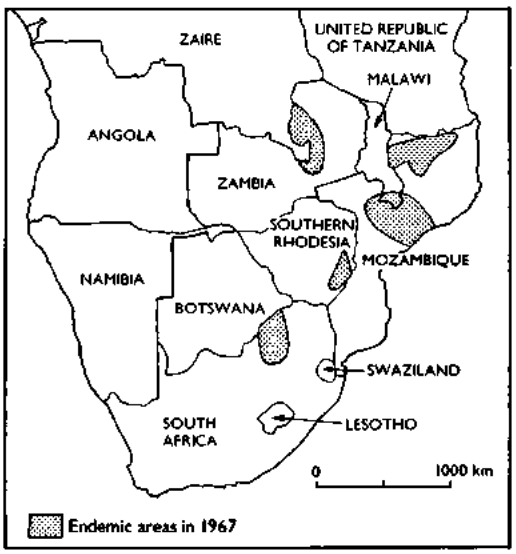

Fig. 20.2. Southern Africa: probable extent of endemic smallpox, 1967.

On the basis of a retrospective review of data collected during the course of the programme and, subsequently, during activities leading to certification, it is probable that in 1967 there were not more than 5 comparatively small foci of smallpox (Fig. 20.2). One was in Zambia in areas adjacent to the then heavily endemic Katanga (Shaba) Province of Zaire. A second straddled the Mozambique–United Republic of Tanzania border, where a Mozambican independence movement was centred and where military forces associated with this movement, as well as refugees, moved into and out of the United Republic of Tanzania. A third lay in central

Mozambique and southern Malawi, likewise an area in which security was a problem; a fourth was in rural mountainous areas of Southern Rhodesia and may or may not have extended into adjacent areas of Mozambique; the fifth was in Transvaal Province of South Africa. In all areas except South Africa, smallpox with a case-fatality rate of 5–15% prevailed; in South Africa, a very mild form of variola minor was present with a case-fatality rate of less than 1%.

In this sparsely populated region of Africa, smallpox was readily interrupted with national or regional mass vaccination campaigns, few of which are believed to have achieved the high levels of vaccinial immunity attained in Zaire and western Africa. Moreover, except in Botswana, programmes of surveillance and containment were never well developed. However, the eradication programme served in some countries to develop reporting systems and to promote routine vaccination against this and other diseases in existing health facilities. It is apparent in retrospect, though, that eradication might have been achieved more readily and more rapidly if freeze-dried vaccine had been supplied to existing health programmes and if simple surveillance activities had been developed.

This chapter discusses first the activities in Zambia and then the programmes in Malawi, Mozambique and Southern Rhodesia. A third section deals with smallpox in the adjacent countries of South Africa, Botswana, Lesotho, Namibia and Swaziland. Lastly, activities in smallpox-free Angola are briefly described.

Table 20.2. Zambia: number of reported cases of and deaths from smallpox and case-fatality rates, 1956–1973, and number of vaccinations performed, 1964–1973

Year	Number of cases	Number of deaths	Case-fatality rate (%)	Number of vaccinations[a]

[b] Imported from Zaire.

ZAMBIA

Zambia, a subtropical country consisting largely of wooded plateau, became independent in 1964. Its population of 3.8 million (in 1967) lived primarily in scattered villages, only 700 000 being resident in the 9 major towns. Its road system was comparatively extensive, as was its network of health facilities, which included 60 hospitals, 93 urban and specialized clinics and 323 rural clinics. Many of these were staffed by expatriates, there being at that time only 3 Zambian physicians and a dearth of Zambian paramedical staff. Few of these health units, however, provided vaccination against smallpox.

Smallpox, with a case-fatality rate of 5–15%, similar to the form existing in neighbouring Zaire, had been prevalent for many years (Table 20.2). Mass vaccination campaigns employing liquid vaccine were conducted during periodic outbreaks.

In 1963–1964, major epidemics began to occur in Zambia (Fig. 20.3), primarily along the Zairian border. The new government responded with a national mass smallpox vaccination campaign utilizing specially con-

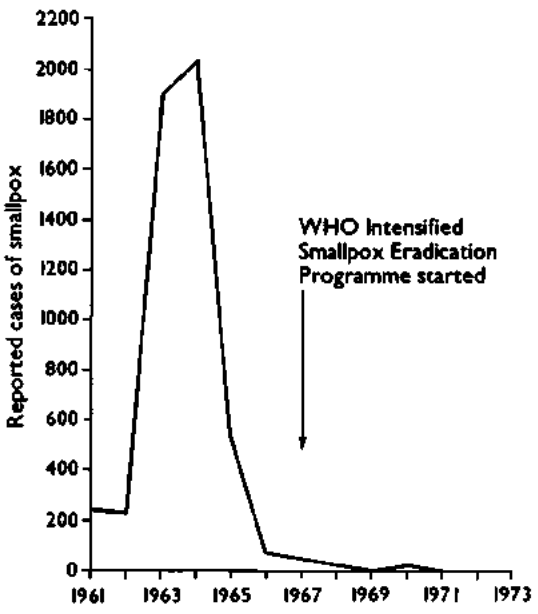

Fig. 20.3. Zambia: number of reported cases of smallpox, by year, 1961–1971.

stituted mobile teams. The programme began in 1964 in each of 8 provinces under the supervision of provincial officials. One hundred and forty vaccinators were recruited and trained locally and discharged when the team had completed its work in a given area. They vaccinated at assembly points, using liquid vaccine. The intent was to vaccinate one-third of the population of each province each year. Vaccinations were performed during the dry season, from May to November. Despite a serious shortage of transport, limited supervision and inadequate refrigeration facilities, 1.66 million vaccinations were reported to have been given during 1964 and 1.5 million in 1965. Take rates among primary vaccinees were found to be about 80%. This was lower than the take rates expected when freeze-dried vaccine was used but, considering the logistic problems in the country, it was a remarkably good result. The number of reported cases decreased sharply, from 2214 in 1964 to 528 in 1965.

In January 1966, freeze-dried vaccine, donated by the USSR, began to be employed. That year, another 1.54 million persons were vaccinated, and the number of cases decreased further to only 63 in 1966.

The government was committed to smallpox eradication and in March 1967 requested WHO to provide vehicles, refrigerators and other equipment as well as 4 advisers—a medical officer counterpart for the director and 3 operations officers to serve in supervisory roles, where needed, at provincial level. Between 1967 and 1973, WHO was to provide 10.6 million doses of vaccine and expend US$644 146, an outlay which included WHO salary payments. The WHO medical officer arrived in November 1967 and the 3 operations officers in 1968. Meanwhile, the government staff for the mass vaccination campaign was increased from 140 to 207.

Under the new WHO-assisted programme, BCG vaccine was given simultaneously to all schoolchildren and, in two of the provinces, to younger children as well. Between January 1966 and the end of 1968, the so-called "first phase" of the programme was completed—i.e., vaccination with freeze-dried vaccine throughout the country. The number vaccinated was roughly equivalent to the estimated population. In 1968, only 33 cases were reported and smallpox transmission appears to have been interrupted in December of that year.

During 1967–1968, the WHO-assisted programme changed little in character. Vaccination was conducted at assembly points; coverage and take rates were assessed only occasionally; little was done to improve the surveillance system. Indicative of the quality of surveillance is the fact that little is known about the last 10 cases reported in 1968, except that 2 were said to have been infected in Zaire.

Beginning in 1968, the established government health units were provided with stocks of vaccine and encouraged to vaccinate all who attended but, as was true in many countries, these units evinced little interest in undertaking even this most simple of preventive measures. Throughout the whole of 1969, they performed only 91 650 vaccinations and many of these were given by programme vaccinators who were assigned to clinics. Fully 3 additional years of concerted effort were required before the staff of the health units began to vaccinate significant numbers of persons.

Although a programme of vaccination had been completed throughout the country, the government decided in 1969 to repeat the national mass vaccination campaign, using special teams as before. Because smallpox was still endemic in neighbouring Zaire, the United Republic of Tanzania and Mozambique and because the existing health units were providing little help, government officials felt that this was the only way that they could ensure a sufficiently high level of vaccinial immunity to prevent spread should introductions occur.

The WHO operations officers were assigned to the provinces bordering on Zaire, and vaccination check-points were established at the principal border crossings to examine persons entering the country and to vaccinate anyone without a scar. In some areas, the coverage achieved was assessed by WHO operations officers after the teams had worked in an area. Throughout Zambia, however, supervision generally remained poor, which was reflected in the unsatisfactory performance of vaccinators, who averaged only 40 vaccinations per day.

The repeat mass vaccination campaign was costly but it did assure the movement throughout the countryside of vaccination teams which could detect any cases that existed. Between 1969 and 1971, an additional 4.6 million vaccinations were performed, the annual average being no more than had been

achieved in 1964–1965, before the provision of WHO assistance.

During 1970, at the midpoint of this repeat round of mass vaccination, a cluster sample survey of the country was carried out by staff of the WHO Epidemiological Surveillance Centre in Nairobi, Kenya, to measure the level of vaccination coverage. In all, 17 927 persons were examined. The proportion with vaccination scars was found to range from 62% to 80% in the different provinces, but in 5 of the 44 districts it was discovered that fewer than 60% of the people had ever been vaccinated. By any standard, the programme had not been notably successful.

The need to recruit at least one experienced team to encourage reporting and to investigate each suspected case had been stressed repeatedly by Ladnyi, the WHO intercountry smallpox adviser for eastern and southern Africa, but not until late 1969 was such a team formed and the first efforts made to ensure that each of the 429 health units provided a weekly report. Even then, the effort left much to be desired: as late as June 1970 the WHO medical adviser to the national programme commented that a report of a suspected case was *usually* followed by immediate investigation. The concept that *every* suspected case was important was not understood.

Meanwhile, in Zaire, mass vaccination throughout the neighbouring Shaba Province was completed during 1969, although a few cases of smallpox were reported each month in early 1971. Despite the continuing presence of endemic smallpox just across the border, only 2 imported cases were detected in Zambia, in April 1970. These cases actually spent less than a day in the country. The individuals concerned—a 4-year-old child and a 7-year-old child—were brought across the river from Zaire by their parents to be examined at a clinic. They were diagnosed as suffering from smallpox by the staff of the clinic and were promptly sent back to Zaire, but the incident was duly reported to the provincial health office. These were Zambia's last known cases.

Not until the beginning of 1971, when the risk of importations seemed to have diminished almost to nil, was a comprehensive surveillance system finally established in northern Zambia, near the borders with Zaire and the United Republic of Tanzania. In these areas each village was visited twice monthly by a surveillance agent to detect cases with rash and fever which might be smallpox. Additional permanent vaccination posts were established along the frontiers and many suspected cases were investigated. Because the United Republic of Tanzania detected no cases in 1971 and Zaire found none after June of that year, it is not surprising that no further cases were discovered in the bordering areas of Zambia.

With the conclusion of the second round of mass vaccination, the number of staff was reduced and the number of WHO advisers decreased from 4 to 2. A maintenance programme was established whereby 15 mobile vaccination teams moved through the provinces vaccinating the more remote populations and encouraging vaccination in established health facilities. In all, 1.4 million persons were vaccinated in 1972 and 1.5 million in 1973, numbers comparable to those vaccinated by the much larger special vaccination campaign staff. In the mid-1970s, immunization against several diseases began to be offered by many of the established health units, and monthly reports giving the number of cases of disease and the number of vaccinations performed were received regularly from 96 hospitals and 689 health centres and subcentres.

The age distribution of cases during 1964–1965 was unusual in that 86% of those recorded were in individuals aged less than 6 years (Table 20.3). This was an unusually high proportion of cases among young children,

Table 20.3. Zambia: age distribution of reported cases of smallpox, 1964–1965 and 1966–1968

1964–1965			1966–1968		
Age group (years)	Number of cases	%	Age group (years)	Number of cases	%
<1	626	23	<1	40	28
1–5	1 733	63	1–4	63	44
6–14	257	9	5–14	26	18
⩾15	126	5	⩾15	14	10
Total	2 742	100	Total	143	100

for which there is no explanation other than that it may have been an artefact of reporting. Data for the 1966–1968 period show a more typical age distribution of cases.

MALAWI, MOZAMBIQUE AND SOUTHERN RHODESIA

Background

Malawi, Mozambique and Southern Rhodesia together had a population of 18 million (in 1970) and a reasonably extensive network of health centres and roads, Southern Rhodesia's being the most fully developed. From 1963, the prevalent form of smallpox in these countries appears to have been variola major, with a case-fatality rate of 5–15%. During the early 1960s, smallpox had been of special concern to the health authorities, and all had organized mass vaccination campaigns employing mobile teams. Reasonably satisfactory control seems to have been achieved. In all, only 142 cases were reported in 1966 and 172 in 1967, although the true numbers were undoubtedly much greater because notifications in these countries, as elsewhere, were very incomplete.

The recurrence of variola major was a recent development. Variola major had been prevalent before 1952, but in that year it was replaced by variola minor. From 1952 to 1958, for example, Malawi recorded 810 cases but only 8 deaths. In 1959, both the number of cases and the case-fatality rate began to increase and by 1961, 1465 cases with 161 deaths were reported (Table 20.4). The source of the strain which infected Malawi was in all likelihood either neighbouring Zambia or the United Republic of Tanzania. In Mozambique, a similar change in the prevalent smallpox strain took place in 1962–1964, at the time of civil conflict along its border with the United Republic of Tanzania. In 1963, fatal cases began to be observed in Southern Rhodesia, virtually all of them occurring in the eastern provinces bordering on Mozambique.

The civil war in Mozambique played a significant role in the persistence of smallpox in these countries. A national independence movement, which had been established in border areas in the south of the United Republic of Tanzania, moved into the 2 northern provinces of Mozambique in 1964. In addition to conducting guerrilla warfare, the independence movement established a political and administrative structure which, during the following decade, expanded into the central and north-western provinces. To combat this movement, the Mozambican government resettled many of the scattered rural population into villages which could be defended and in which health and educational services could be provided. Thus, village health units capable of reporting cases of smallpox existed throughout the country, but few activities were possible in the sparsely populated rural areas, including extensive tracts adjacent to the United Republic of Tanzania, Malawi and Southern Rhodesia.

Table 20.4. Malawi, Mozambique and Southern Rhodesia: number of reported cases of and deaths from smallpox and case-fatality rates, 1959–1972

Year	Malawi			Mozambique			Southern Rhodesia

Vaccination Campaigns

For a number of years prior to 1967, a considerable proportion of the population in each country was reported to have been vaccinated each year (Table 20.5), but none of the programmes incorporated a system for assessing the level of coverage achieved, and only in Southern Rhodesia were take rates regularly appraised.

Freeze-dried vaccine was used only in Mozambique, the vaccine having been produced at the Instituto de Investigação in Lourenço Marques (now Maputo). Samples of this vaccine were tested by the International Reference Centre for Smallpox Vaccine in Bilthoven, Netherlands, in 1968 and 1972 and found to meet WHO standards. Vaccination in Mozambique was offered in hospitals as well as in health and first-aid posts and by mobile teams, each of 9 districts having 3 or 4 teams which sought to vaccinate one-third of the population each year. BCG vaccination was given simultaneously. During 1968, a special campaign was conducted which succeeded in vaccinating against smallpox half of the 8 million residents, although, because of security problems, 2 districts in the north, Niassa and Tete, could not be well covered. A repeat campaign was conducted in 1972, during which, because hostilities had subsided in Tete District, it was possible to vaccinate most of the people in this area. Although the coverage was not assessed, vaccinial immunity was probably reasonably good among accessible populations, considering that a large number of people had been vaccinated and freeze-dried vaccine had been used. However, immunity was undoubtedly much lower among the inhabitants of the large sparsely populated rural areas of the central and northern parts of the country.

In Southern Rhodesia, a similar type of programme was conducted, with vaccination being given by mobile teams and in existing health facilities. Poliomyelitis and BCG vaccines were administered simultaneously to children. Until 1970, liquid smallpox vaccine produced in South Africa had been employed. A continuing assessment of take rates among primary vaccinees was conducted by local health authorities, and these showed 75–90% successful vaccinations—rates which were lower than those obtained with freeze-dried vaccine, but higher than those in most countries that used liquid vaccine. The only available data regarding the prevalence of vaccinial immunity are from a 1978 government survey, which found that 74% of children aged 1–6 years and 92% of those aged 7–10 years had vaccination scars.

In Malawi, a permanent staff of 42 vaccinators regularly travelled by bicycle through their assigned regions, giving smallpox vaccine only; a 10-man mobile team was available for vaccination where outbreaks occurred. The mobile team worked primarily in the south, where, after 1965, almost all cases were found. Until 1966, liquid vaccine was employed; primary take rates, when measured in the field, were only 25–50%. The programme was not particularly successful, as was apparent from a survey in 1965, which showed that only 360 of 2566 schoolchildren (14%) in and around the capital city had vaccination scars. In January 1966, freeze-dried vaccine was made available by UNICEF and thereafter only this type of vaccine was employed. WHO staff visiting the country in 1966 and 1968 found that the supervision of vaccinators was poor, their productivity was low and the vaccinial immunity of the population was unsatisfactory. In one area of southern Malawi, in which United States Peace Corps volunteers assisted in mass vaccination in 1968, 50% of the inhabitants remained unvaccinated at the end of the campaign. Late in 1969, the government decided to request assistance from WHO in conducting a national smallpox eradication programme, but a better-organized vaccination campaign did not begin until April 1972. That programme included the administration of both BCG and smallpox vaccines. When the campaign was launched, surveys in different areas showed that 30–60% of children aged 0–4 years and 36–76% of those aged

Table 20.5. Malawi, Mozambique and Southern Rhodesia: number of reported vaccinations performed, 1964–1973

Year	Number of vaccinations (% of total population)		
	Malawi	Mozambique	Southern Rhodesia
1964	1 569 000 (40)	1 056 726 (15)	2 495 112 (59)
1965	751 413 (19)	2 139 489 (29)	1 371 600 (31)

1973	489 111 (10)	2 533 968 (28)	1 119 614 (19)

5–14 years had vaccination scars. Only 5 months after the programme had begun, it was stopped by the government on account of the occurrence of abscesses due to BCG vaccination. It did not recommence until August 1973—almost a year later—but was halted once again, in December 1973, when cholera broke out and the teams were reassigned to perform cholera vaccination.

Finally, in 1974, an extensive vaccination campaign began, long after the last cases had been detected. It concluded in 1976. WHO financial support throughout the course of the programme amounted to US$311 011; in addition, 7.8 million doses of vaccine were supplied.

The Smallpox Situation

In the 3 countries under review, information about smallpox, from 1967 until 1971, when the last known cases were detected, is sketchy. Undoubtedly, many cases occurred which were not reported and some which were reported may not have been smallpox. Health authorities at district or provincial level in each country usually performed area-wide vaccination when cases were reported but rarely did they conduct investigations to detect additional cases or to identify the source of infection. Ladnyi, during visits to Malawi, tried to persuade the government to initiate a surveillance programme, but not until 1973 was a satisfactory programme established for the investigation of suspected cases of smallpox. Since there could be no direct official communication between WHO and the health authorities in Mozambique and Southern Rhodesia, a similar effort to encourage proper surveillance in these areas was greatly delayed. At the end of 1969, some WHO staff began corresponding personally with university faculty members in Salisbury, Southern Rhodesia, who soon thereafter undertook to examine specimens from many suspected cases although few epidemiological investigations were conducted. Not until the spring of 1972 did WHO and the countries concerned reach agreement to give Henderson special permission to visit Mozambique (as well as Angola and South Africa although not Southern Rhodesia) to assess the nature of their programmes and to discuss needed surveillance measures in areas then believed to be smallpox-free. Information about smallpox, even that pertaining to the last outbreaks, is thus fragmentary in all the countries concerned.

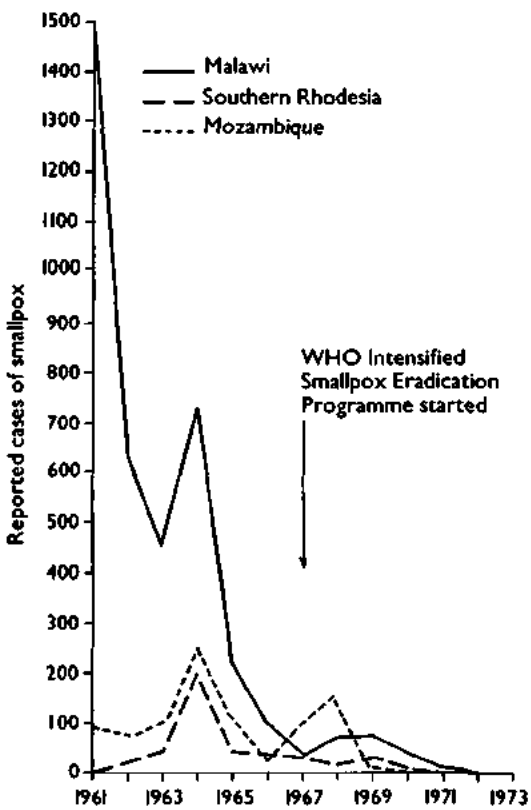

Fig. 20.4. Malawi, Mozambique, Southern Rhodesia: number of reported cases of smallpox, by year, 1961–1972.

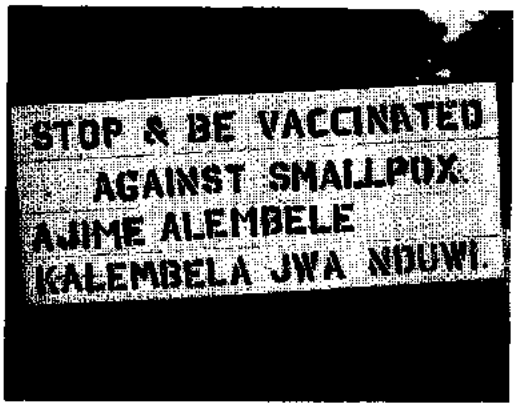
Mozambique detected 104 cases in 1967, 145 in 1968 and 11 in 1969 (the last occurring in February) (Fig. 20.4). Of the 145 cases in 1968, 142 were reported from parts of only 3 provinces, all in the north of the country (Fig. 20.5). Most of the outbreaks occurred in villages in Tete District, near the border with Malawi, and in Niassa District, which adjoined endemic areas in the United Republic of Tanzania. The 11 cases detected in 1969 were all in Niassa District. Because the guerrilla forces of the independence movement continued to travel between Niassa and the southern part of the United Republic of Tanzania, it is possible that these foci were related. This is speculation, however, since in neither country were outbreaks investigated to determine their sources. Few smallpox cases were reported in the south of the United Republic of Tanzania after 1969 but it later became apparent that the disease persisted in

border areas of Malawi and Southern Rhodesia, at least until the end of 1970. In Mozambique, however, no further cases were detected after 1969. Because security in many of the border areas was problematic, cases may well have occurred but remained undetected.

In Malawi, all cases after 1966 were reported from the south of the country. Southern Malawi presented an especially difficult problem. Large numbers of refugees from Mozambique lived in the region, most of whom crossed into the country through forest areas rather than at official border crossings. As illegal immigrants, they sought to avoid any contact with government authorities and often fled into the jungle when teams came to vaccinate. In order to contain outbreaks, villages were sometimes surrounded by a police cordon to prevent villagers from leaving the area until all had been vaccinated. In addition, some outbreaks were discovered during which variolation had been performed, supposedly in order to quell the spread. Cases which were detected were frequently reported as occurring among refugees from Mozambique or residents who had been in contact with them. Whether the cases represented new importations or continuing transmission among immigrants is unknown. Malawi reported only 61 cases in 1968 and 65 cases in 1969. In December 1969, the last case was reported by the health services. No cases were notified during 1970–1971.

By early 1972, it appeared that smallpox transmission might have ceased in the Malawi–Mozambique area. More than a year had elapsed since the last cases had been detected in Malawi and nearly 3 years since the last case had been reported in Mozambique. However, neither country was believed to have adequate surveillance programmes



I. D. LADNYI, 1967

Plate 20.1. Important foci of smallpox in southern Africa were situated along the border between Mozambique and Malawi, which was frequently crossed by Mozambicans fleeing the civil war. They were stopped and vaccinated if they used the official crossing points, but most went along forest trails and so escaped vaccination.

and thus doubts persisted as to whether smallpox was really absent. WHO staff could not participate in confirmatory studies in Mozambique but they could do so in Malawi. In April 1972, Dr Ziaul Islam, who had replaced Ladnyi as the WHO intercountry smallpox adviser, undertook a village-by-village field survey in areas of southern Malawi in which smallpox outbreaks had repeatedly occurred between 1966 and 1969. In 5 villages, he discovered 48 individuals with facial pockmarks who had developed smallpox in 1970 and 1971 (Table 20.6). The area was densely forested, populated with many refugees from Mozambique, including groups which, for religious reasons, refused vaccination. The first case that he could identify in the chain of transmission had

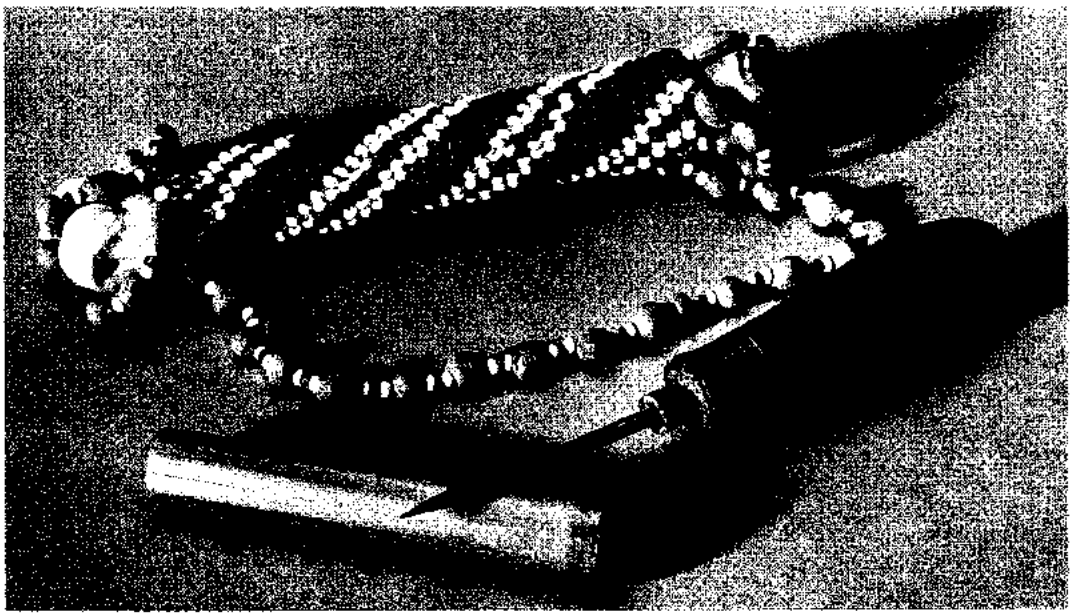
become ill in April 1970, and the last in February 1971. The earliest source of infection could not be specifically linked to previous outbreaks in Malawi although outbreaks had occurred in the same area in the past. During a vaccination scar survey in the affected area, Dr Islam found that 61% of children under 4 years of age, 84% of those aged 5–14 years, and 67% of persons aged 15 years and over had vaccination scars. Because of the proximity of the villages to Mozambique, the authorities there were notified. Mozambican teams subsequently undertook an extensive programme of vaccination and search throughout the adjoining area in Mozambique but found no cases. During 1977, WHO and Malawian staff undertook a more extensive survey of the entire affected area in Malawi. They confirmed Dr Islam's earlier report but failed to detect further spread. They did, however, discover a pockmarked girl who was said to have become ill in September 1972, 19 months after the presumed last case in February 1971. Extensive investigation failed to reveal any other cases among family contacts and eventually it was concluded that the reported year of illness was erroneous. Malawi's last known case is



I. D. LADNYI

Plate 20.2. Variolator's kit obtained in 1966. Scabs and pustular material were carried in the bamboo stick; the awl was used for inoculation. Malawi was the only country in southern Africa where variolation was still being practised in the 1960s.

thus thought to have occurred in February 1971 in an outbreak which terminated spontaneously without being detected by health staff.

Southern Rhodesia's surveillance programme was little better than the corresponding programmes in Malawi and Mozambique, and the origin of its last outbreaks no less mysterious. Southern Rhodesia reported only 10 cases in 1968 (Victoria Province) and 33 in 1969 (19 in Manicaland Province and 14 in Victoria Province). The outbreaks were all within 100 kilometres of the border with Mozambique. Mass vaccination was reported to have been performed in the area of each outbreak but only occasionally did provincial medical officers investigate outbreaks to ascertain the sources of infection. Indeed, as a review of records in 1978 was to show, none of the cases occurring in 1969 was investigated to determine the source of infection; a report of 10 cases was found which had been received by the provincial medical officer but had not been transmitted to the national authorities. (These cases do not appear in the official records and are not included in Table 20.4 or Table 20.6.)

In 1969, Dr Keith Dumbell from the WHO Collaborating Centre for Poxvirus Research in London and Henderson from Geneva began to correspond with Dr J. G. Cruickshank, a virologist at the University College in Salisbury, to encourage the taking of specimens from cases to confirm the diagnosis and to obtain virus strains for laboratory study. Subsequently, in March 1970, the Secretary of Health of Southern Rhodesia directed provincial medical officers to obtain such specimens, and Dr Cruickshank, employing electron microscopy and standard virus isolation techniques, began to process a flow of specimens (Swanepoel & Cruickshank, 1972). Throughout most of 1970, some of the specimens submitted showed herpes–varicella virus but none showed any poxviruses. No cases were reported to WHO from Southern Rhodesia during 1970 until 13 August, when a telex

Table 20.7. Malawi: number of reported cases of smallpox, by age group, 1960–1965[a]

Total	2 873	99

[a] Data by age group not available for 1422 other cases reported during this period.

from the government was received in Geneva reporting a case of smallpox. Because the notification had been made under provisions of the International Health Regulations, official inquiry to Southern Rhodesia was permitted: "Would appreciate receiving urgently further particulars on source of infection of recent smallpox case and confirmation of diagnosis. No known smallpox in recent months in eastern Africa within 325 miles of Chipinga District [the location of the case]." The reply, telexed a week later, indicated that the case had not been confirmed because the patient had left the hospital before being questioned and was thought to have returned to Mozambique. The official weekly reports from Southern Rhodesia subsequently reflected no cases; only much later was the case added to the official records.

No other cases were notified until November 1970, when the government reported, by telex, 2 further cases. The existence of these cases implied that there was a persistent focus of endemic smallpox, and undoubtedly many more cases had occurred to sustain the chain of transmission. Letters and telegrams were exchanged, but to little avail. Southern Rhodesia was eventually to record officially 6 cases in late 1970. Four were reported from Chipinga Town, 25 kilometres from the Mozambican border; 2 of them were considered to have been possible importations from Mozambique but the information available was too vague to confirm this. The remaining 2 cases were reported from another province near the border and confirmed by electron microscopic examination. Their onset occurred in December 1970. It was reported that the patients had been in Mozambique 2 weeks earlier, but again the investigation was perfunctory.

Over the succeeding 5 years, Dr Cruickshank examined 17 specimens taken from suspected cases of smallpox and others from patients with chickenpox and other rash-producing illnesses. None proved to be smallpox. During 1978, in preparation for certification, extensive pockmark surveys were conducted to detect cases that might have been missed. Only 1 case was found, which had occurred in mid-1970, some 6 months before the last 2 cases were recorded. (This case does not appear in the official records and is not included in Table 20.4 or Table 20.6)

In summary, only 6 cases of smallpox were officially reported by Southern Rhodesian health staff during 1970–1971. Later, another 49 cases were discovered during special surveys in Malawi and 1 further case in Southern Rhodesia. Such investigations as were carried out suggest that persistent transmission may have continued throughout 1970 and possibly during the early months of 1971 in border areas of Mozambique as well as in Malawi and Southern Rhodesia. At all events, the number of cases was undoubtedly substantially greater than the official records indicate.

Age Distribution of Cases

Information regarding the age distribution of cases is available for only a proportion of the cases from Malawi during 1960–1965 (Table 20.7) and for all of those in Mozambique in 1968 (Table 20.8).

Cases in Malawi occurred predominantly among children—a characteristic of endemic smallpox—during the period 1960–1965. In Mozambique during 1968, a larger proportion of cases was found among older persons, perhaps reflecting the fact that many cases occurred among more isolated groups living in sparsely settled areas. However, because reporting in both countries was incomplete, these data must be interpreted with caution.

SOUTH AFRICA, BOTSWANA, LESOTHO, NAMIBIA AND SWAZILAND

Background

South Africa, Botswana, Lesotho, Namibia and Swaziland are closely related geographically as well as by trade and commerce. South Africa is by far the largest of these countries, with a population of 22.8 million (in 1970).

The others had a combined population of only 3.2 million, many of whom were employed in South Africa, principally in mining, or travelled there regularly. An extensive, well-developed network of health services, roads and communication facilities extended throughout South Africa; the other countries had fewer resources of this kind.

The persistence of endemic smallpox in this part of southern Africa can be attributed primarily to the fact that, for more than 50 years, the predominant type of smallpox had been a form of variola minor which was even less severe and with a lower case-fatality rate than that in the Americas. Described first in South Africa in the late 1800s, it was known as "amaas" or "kaffir-pox" (see Chapter 5). Its mild character is illustrated by the fact that from 1922 to 1944, 9122 cases were notified in South Africa but only 17 deaths were recorded. Between 1945 and 1952, however, case-fatality rates tended to approach those associated with variola major in African countries to the north. But after 1952, variola minor again displaced variola major. From 1953 to 1971, only 13 deaths attributed to smallpox were reported, of which 11 occurred in 1964 (Table 20.9) during an outbreak of 54 cases in Port Elizabeth, Cape Province. This outbreak was attributed to an importation from Zambia. Evidence that the low case-fatality rate was not an artefact due to incomplete recording of deaths was provided when variola minor spread from South Africa to Botswana in 1971. There, cases and deaths were much more carefully documented. Of 1122 patients, only 2 died.

Table 20.9. South Africa: number of reported cases of and deaths from smallpox and case-fatality rates, 1951–1972

[a] .. = data not recorded.

Continuing vaccination campaigns employing liquid vaccine produced in South Africa had been in progress in each of the countries for many decades. The programmes were intended primarily to prevent large-scale outbreaks of variola major should it be reintroduced rather than to control the relatively innocuous variola minor, against which the vaccine also provided protection.

Until 1972, little information regarding the epidemiology of smallpox and the control programme in South Africa was available to WHO. That which was available was gleaned from a monthly infectious diseases bulletin published by the government and occasional reports of outbreaks sent to WHO by the Secretary of Health, in partial conformity with the International Health Regulations. Information regarding the geographical distribution of cases would have been helpful but the reports listed cases only by month and by racial group.

Data from South Africa, such as they were, were regularly included in published reviews which appeared in the *Weekly epidemiological record*. As country after country in Africa became free of smallpox, South Africa's dubious distinction as one of only a few endemic countries became politically intolerable to its authorities. Although the disease was not a public health problem, South Africa began to take an interest in smallpox in 1970 and commenced an intensive vaccination campaign in the endemic areas. Surveillance was incomplete, and it is therefore uncertain when transmission was actually interrupted. The last known endemic case occurred on 3 May 1971.

Only a few months later, neighbouring Botswana began to detect cases. Perfunctory control measures were taken but smallpox continued to spread. Not until May 1972, almost a year later, was an adequate programme begun. By then, the disease had spread widely across the country. Smallpox persisted in Botswana until November 1973.

Lesotho, Namibia and Swaziland

Events in South Africa and Botswana are described in greater detail later in this chapter. Smallpox occurrence and programme

activities in Lesotho, Namibia and Swaziland may be briefly summarized. Namibia (population in 1970, 1.04 million) was one of the most sparsely inhabited countries in southern Africa; its last known case of smallpox was reported in 1956. Vaccination programmes employing mobile teams which administered poliomyelitis and BCG vaccines as well as smallpox vaccine were well established and had been operative for many years. Because smallpox transmission had been interrupted throughout western South Africa and Angola by 1960 and in Botswana in 1964, the risk of importations was small. Even the 1971–1973 epidemic in Botswana posed little threat because the outbreaks were concentrated in the eastern part of that country, separated from population centres in Namibia by hundreds of miles of desert. Consequently, no special activities were undertaken in Namibia during the Intensified Programme.

Swaziland was first visited by Ladnyi in 1968 and Lesotho in 1970 to assess the status of their activities and to offer such assistance from WHO as might be required. Lesotho (population in 1970, 1.06 million), after many years of freedom from smallpox, experienced an outbreak of 84 cases in 1961. The outbreak extended through June 1962, 52 cases being reported that year. No deaths occurred. In 1961, 700 000 persons were vaccinated in a 3-month mass campaign and, thereafter, mobile teams supported by UNICEF vaccinated between 50 000 and 150 000 people each year, administering liquid smallpox vaccine simultaneously with BCG vaccine. In 1970, WHO began to provide freeze-dried smallpox vaccine for the programme. No further cases were found. Swaziland (population in 1970, 426 000) began experiencing smallpox outbreaks in 1963, its first since 1950. From 1963 to the end of 1966, 182, 517, 85 and 73 cases were notified for the respective years, but only 9 deaths were reported during the entire period. How many of these were genuine cases of smallpox is unknown. Of a series of 73 cases diagnosed as smallpox by auxiliary health workers, 55 were sent to hospital but none was confirmed clinically as smallpox by the physicians who saw them. In areas in which outbreaks occurred, between 44 000 and 90 000 vaccinations were performed each year from 1963 to 1966, using liquid vaccine produced in South Africa. In September 1967, a UNICEF-assisted mass vaccination campaign began, employing BCG and freeze-dried smallpox vaccine. Between 1967 and 1972, when the mass campaign concluded, between 34 000 and 64 000 persons had been vaccinated each year. Thereafter, vaccination was performed by the health centres. A survey in 1970, 3 years after the programme had started, revealed that only 51% of persons under 15 years of age and 20% of those aged 15 and over had vaccination scars. The year in which smallpox transmission was interrupted in Swaziland is unknown. Twenty-five cases were reported to WHO in 1967, 20 in 1968, and 24 in 1969. Because of this, Swaziland was originally listed as an endemic country. However, government records reviewed during certification activities show no cases after 1966 and no one at that time could be found who knew anything about the cases that were said to have occurred between 1967 and 1969. Whether these cases represented clerical error or were indeed cases of smallpox could not be ascertained. As in most countries of southern Africa, smallpox transmission had ceased spontaneously during the course of an indifferently executed vaccination campaign. When surveillance programmes eventually began, no cases could be found.

South Africa

Richly endowed with natural resources and with a large and expanding industrial base, South Africa had many of the attributes of developed countries in temperate climates. Almost half of South Africa's population of 22.8 million (in 1970) lived in urban areas. Preventive health services were administered by regional medical directors, 2 of whom were assigned to the 2 larger provinces (Cape and Transvaal) and 1 each to the 2 smaller (Orange Free State and Natal). They, in turn, oversaw the work of medical officers of health in each local authority. The pattern of vaccination activities differed somewhat from province to province but, in general, all provided vaccine through health centres and clinics, and supplemented this in rural areas by mobile teams which performed vaccinations at collecting points. Poliomyelitis, smallpox and BCG vaccines were administered to young children and smallpox vaccine to older children and adults. The smallpox vaccine, until 1970 a liquid vaccine, was produced at the State Vaccine Institute in Cape Town. Vaccination was also given to all children at school entry, and to the 100 000 or

so men who came each year to work in the mines. From 1968 to 1975, between 600 000 and 900 000 persons received smallpox vaccine each year through government facilities. The number of vaccinations was small in proportion to the population, but the total did not include those, said to be many, that were provided by private physicians.

Reporting from the more than 10 000 health units which regularly saw patients was thought to be reasonably good, but because smallpox in South Africa was so mild, the government authorities believed that many persons with smallpox did not seek medical attention and so did not come to the attention of the health services. Teachers and heads of families were also supposed to report cases when they occurred but their level of compliance was uncertain, especially in areas in which religious sects objected to vaccination of any type.

Information about smallpox was very incomplete for other reasons. Responsibility for health problems, as well as the investigation and control of outbreaks of smallpox and other diseases, was regarded as a provincial responsibility, and in the provinces, as mentioned above, this function was primarily discharged by local medical officers of health. Diligence in the investigation of cases and the conscientiousness with which notifications were forwarded varied from area to area. Since the mild variola minor caused the provincial health authorities little concern, not much time was devoted to the investigation or control of outbreaks. The problem was compounded by a national morbidity reporting system considered to be so unsatisfactory that in 1970 a complete

[a] Case imported from Botswana.

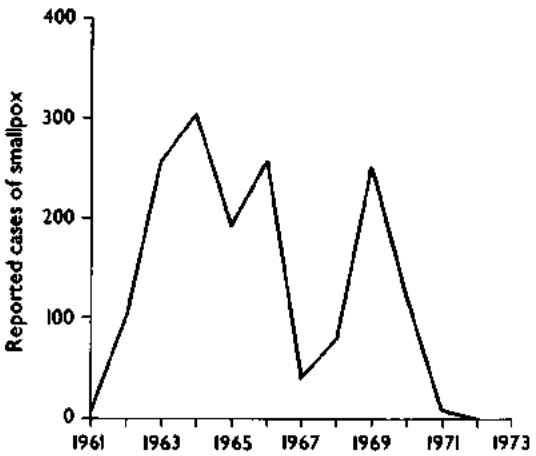

Fig. 20.6. South Africa: number of reported cases of smallpox, by year, 1961–1973.

restructuring of the system was begun. Pending completion of this effort, national morbidity reports ceased to be published in March 1970. Until 1978, further data regarding cases and their geographical location, as notified nationally, were not made available to WHO. When reviewed by WHO in 1978, reports revealed that the Transvaal accounted for most of the cases after 1960 and for all but 41 of the 502 cases reported after 1966 (Table 20.10).

South Africa reported only 43 cases to WHO during 1967, and 81 cases in 1968. Because so few cases were being reported in a country in which health services were so extensive, WHO had originally assumed that these cases must have occurred following importations and had provisionally classified South Africa as a non-endemic country.

In 1969, however, the number of reported cases increased (Fig. 20.6; Table 20.10). Because communication with South Africa through the usual official channels was not possible, Henderson addressed a personal letter to the Secretary for Health on 27 August, noting that as of that date: "South Africa now accounts for about 10% of all cases recorded in Africa this year" and asking for a fuller statement of the epidemiological situation as well as a description of the problems being encountered in controlling spread. By the end of that year, 246 cases had been reported to WHO.

A reply was not received until February 1970. In his letter addressed to Henderson at WHO, the Director of Medical Services showed a dismaying lack of understanding of

the epidemiology of smallpox. He asserted that the cases were sporadic and explained that, with variola minor, "very mild undetected cases and subclinical cases, harbouring the virus in their tonsils, the lymph follicles of the tongue and pharynx are liable to spread the disease to every person not vaccinated against smallpox. Due to this mode of spread, a population with a successful vaccination rate of more than 80% is not protected." He indicated that mass vaccination would continue in order to limit the spread of disease. In reply, Henderson pointed out that in Brazil, in which variola minor was also endemic, "smallpox is transmitted only by cases with definite lesions of smallpox and during the period ... of rash ... and that 80–90% of cases can be traced to personal contact in a house." The favourable experience of other countries in investigating and containing each outbreak was noted and procedures for outbreak containment were described. What effect this correspondence had is unknown.

As it was later learned, the most important stimulus which precipitated a more vigorous programme in South Africa was the WHO Director-General's report on smallpox eradication, prepared as a document (EB45/16; dated 1 December 1969 but never published in WHO's Official Records) for the forty-fifth session of the Executive Board in January 1970 and obtained by South Africa. The report stated:

"Of the endemic countries in Africa, South Africa and Ethiopia are the only ones which have not yet initiated eradication programmes. The number of cases recorded this year by South Africa more than doubled [246 cases in 1969 compared with 81 cases in 1968] ... However, little additional information is available ... The continuing reservoir of smallpox in South Africa and Ethiopia is of increasing concern to neighbouring countries, most of which have become, or are rapidly becoming, smallpox free ... With only three known exceptions, freeze-dried vaccine of satisfactory potency, stability and purity is now used in all endemic countries. However, in South Africa, liquid vaccine continues to be employed..."

South African health officials were angered by the report, considering it to be unfair for three reasons. The first was that the report and the tables of data referred to smallpox only generically, drawing no distinction between the severe variola major of Asia or many other countries of Africa and the mild form of variola minor present in South Africa. This, however, had been a policy followed by WHO since the inception of the programme because the mandate of the World Health Assembly was the eradication of smallpox of whatever variety. The second was the issue of whether or not South Africa could be said to have an eradication programme. As the health authorities viewed it, an effective vaccination campaign was being conducted throughout the country and local authorities were expected to control outbreaks when these occurred. In WHO's view, however, an eradication programme had as its objective the complete interruption of smallpox transmission, an unrealistic aim as seen by the South African Director of Medical Services. The third reason was the emphasis on the use of freeze-dried vaccine—clearly of importance in tropical countries in which ambient temperatures were high and refrigerated storage was scarce. In South Africa, however, ambient temperatures were not so high and refrigerated storage for vaccine was not considered a problem. WHO's emphasis on the need for freeze-dried vaccine in endemic areas was based on the recognition that even when refrigerated storage was adequate, health and medical personnel, even in industrialized countries, often failed to preserve vaccines properly.

Although highly sceptical that other African countries were making as much progress as was claimed, the South African health authorities decided early in 1970 to take additional measures to control smallpox and, by so doing, avoid the expected criticism of other independent African countries. A special programme was launched to produce large quantities of freeze-dried vaccine; by May, all mobile vaccination teams were using this. The vaccine was said to meet WHO standards although it was not examined by a WHO reference laboratory. By the end of 1970, liquid vaccine was being provided only to private practitioners.

In June 1970, an intensified systematic vaccination campaign was begun in the northern Transvaal, from which most smallpox cases were reported. It was termed a house-to-house campaign although, for convenience and efficiency, vaccinators usually assembled persons from a group of neighbouring houses. By the end of the year, more than 350 000 persons had been vaccinated. This represented only a small proportion of the 6.3 million people then resident in the province, although coverage in

the infected but sparsely populated northern areas was said to be high.

By the end of June 1970, 117 cases had been reported to WHO, but thereafter none was notified until December (4 cases) and again in January 1971 (7 cases). As was learned only much later by WHO, all were in the Transvaal, not far from the border with Botswana (Fig. 20.7). Reports from South Africa then ceased. Repeated inquiries were made by WHO officials and others in South Africa after January 1971, under the provisions of the International Health Regulations, asking for confirmation that no further cases had occurred, but there was no response. It was unclear whether there were indeed no cases or whether the government had decided not to report any more cases of smallpox to WHO.

In June 1971, Botswana reported a case of smallpox in Gaborone, the capital, but 2 weeks later asserted that the case had actually been chickenpox. In August, additional cases were reported and these were confirmed as smallpox by laboratory examination. The information was promptly relayed to South Africa and Southern Rhodesia, and teams from both countries immediately went to border areas to conduct intensive vaccination campaigns. The Botswana outbreak continued but only 1 case is known to have been reimported into South Africa—in a labourer who became ill on 14 February 1972.

The question of concern in the autumn of 1971 was how and where smallpox transmission was being sustained in the South Africa–Botswana area. As has been noted, South Africa had reported 11 cases during the 2-month period, December 1970 to January 1971, after 5 months during which no cases had been notified. Following this, 7 months had elapsed before cases were confirmed in Botswana. It was certain that many additional cases had occurred during these two intervals in order to sustain the chain of transmission. Discovery of the infected area was important. Botswana, whose surveillance system was poor, was a candidate area but, because of the letter from South Africa's Secretary for Health, the programme in the latter country had to be regarded with suspicion. WHO Headquarters staff believed it imperative that a visit should be made to South Africa, as well as to Angola and Mozambique, to assess the situation. This was proposed on the grounds that such contact with South Africa was permissible under the terms of a resolution adopted by the WHO Executive Board

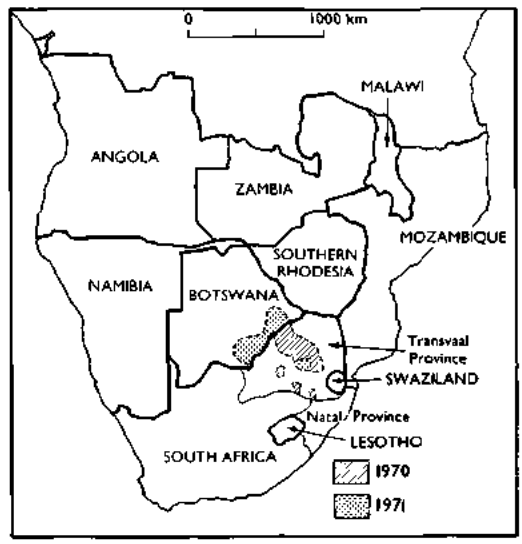

Fig. 20.7. Southern Africa: areas known to have had endemic smallpox, 1970–1971.

(EB45.R20), endorsed by the Twenty-third World Health Assembly in resolution WHA23.46, which had requested the Director-General "to continue to take all necessary steps to assure the maximum co-ordination of national and international efforts". This, it was felt, implied licence to visit South Africa. The proposal was discussed at length and eventually agreement was reached between WHO and the South African government that Henderson should visit South Africa, which he did in June 1972.

In the Transvaal, he found a well-organized vaccination campaign in progress, with attention being given to the detection and laboratory confirmation of suspected cases. During 1972, only a single importation from Botswana had been detected, but health officials were alert because they believed there would be more—if not from Botswana, perhaps from Angola or Mozambique, which they believed continued to harbour endemic smallpox even though neither reported cases.

However, when Henderson endeavoured to obtain epidemiological data regarding the cases reported in 1971, it became apparent that there had been many more cases of smallpox than had been reported to the national authorities. Official records at that time showed only the 7 cases which had occurred in January 1971, in a hospital some 300 kilometres from the border with Botswana. On the other hand, a review of records

at the National Institute for Virology, Sandringham—the diagnostic reference centre—showed 10 poxvirus isolations during 1971, the last from a patient who became ill on 3 May 1971.

The laboratory itself, well equipped and well staffed, was in part inadvertently responsible for problems in smallpox control. It employed an unorthodox approach to the examination of specimens. Standard virological technique called for the isolation of virus on the membrane of fertile hens' eggs. By visual examination of the pocks that grew, variola virus could readily be distinguished from vaccinia virus. At the Institute, the specimens were grown in tissue culture in which, if virus growth occurred, it was impossible to discriminate with certainty between variola virus and vaccinia virus. Accordingly, the laboratory reported only whether or not a virus of the "vaccinia–variola virus group" had been isolated. The laboratory director's view was that whoever sent the specimen should be able to make a clinical distinction between smallpox and disseminated vaccinia, and thus he saw no need to differentiate the viruses by laboratory study. Recipients of the reports, however, sometimes misinterpreted them and reclassified cases of smallpox as vaccinia.

Cases and outbreaks were notified to the regional medical directors by local health officials, who controlled any outbreaks that were found with varying levels of diligence. At neither the national nor the provincial level was there a health official responsible for ensuring that the outbreaks were properly investigated and contained. In no instance had an effort been made to trace the spread of smallpox or to define endemic areas. Reports of variola virus isolations by the reference laboratory were made known only to the persons submitting the specimens; provincial officials were not provided with copies of the reports.

Following Henderson's visit in June 1972, health officials endeavoured to reconstruct the epidemiological pattern of spread of smallpox during 1971. This was important, for if it could be shown that the cases had been closely related and the outbreaks contained, there would be greater assurance that South Africa by 1972 was indeed free of smallpox. Conversely, if the cases had been scattered and unrelated to each other, widespread and perhaps continuing endemicity was implied.

The investigations eventually revealed that smallpox had indeed persisted in South Africa until at least May 1971, all the cases occurring after February having acquired the infection at a hospital about 100 kilometres north of Pretoria, in the Transvaal. As far as the outbreak could be reconstructed, 3 unvaccinated children from a village 30 kilometres distant were hospitalized with typical smallpox in January and February 1971 and the diagnosis was confirmed by virus isolation. The mother reported that her other 4 children, as well as a number of children in the vicinity, had been ill with a similar disease. Three additional children from the same village were admitted with smallpox during January and February, although no specimens were collected. On 26 March, a child hospitalized with tuberculous meningitis and receiving steroid therapy developed a rash at first thought to be drug-induced. Specimens were taken and the National Institute for Virology reported the isolation of a virus of the vaccinia–variola group. The report was misinterpreted and it was concluded that the child had experienced disseminated vaccinia. The patient died on 3 April. Three additional cases occurred in previously hospitalized children on 12, 14 and 19 April respectively, all of which were confirmed by virus isolation. The Regional Medical Director, who was asked to investigate, reported as follows:

> "The suspected outbreak has occurred in the TB ward. One death [not officially notified] is attributed to the disease which had been diagnosed also in 3 other children who were examined. In addition, 3 cases of healing chickenpox were examined. According to my information, the latter disease has been "endemic" amongst children in this ward for many months. That is to say chickenpox has been diagnosed also amongst other children who have no visible lesions now and also in children who have been discharged already ... Vaccination of patients and personnel ... carried out 7 April did not give a satisfactory percentage of takes ... The ward was placed in quarantine only this week. Therefore, a list was compiled of all inmates and also of all patients discharged ... The homes of all will be visited by departmental field staff."

A large hospital-based outbreak of smallpox and possibly of chickenpox had obviously been in progress for at least 2 months. Extensive vaccination campaigns were conducted subsequently in the many

areas from which the hospital patients had come. Three additional cases were found, all of whom had been infected at the hospital: a child who had been hospitalized became ill on 3 May, and 2 labourers who had been seen in the outpatient department 2 weeks earlier became ill in March on a farm 100 kilometres distant. In all, 10 cases and 1 death appear on the official records for 1971 but, as is apparent from this account, there were at least 20 cases and possibly many more. Fortunately, the outbreak occurred at the end of the summer, the low point in seasonal transmission, so that despite greatly delayed containment measures, smallpox spread slowly and transmission was soon interrupted.

In South Africa, as in other countries of southern Africa, extensive vaccination rather than an organized surveillance–containment programme served to interrupt transmission. During the continuing vaccination campaign, no further cases were detected and none was reported by the 11 000 reporting units. Among 77 specimens submitted to the laboratory over the period 1972–1977, only 1 further isolation of the "vaccinia–variola group of viruses" was made, the specimen concerned being from the case (see above) that was imported from Botswana in 1972.

Botswana

Botswana, which became independent in 1966, is large but sparsely populated, the great Kalahari desert extending over the south-west portion of the country and occupying more than half the land area. Over 80% of its population of 623 000 (1970) lived along a strip of land in the south-east, not more than 200 kilometres wide, adjacent to the Transvaal Province of South Africa. Travel between Botswana and South Africa was frequent; population movement within the country was extensive and followed an unusual pattern. A large proportion of the population maintained 3 dwellings: one in a village, a second at a cattle post and a third in a farming area. Family members spent time each year in the different locations, which were often widely separated. Moreover, an estimated one-third of the adult males left rural areas each year seeking employment in the country's urban areas or in South Africa. Government health facilities were comparatively numerous; in 1966 there were 7 hospitals, 73 clinics and 65 health posts.

Several missionary groups also provided medical care.

In this small and scattered but highly mobile population, smallpox was characterized by periodic outbreaks followed by long intervals with few or no cases. An outbreak of 175 reported cases and 34 deaths in 1964 was controlled by a mass vaccination campaign and during the following 6 years only 1 case was notified (Table 20.11).

Because Botswana was believed to be smallpox-free when the Intensified Smallpox Eradication Programme began and because adjacent countries were reporting few or no cases, the development of a special programme was not considered by WHO to be of high priority—if it was required at all. As time passed, the apparent need for a programme diminished. Neighbouring Namibia and Angola reported no cases and Zambia became smallpox-free in 1968. The only other

adjacent countries notifying cases, South Africa and Southern Rhodesia, reported so few in 1967–1968 that WHO suspected that they were the result of importations rather than of endemic transmission. By the end of 1969, however, the number of reported cases in South Africa had increased so greatly that it seemed certain that endemic smallpox was present there. Although the government informed WHO that some of the cases were in Transvaal Province, their exact whereabouts were not revealed. Only in 1972 did it become known that virtually all the reported cases had occurred in the Transvaal, many near the border with Botswana.

Ladnyi paid his first visit to Botswana in January 1971 to discuss the status of its vaccination campaign and the assistance that WHO might be able to offer. After Botswana's mass vaccination campaign of 1964, some vaccination activities had continued (Table 20.12). Liquid vaccine from South Africa had been employed up to the end of 1969, and thereafter freeze-dried smallpox vaccine, also purchased from South Africa, was used. Vaccinations were given by mobile teams in 3 of the 6 health districts and offered by hospitals and clinics throughout the country. However, the health facilities for the most part vaccinated persons leaving for South Africa and Zambia, both of which countries required certificates of vaccination. The number vaccinated each year was equivalent to no more than 5–10% of the population. The proportion of successful vaccinations is unknown but was probably not high even when freeze-dried vaccine began to be used. The freeze-dried vaccine was provided in 100-dose containers and was normally used for 1–2 weeks after reconstitution, although its potency would have fallen to nil within 2–3 days.

Ladnyi found that 80% of the pre-school children had no vaccination scar, and in a school near the capital whose pupils had recently been vaccinated by a mobile team, only 136 of 334 children (41%) had a vaccination scar. Better handling of the vaccine was obviously needed and he provided appropriate advice.

Ladnyi was concerned that smallpox might be imported, and his principal recommendation was that every suspected case of smallpox should be treated as an emergency and all necessary containment measures carried out with a minimum of delay. He recommended that a specimen should be taken from each suspected case and sent to WHO Headquarters for examination; meanwhile the suspected case should be dealt with as though it were smallpox. In a country in which vaccinial immunity was so low, there was a special need for prompt action. The government requested vehicles and vaccine in support of the programme, a request which was forwarded to the WHO Regional Office for Africa.

On 1 June 1971, only 5 months after Ladnyi's visit, a cable was received in Geneva from Botswana reporting a case of smallpox. At that time, no cases had been reported from anywhere in southern Africa since January, although it was learned later that cases in South Africa continued to occur through May. Cables sent on 4 and 8 June from Botswana indicated that the case was in a patient already hospitalized in Gaborone, and that it had been confirmed virologically at South Africa's National Institute for Virology.

Urgent action was indicated. However, permission for WHO Headquarters staff to visit a country required the prior agreement both of the WHO regional office concerned and of the country itself. Henderson immediately telephoned the regional office in Brazzaville to point out the urgency of rapid containment and of a thorough investigation and to propose that an experienced epidemiologist from Headquarters should visit Botswana immediately. The regional office contacted Botswana and, on 16 June, reported that a cable had been received from the government indicating that the situation was misunderstood, that the case had turned out to be chickenpox, and that no visit was required. A return telex from Geneva to Brazzaville again urged an early visit by a WHO adviser in view of the fact that the case was said to have been confirmed by laboratory investigation. The regional office replied that such a visit was not considered advisable.

On 27 August, additional cases of smallpox were reported from Botswana, and specimens were sent by the government direct to Geneva. By 6 September, the WHO Regional Reference Centre for Smallpox in Atlanta, USA, had confirmed the isolation of smallpox virus. This caused a flurry of telex messages and letters between Geneva and Brazzaville. Headquarters staff repeatedly urged an emergency visit by Arita, pointing out that the Botswana focus presented a continuing threat to Botswana as well as neighbouring coun-

tries and noting that this was clearly as much an international as a national problem. The regional office requested more information from Botswana and asked whether WHO assistance was required.

On 7 September 1971, a letter was received in Geneva addressed to the Chief of the Smallpox Eradication unit from the Director of Medical Services of Botswana. Contrary to the cabled information received by the regional office, he reported that in May a 3-year-old child, hospitalized for tuberculosis, had developed smallpox and that a second case had been detected in a government employee in Gaborone on 16 August. Specimens from both had been confirmed as "vaccinia–variola type virus" by the South African National Institute for Virology. The second case had been vaccinated during a June vaccination campaign in Gaborone but showed no scar. The Director of Medical Services noted that "... no source of infection has been identified. There must, however, be a focus of infection somewhere".

On 20 September, Botswana requested a supply of freeze-dried vaccine—which was immediately sent from Geneva—and an operations officer to organize a vaccination campaign. However, as a new intercountry smallpox adviser, Dr Islam, had just replaced Ladnyi, whose current term of service in WHO had expired, he was sent instead. Unfortunately, despite his experience in the control of communicable diseases, he had not yet had direct experience with smallpox eradication and had not yet been briefed regarding techniques for surveillance and containment.

He arrived for a 15-day visit on 8 October by which time 3 additional smallpox cases had been detected and a fourth suspected case had been admitted to hospital. He was unable to trace the sources of these cases. The cases he did identify were in people who presented themselves at the hospital, and he indicated that "there is strong evidence that a smallpox focus exists ... in the southern part of Central District ... the investigations do not support the notion of recent importation". A mass vaccination campaign was said to have been conducted but, in fact, only 38 600 vaccinations had been recorded between January and August 1971. In the area of the smallpox focus, he found that 80% of 1767 primary-school children and 60% of 541 pre-school children had vaccination scars. In adjacent areas, however, only 20% of those aged 0–6 years had ever been vaccinated. He recommended a mass vaccination campaign in the primarily infected area, offered advice to the government regarding vaccine handling and vaccination technique and stressed the importance of surveillance. At this time, these were the only known cases of smallpox in the entire WHO African Region, the other countries in the African continent in which the disease was still endemic, Ethiopia and the Sudan, both then being in WHO's Eastern Mediterranean Region.

Cases continued to be reported from Botswana and all specimens sent for examination to the WHO collaborating centres were confirmed as smallpox, but no information was provided by the government as to what was being done to control the spread of the disease. Faced by frequent and increasingly urgent requests from WHO Headquarters to respond to Botswana's request for an operations officer, the regional office could only reply that no action could be taken unless it received an official application from the government.

In November 1971, an unexpected opportunity arose that permitted direct communication with Botswana. Mr John Phillips, the Resident Representative of the United Nations Development Programme in Botswana, stopped in Geneva on the way back to his duty station. After a full discussion of the problem with WHO staff, it was agreed that he would discuss it with government officials and ask them to submit a formal request to the regional office for the immediate assignment of an operations officer. The request was made forthwith, and Dr Pierre Ziegler, in charge of smallpox eradication in Zaire, was asked to make available his most experienced operations officer, Mr Garry Presthus (see Chapter 18, Plate 18.5). His transfer was not, however, arranged until the end of February 1972, nearly 9 months after Botswana had notified its first case.

On arrival, Mr Presthus, with his counterpart, Mr J. B. Sibiya, Senior Health Inspector for Botswana, rapidly set in motion a mass vaccination campaign and a programme which, unique among the programmes of southern Africa, emphasized the prompt detection of cases and their containment through vaccination. More than 18 months would elapse, however, before transmission could be interrupted.

Within a month of his arrival, Mr Presthus had met the director of the Botswana Red

Plate 20.3. **A:** Joseph B. Sibiya (*far left*), Senior Health Inspector, with one of Botswana's 4 surveillance teams. **B:** Many cases of smallpox were discovered in remote cattle posts in the Kalahari desert by the teams.

Cross, Ruth Seretse Khama, to explain the importance of smallpox eradication in Botswana and its significance for the global programme. In mid-April 1972, her husband, Sir Seretse Khama, the President of Botswana, had signed a special bill allocating US$25 000 from the government budget. Although not a large sum in comparison with funds provided in some other eradication programmes, this represented a substantial commitment for Botswana.

Using such vehicles as could be borrowed from other programmes, Mr Presthus and Mr Sibiya formed 4 teams to contain outbreaks in known foci and to encourage the network of health facilities to begin vaccinating both

people attending clinics and the inhabitants of nearby villages (Presthus, 1974). By early May 1972, forms had been prepared to be used for weekly reports from each health unit. Volunteers of all types offered assistance.

Field investigations conducted during March documented 36 cases which had occurred during 1971, the first in March near the South African border. Mr Presthus believed that there had been many more cases, but with new cases being detected daily there was no time to document further the previous year's experience.

In 1972, the number of reported cases increased to 63 in April and to 66 in May (Table 20.13). In that month, one of the cases was reported from Ngamiland, in the northwestern part of the country, an area of great concern because of the frequent movement of rebel forces between it and areas in southeastern Angola which were only partially accessible to the government of Angola. A surveillance team was hurriedly sent to the area, but fortunately there was an able District Medical Officer, in Ngamiland, Dr Nicholas Ward, who had already organized the health staff for extensive vaccination and search activities. Only 5 other cases were eventually detected in Ngamiland. A year later Dr Ward was recruited by WHO, which he served with distinction in smallpox eradication work in Bangladesh and India.

The increase in the number of cases in April and May 1972 was of profound concern. Although little was known of past seasonal trends of smallpox in Botswana itself, it was assumed that more rapid transmission would occur during the cooler months of the year, from June to the end of October. Accordingly, at the end of May, the WHO intercountry smallpox adviser was directed to assist Mr Presthus and Mr Sibiya in surveillance–containment operations.

Hospital and clinic staff meanwhile had responded enthusiastically to the request that they should vaccinate people in nearby villages, and by the end of July more than

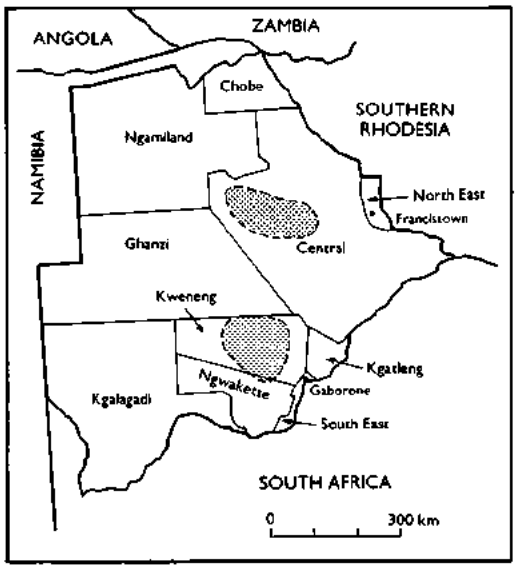

Fig. 20.8. Botswana: areas affected by smallpox, by district, at the end of July 1972.

200 000 had been vaccinated—5 times as many as were customarily vaccinated in an entire year. Meanwhile, the 3 surveillance teams sought to detect and contain outbreaks. The investigation of 48 hospitalized cases revealed 321 others. Because many were being traced to Kweneng District (Fig. 20.8), a systematic search was conducted throughout this area, revealing another 355 cases. Virtually all the cases were detected at cattle posts in rural areas, far distant from the clinics and health posts. Meantime, a second but less seriously affected area was found in Central District.

The number of cases detected increased to 121 in June and to 565 in July. Most were in Kweneng and Central Districts (Table 20.14). Analysis of 39 outbreaks comprising 353 cases revealed an average of 9 cases in each outbreak with a range of 3–30 cases; one-fourth of the outbreaks had persisted for 4 or more genera-

[a] Population estimates as recorded in 1973. United Nations (1985) data show a total population of 698 000 for Botswana as a whole in 1973.

tions of disease. The interruption of transmission was difficult, however, because the mildness of the disease permitted infected persons to travel between their different residences, which they did frequently.

Lack of vehicles hampered the work of the smallpox eradication teams. Four Land Rovers had been ordered in February but, despite efforts to speed their delivery, they did not arrive until November 1972. Nevertheless, the teams organized by Mr Sibiya and Mr Presthus worked tirelessly, and by the end of the year 402 000 persons had been vaccinated. From July onwards, 83% of the 19 designated reporting units sent in weekly reports, although some of these were not received until 1 or 2 months after dispatch because of the poor postal service. Accordingly, health staff throughout the country were instructed to use the telephone or telegraph if a case was found. However, an analysis of reports at the end of November showed that only 5% of cases were seen by the health care units, the remainder being detected by outbreak investigation and active search.

Although it was the season of high transmission, the numbers of cases decreased sharply after July. Meanwhile, in response to warnings about the problem in Botswana, South Africa and Southern Rhodesia undertook extensive vaccination campaigns throughout their border regions, and in Angola, military forces were employed in vaccinating the inhabitants of large areas in the south-east. They detected no cases.

Although resources available to the programme were limited and the population was widely scattered, relatively high levels of vaccinial immunity were achieved in less than a year (Table 20.15).

The search for cases continued after November 1972 but none was found until March 1973. On 7 March, a 22-year-old man was admitted to the hospital in Gaborone with suspected chickenpox, which proved to be smallpox. A house-by-house search began in the vicinity of the patient's home; it was extended to Gaborone and, finally, to a cattle post, 40 kilometres away, in which the patient had spent a night. No other cases could be found until, after 3 weeks of search, a schoolchild identified a person who had recovered from smallpox and was being hidden from the teams. The patient was a member of a Christian sect, known as the Mazezuru, which opposed medical treatment and resisted vaccination.

The search was then focused on Mazezuru families, and 19 cases were eventually identified, the first having been infected in late September 1972 in Kweneng District in an area in which the last cases had been detected that year. Two slowly spreading chains of infection had developed: one chain consisted of 9 cases in Gaborone, of whom all but the hospitalized patient were Mazezuru; and one chain of 10 cases in a town 400 kilometres to the north, in which 4 Mazezuru had been infected. The last of the cases occurred on 13 April 1973.

G I PRESTHUS

Plate 20.4. The child in this Mazezuru family developed smallpox on 7 November 1973; another patient with the same source of infection, who became ill on 15 November, was the last known case in Botswana.

Active search continued, with special attention to the Mazezuru. This sect was estimated to comprise only 3500–5000 persons, who lived in 9 closed or semi-closed communities in towns near the railway. They were traders who travelled frequently to visit relatives and friends in South Africa and Southern Rhodesia as well as in other areas of Botswana. Fortunately, they were distinctive in that the women wore all-white clothing and the men were frequently bearded. So strongly did they object to vaccination that on one occasion in April a community of 100 persons left by train when they learned that a team was coming to vaccinate them. Extensive discussions with Mazezuru church leaders led to a verbal agreement that they would persuade their people to accept vaccination. Later, it was learned that the leaders had privately advised the members of their sect to refuse to cooperate.

From April to September, no cases were detected, but in September another case appeared at a hospital; the patient was a non-Mazezuru girl who lived in the Mazezuru quarter of a migrant settlement near a mining complex. Five weeks of intensive search turned up 5 more cases, but from discussions with people living in the area, it was suspected that at least 6–10 additional cases had occurred. The first patient had become ill in June and the last on 14 September. Again, nearly 2 months elapsed, when, on 21 November, yet another case was found in the mining camp, and this in turn led to 2 more cases at the camp and 3 cases in Gaborone, the last of whom had become ill on 15 November.

More stringent measures were required to interrupt the tenuous but tenacious chain of transmission among the Mazezuru. Most Mazezuru were comparatively recent immigrants to Botswana, having come mainly from Southern Rhodesia. To enter South Africa or Southern Rhodesia they were obliged to be vaccinated and they accepted this as a necessity. Mandatory vaccination in Botswana was proposed to the President of the country. He concurred and informed Mazezuru leaders that either their co-religionists must accept vaccination or they would be deported. They agreed to be vaccinated.

From 1974 onwards, both smallpox and BCG vaccinations were administered by the health facilities in substantial numbers, scar surveys in 1974 revealing an overall level of vaccinial immunity of 95%. The 4 surveillance teams continued to encourage and supervise this activity and to search for cases. Many suspected cases were investigated and specimens examined but none proved to be smallpox.

Information regarding the age and vaccination status of cases is shown in Table 20.16. Nearly half the cases occurred in individuals aged between 5 and 14 years. The occurrence of 34% of cases among adults is

Table 20.16. Botswana: number of reported cases of and deaths from smallpox, by age group and vaccination status, 1971–1972[a]

Age group (years)	Number of cases (%)	Number with vaccination scar	Number of deaths
<1	17 (2)	0	1
1–4	195 (18)	3	1
5–14	505 (47)	11	0
≥15	365 (34)	18	0
Total	1 082	32	2

[a] Further details not available for 13 other cases reported during this period.

high compared to the situation in most countries, but it is not unexpected considering the low level of vaccinial immunity in Botswana. Cases in infants (0–12 months) were thought to have been underenumerated because of the tendency of parents to hide young children with smallpox. Thirty-two of the cases (3%) were reported to have had a vaccination scar, but some of these were individuals vaccinated late in the incubation period. Only 2 deaths are known to have occurred (a reflection of the mildness of the disease); one of them was the child with tuberculosis, already mentioned, who was receiving steroid therapy and the other was a 2-week-old infant.

ANGOLA

Angola (population in 1970, 5.6 million) reported no case of smallpox after 1966. It had an extensive network of hospitals, health centres and rural dispensaries which offered smallpox vaccination. In addition, 300 "rural agents" travelled through assigned areas of the countryside giving vaccinations. Separate mobile units, numbering 26 in all, dealt with leprosy, trypanosomiasis and tuberculosis; they also administered smallpox vaccine. Freeze-dried vaccine obtained from Portugal, France or Switzerland had been used since the mid-1960s. Because freeze-dried vaccine was in use and the number vaccinated annually amounted to 30–60% of the population, vaccinial immunity was probably high. Until 1959, when transmission appears to have been interrupted, variola minor was the prevalent strain: among 1712 cases reported between 1950 and 1959, there were only 23 deaths. Outbreaks due to smallpox imported from Zaire occurred in 1962 (23 cases), 1963 (50 cases), 1964 (1 case) and 1966 (3 cases). Each was investigated by epidemiologists from Luanda, the capital, and confirmed by virus isolation at a laboratory there. The extensive national programme of vaccination continued until the end of 1974, a special campaign being conducted in 1971–1972 in areas adjacent to Botswana; no imported cases were discovered after 1966. Vaccination and surveillance activities were sharply curtailed during 1974–1975, when civil war erupted, but by then more than 2 years had elapsed since the major outbreaks in Botswana and more than 3 years since the last cases had occurred in Zaire.

CONCLUSION

As had been expected in 1967, smallpox in southern Africa was not a major problem, but transmission continued far longer than had been anticipated. Constraints on official communication between WHO and the health authorities in several of the countries or areas unquestionably inhibited progress. In most instances, national health officials were capable of investigating and containing outbreaks, but they needed instruction and assistance to carry out the task in a proper manner. Because the incidence of smallpox was low, effective surveillance and containment might have interrupted transmission much earlier and the final epidemic in Botswana would not have occurred.

Considering the extensive number of health units and special vaccination campaigns in operation throughout southern Africa, it is perhaps surprising that smallpox was not eliminated from this area long before 1967. However, in many of the countries few of the health units offered vaccination, even to people attending their clinics. Moreover, except in Angola and Mozambique, liquid vaccine was the only type of vaccine used, and when supervision was poor, as in Botswana, Malawi and Zambia, the vaccine was not properly refrigerated and there were comparatively few successful takes. When freeze-dried vaccine became widely available, the numbers of cases of smallpox diminished rapidly and transmission was soon interrupted, even though, with the exception of Angola and Botswana, few outbreaks were investigated or contained.

The concluding episode in southern Africa—namely, the reinfection of and extensive spread of smallpox in Botswana—was regrettable and, in retrospect, avoidable. Re-establishment of endemic smallpox might have been averted if a programme in Botswana had been initiated a year or more earlier. That Botswana was at significant risk, however, had not been appreciated. The principal endemic focus of smallpox in South Africa was in the Transvaal, near the border with Botswana, but this was not made known to WHO until after smallpox had become endemic in Botswana. For their part, the South African authorities had been little concerned with the mild variola minor that was present and rarely investigated or contained the outbreaks that did occur. However, even as late as June 1971, when the

first case was reported in Botswana, prompt action might have aborted the ensuing epidemic. Unhappily, there was a delay of fully 9 months before an effective programme began. By then, an intensive and more costly effort was required to stop transmission. Botswana's programme, once begun, was imaginatively and competently executed—the best of any in southern Africa.

The exceptionally mild form of variola minor found in Botswana and South Africa did not constitute a problem of public health significance; had this form of smallpox prevailed throughout the world, a global eradication programme would not have been warranted. It was clear, however, that unless smallpox as a disease, whatever its degree of severity, were eradicated, long-standing programmes of vaccination and the issuing of vaccination certificates for travellers would continue to be required. The eradication of variola minor in Botswana and South Africa was as important to the global programme as was the eradication of variola major.

INTRODUCTION

The execution of successful eradication programmes was a challenge to all countries, but for those which in 1967 had only just begun to develop national infrastructures for health, transport and communication it presented a staggering problem. Ethiopia, with a population of 25.5 million (in 1970), was by far the largest and most populous of countries in this category. Across the Red Sea lay the much smaller states of Yemen (population, 4.8 million) and Democratic Yemen, with its sparse population of 1.5 million (Fig. 21.1). The problem was complicated by civil strife, which was present in all 3 countries either at the beginning or during the course of the Intensified Smallpox Eradication Programme.

In 1967, smallpox was considered to be endemic in both Ethiopia and Yemen; Democratic Yemen, which had reported no cases since 1961, was provisionally categorized as smallpox-free. Because health services were sparse and so few persons were routinely vaccinated, it was feared that the incidence of smallpox in Ethiopia and Yemen might be among the highest in the world; also, the smallpox-free status of Democratic Yemen had to be regarded with some scepticism.

Recognizing that effective national eradication programmes would take time to establish, WHO began to explore the possibility of developing such programmes in each of the 3 countries as soon as the Intensified Programme was launched in 1967. Four years elapsed, however, before eradication activities had been established in all 3 countries. Plans for a programme in Yemen had been discussed by government and WHO staff as early as 1959, a plan of operations had been signed in 1961 and some vaccine had been provided. However, a civil war broke out which lasted 5 years, and little could be achieved until 1969, when a revised plan of operations was agreed on and a special smallpox eradication unit created within the Ministry of Health. Democratic Yemen embarked on a programme in 1970 and, finally, in 1971, Ethiopia followed suit—the last of the countries which had endemic smallpox in 1967 to participate in the Intensified Programme.

The programmes were each very different in character and operated independently of

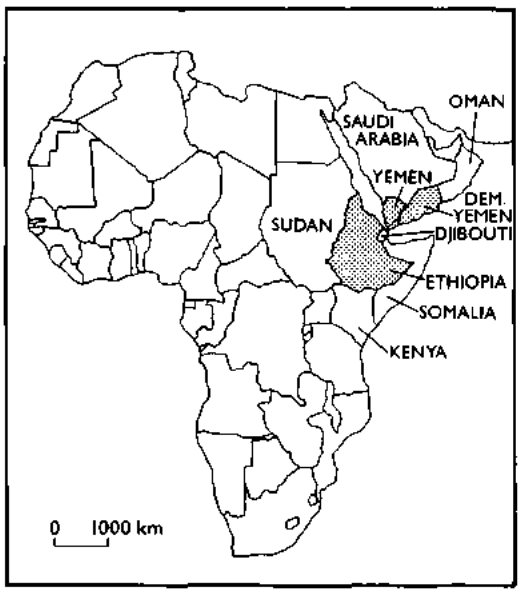

Fig. 21.1. Horn of Africa and adjacent countries.

one another. Epidemiologically, they were also distinct. Despite their geographical proximity, none of the 3 countries is known to have imported cases from either of the others after 1967.

Yemen began a systematic vaccination campaign in 1969 in urban districts and areas accessible by road. After little more than a year, during which 1 million vaccinations were performed, the campaign quickly deteriorated to the point that 5 years elapsed before another million persons were vaccinated. After the programme had begun, only 29 poorly documented cases were recorded in 1969, and none thereafter. From 1971 to 1977, specimens were obtained from 26 suspected cases but none showed evidence of variola virus. Although WHO provisionally reclassified Yemen as a non-endemic country in 1970, this decision was grounded primarily on the absence of reported cases; little other information was available. Because the reporting system was poor and surveillance all but nonexistent, the true status of smallpox remained uncertain until 1978. In that year, a carefully conducted national survey confirmed the absence of smallpox during recent years and suggested that the disease had indeed been absent since 1969.

Between 1970 and 1972, Democratic Yemen conducted an extensive vaccination campaign in and around Aden, the capital city, and in 1973 extended it to other parts of the country. Surprisingly, only 1 case of smallpox was reported, in 1968, but this report was subsequently retracted, it being alleged that the case had been one of misdiagnosed chickenpox.

Ethiopia's participation in smallpox eradication did not begin until 1971, and up to 1975 the government gave it limited support. Two factors were primarily responsible: (1) national and international malaria eradication programme staff had initially opposed undertaking a programme which they believed would adversely affect their own activities; and (2) when the smallpox eradication programme finally began, it was discovered that only the mild variola minor form was present in Ethiopia, and among the many health problems confronting the government, this disease was not of major consequence. During the first 4 years of the programme, fewer than 100 Ethiopian health personnel, WHO staff and international volunteers, travelling mainly on foot and on muleback, struggled desperately to contain widespread and persistent smallpox. The task was made more difficult by the wide dispersal of the population, more than half of whom lived more than a day's walk from any sort of road in extraordinarily rugged terrain; by a rudimentary governmental infrastructure; and by a dearth of health facilities and manpower. Continuing civil war, hostile groups who resisted vaccination, famine and flood further complicated the effort. Yet, surprisingly good progress was made with the limited resources available. However, smallpox persisted stubbornly throughout vast rural areas, in contrast to the situation in Yemen, in which control measures in the few urban areas were quickly succeeded by the interruption of transmission in the country as a whole. Following the eradication of smallpox in Asia in 1975, greater resources could be made available to Ethiopia, and the new revolutionary government gave substantial additional support. An intensified programme with more adequate resources succeeded in interrupting transmission in August 1976.

The 3 national programmes are described in this chapter in chronological order of commencement, beginning with a brief account of activities in Yemen and Democratic Yemen and concluding with a more detailed description of the Ethiopian programme, which was one of the most difficult, complex

and imaginative of any national eradication campaign.

In this chapter, the spelling of Ethiopian geographical names adopted by the Ethiopian Mapping Agency in 1978 has been followed (Tekeste et al., 1984).

YEMEN

Yemen, the most densely populated country in the Arabian Peninsula, is situated on an ancient route used by pilgrims, many of them from Asia and some from Africa. After travelling by sea to the port of Aden, 100 kilometres to the south of Yemen, or to other ports on the Arabian Peninsula, or overland, many pilgrims passed through Yemen on their way to Mecca.

The country has an area of 195 000 square kilometres and consists of 3 different geographical regions. The first is a hot arid semi-desert strip, 30–70 kilometres wide, extending along the shores of the Red Sea and inhabited, in 1967, by perhaps 20% of the population, many of African origin. The second area, inhabited by 75% of the population, is a high plateau, about 100 kilometres wide, with densely populated river valleys and scattered villages among rugged mountains. The third area, in the east of the country, is a sparsely populated arid desert in which, in 1967, not more than 5% of the population lived.

Until 1962, when it became a republic, Yemen had been ruled by feudal tribal leaders and was largely isolated from the outside world. According to the first census, taken in 1975, 5.2 million persons were living in the country, and an estimated 1.2 million were working abroad, mainly in Saudi Arabia. Less than 1000 kilometres of roads connected the 3 main towns, Sana'a (population, 100 000) and Taiz (population, 30 000) in the mountains and Hodeida (population, 50 000) on the coast. Most of the population lived in an estimated 15 000 villages, the majority of which could be reached only on foot or on muleback.

During the rule of the tribal leaders, neither health nor educational facilities had been widely developed and such facilities as did exist were primarily confined to the 3 main towns. When the country became a republic in 1962, efforts were made to introduce a modern form of central government, but they were severely hampered by 5 years of civil war. In 1967, more than 90% of the population was illiterate and few people had access to either curative or preventive health services. As recently as 1978, 70% of the 162 districts in the country had no health facilities whatsoever.

Little is known about smallpox in Yemen, there having been no national reporting system until 1975. However, because of the relative isolation of the population, outbreaks were probably infrequent in much of the country. Data from what had been the Protectorate of South Arabia, which included the port of Aden, now the capital of Democratic Yemen, show few or no cases and very few deaths in recent decades, until 1957, when 65 cases with 19 deaths were recorded. The source of infection was reported to have been Pakistan. Outbreaks continued in the Protectorate between 1957 and 1961, and smallpox may well have spread from Aden to Yemen, in which an epidemic started in 1957 or 1958 and continued for several years. It was said to have resulted in not less than 30 000 cases and 18 000 deaths. Assistance from WHO was requested and a team was sent to investigate in June 1959. The team found no active cases in Sana'a, the capital city, but noted large numbers of persons with facial pockmarks. A report from a village of 800 inhabitants stating that only 200 of them had survived the epidemic was indicative of its severity. The evidence, such as it is, suggests that a severe epidemic of variola major had occurred among a population which had experienced little smallpox in recent decades.

During succeeding years, some vaccine was provided by WHO and through bilateral assistance. Vaccination was made available in hospitals in the 3 major towns and at the 20 or so health centres when outbreaks occurred. However, not more than 15 000 or 20 000 individuals were vaccinated each year. In 1962, with assistance from WHO, a national vaccination campaign commenced. Forty vaccinators were recruited and trained; the population of Sana'a was vaccinated in a house-to-house campaign, but thereafter these activities diminished with the gradual intensification of civil strife. Reports obtained during the certification procedure in 1978 suggest that the epidemic of variola major subsided in 1963. WHO was officially notified by Yemen of the occurrence of 5 cases of smallpox in 1964, of 1 case in 1966 and of 3 in 1967, but nothing more is known of these cases or where exactly they occurred.

Reporting at that time was not good and WHO did not endeavour to elicit more complete information about cases until the Intensified Programme was well under way.

In 1967, Yemen was provisionally classified by WHO as an endemic country with the expectation that an effective surveillance programme would probably reveal many hundreds, if not thousands, of cases. Because one of the principal routes of the Mecca Pilgrimage passed through it, Yemen constituted a potential focus for the spread of smallpox to Africa and other countries of Asia. The early initiation of an eradication programme was therefore thought to be vitally important. However, a *coup d'état* in 1967 and continued fighting between republican and royalist forces delayed the start of the work.

In 1968, discussions with government officials led to the approval of a plan of operations for a WHO-supported programme, to begin in July 1969. WHO agreed to provide a medical officer, vaccine, vehicles and a per diem allowance for national staff travelling in the field. In the course of the following decade WHO provided some US$313 000 in support of the programme (about US$0.06 per head of population), as well as 3 million doses of vaccine (Table 21.1). The government agreed to provide a counterpart medical officer, 53 vaccinators and 20 auxiliary staff for a 3-year national vaccination campaign during which it was planned to vaccinate 4 million persons (Table 21.2). The development of surveillance was considered an essential component of the plan although it received little attention from the programme staff.

Table 21.1. Yemen: WHO support provided to the smallpox eradication programme, 1967–1979

1973	170 000	-	0
1974	21 000	-	0
1975	425 000	-	0

[a] According to plan of operations (1968) for mass campaign.

Headquarters were established in Sana'a under the national programme director, Dr M.K. Al Aghbari, and in July a WHO epidemiologist arrived. Because of the paucity of health staff and facilities, the smallpox eradication programme was envisaged as one which would lay the foundation for other national communicable disease control activities.

A house-to-house vaccination campaign began in October 1969 and at first progressed reasonably well, with assessment showing more than 90% coverage. By the end of the year, 119 752 residents of Sana'a and 192 surrounding villages had been vaccinated, 25% of them for the first time; 80 000 people were vaccinated in other parts of the country. In 1969, 29 cases of smallpox were officially reported by the government to WHO, although at a WHO regional smallpox eradication seminar held in November of that year, the government submitted a report indicating that 47 smallpox cases had occurred. The WHO smallpox adviser in Yemen was asked to investigate and confirm these cases; he merely reported that he thought they were all cases of chickenpox. It was not long before the reliability of his observations was called into question when, in a quarterly report, he stated that, having examined the staff of the smallpox eradication programme, he had been able to ascertain that none were "carriers" of the disease. The quality of surveillance in Yemen did not improve materially thereafter.

In January 1970, when vaccination could be more readily performed than during the intolerably hot summer months, the vaccination campaign shifted to the coastal strip (Fig.

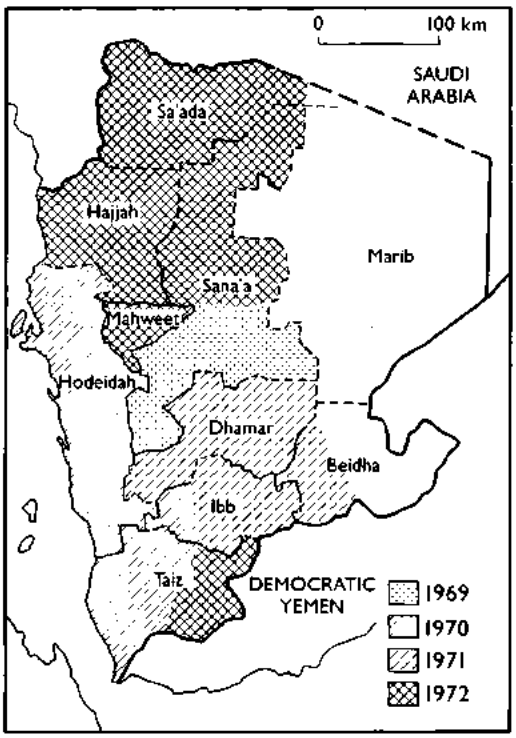

Fig. 21.2. Yemen: progress of the smallpox vaccination campaign, 1969–1972.

21.2). Three vaccination units, each equipped with a vehicle and consisting of a national supervisor and 8 vaccinators, proceeded systematically through the area performing house-to-house vaccination. Staff from the local health services, where such existed, worked with the teams in the expectation that they would continue maintenance vaccination after the teams had left. Each vaccinator averaged about 140 vaccinations a day. An assessment team checked vaccination takes and coverage 1 week later. By the end of the year, more than 800 000 people had been vaccinated.

Towards the end of 1970, the vaccination campaign began to deteriorate. Dr Al Aghbari was asked to assume direction of all preventive services for the Ministry of Health and was therefore obliged to spend less time in the field; project vehicles broke down more often and the field staff began to take increasingly frequent and extended holidays. The WHO adviser rarely left the capital city, and in March 1971 his assignment was terminated.

During the whole of 1971, only 290 000 persons were vaccinated; the level of coverage was unknown because assessment had ceased. The few reports of smallpox received were seldom investigated; the cases that were examined were diagnosed as chickenpox or dermatitis. The vaccination campaign was gradually extended to most other areas of the country and finally concluded in April 1973, although the inhabitants of most rural areas throughout the north and east remained unvaccinated. Only 231 000 persons were vaccinated in 1972, 45% of them for the first time. From the campaign's inception to its conclusion, the staff succeeded in vaccinating only about 2 million persons—less than half the estimated population. Of this number, nearly 300 000 were vaccinated by teams of the Swedish Save the Children Foundation, who were then providing health services in coastal areas of the country.

The government was dissatisfied with the programme and repeatedly requested the WHO Regional Office for the Eastern Mediterranean to assign another full-time WHO epidemiologist. This request was not met until April 1973, when the former WHO smallpox adviser in the Sudan, despite an unsatisfactory performance there, was transferred to Yemen. In addition to dealing with smallpox, he was made responsible for developing a preventive medicine section in the Ministry of Health and creating a health statistics unit.

About the time of his arrival, the systematic vaccination campaign was terminated and the teams were disbanded. Vaccination continued to be offered through existing health facilities. However, of the 170 000 recorded vaccinations in 1973, 60% were reported to have been given to adults who required international certificates of vaccination in order to leave the country.

None of the health units provided weekly or monthly reports of smallpox cases nor did they submit reports on other diseases. When suspected cases of smallpox were notified, national staff or the WHO epidemiologist investigated them and sent specimens to one of the WHO reference laboratories. In all, 26 specimens were submitted during the 7-year period 1971–1977. None contained poxvirus.

In 1975, a monthly communicable diseases reporting system was at last introduced and reports of smallpox and chickenpox were carried by hand to the capital. This was intended to facilitate investigation by the newly created Department of Preventive Health Services, consisting of a national medical officer, the WHO epidemiologist and

a clerk. Most of the reports received were from the 3 major towns. Five suspected cases of smallpox and 79 cases of chickenpox were reported in 1975 and 2 suspected cases of smallpox and 88 cases of chickenpox in 1976. None of them was confirmed to be a case of smallpox.

From 1970 to the end of 1977, neither WHO Headquarters staff nor the WHO regional smallpox adviser had devoted much attention or effort to the programme in Yemen. Smallpox eradication in other parts of the world commanded a higher priority. Because no confirmed cases of smallpox had been reported from Yemen since 1969 and none was being detected among the numerous pilgrims or Yemeni workers who travelled to Saudi Arabia and to other countries, WHO staff were cautiously hopeful that smallpox transmission had been interrupted.

By the autumn of 1977, when smallpox had been eliminated in Ethiopia (see below) and its interruption in Somalia was imminent, a more detailed appraisal of the situation in Yemen was considered to be essential. A WHO smallpox consultant who visited the country in September 1977 found large numbers of refugees from Ethiopia and some from Somalia living in villages along the coastal desert strip. Few had vaccination scars. An extensive vaccination campaign and search for cases were subsequently initiated in this area, but no cases were found.

In December 1977, another WHO consultant travelled through the highland areas, and, although he found no cases, he discovered that only people living in the larger towns and along the principal roads had been vaccinated during the campaign. Many of the more remote villages had not been visited by programme staff or vaccination teams for 6–8 years. If variola minor had been imported—from Ethiopia, for example—he believed that it might still be present, spreading slowly through sparsely settled areas, as had been the case in Ethiopia. Accordingly, it was deemed essential to conduct a thorough country-wide search for cases.

From June 1978 to the end of March 1979, a search programme under the direction of an experienced WHO epidemiologist, Mr Robert Steinglass, was conducted by Yemeni staff assisted by personnel of the Swedish Save the Children Foundation and Peace Corps volunteers from the USA, who were engaged in other health programmes in Yemen at that time. Three surveillance teams, each consisting of a team leader, 1 or 2 surveillance workers, a driver and locally hired temporary staff searched 146 of 162 districts and 920 villages and towns with a population of more than 500 persons. In all, 116 184 persons were examined in villages and towns whose total number of inhabitants amounted to 897 488—i.e., 13% of Yemen's resident population. Four hundred and eighty reports of illness with rash and fever were investigated; 43 specimens were submitted for laboratory examination, but none showed evidence of smallpox.

Vaccinial immunity was low, as had been expected. Only 23% of children under 4 years of age and only 63% of the population as a whole had vaccination scars (Table 21.3).

Of 2514 persons with the facial pockmarks of smallpox none was younger than 11 years of age and none had experienced smallpox

[a] The Governorate of Marib (population 40 896) was not accessible to government staff and thus area-wide search was not possible.

after 1969. Persons with facial pockmarks were found in 95% of the 146 districts and in 72% of the villages. More than 60% had contracted the disease during the 1957–1963 epidemic.

It had been feared that smallpox eradication in Yemen would present a formidable problem; ironically, the last known cases had occurred just before the mass vaccination campaign began in October 1969. Natural immunity conferred by the extensive epidemic of variola major in 1957–1963, coupled with the practice of variolation, apparently served to reduce the number of susceptible subjects to a sufficiently low proportion of the population that transmission ceased. It is possible that undetected importations, notably from Ethiopia, Yemen's nearest endemic neighbour, may have occurred, but if so they terminated spontaneously. Whatever its problems, the programme served eventually to foster an infectious disease reporting system and provided an impetus to a broader immunization programme, which commenced in 1977.

DEMOCRATIC YEMEN

Democratic Yemen occupies a vast barren area in the south-western part of the Arabian Peninsula, but as was revealed in its first census in 1973, 55% of the country's population of 1.6 million lived in 12% of the land area in and around Aden, the capital. In 1967, Democratic Yemen was considered to be free of smallpox, the last endemic case having occurred in 1960. However, it was thought to be at high risk of importations. Ships carrying Mecca pilgrims from Asia and Africa regularly called at Aden; and travellers as well as refugees, especially from areas of Ethiopia with endemic smallpox, were numbered in the tens of thousands. Accordingly, a WHO-supported programme was planned for Democratic Yemen.

Until it achieved independence in 1967, the area constituting Democratic Yemen consisted of the British crown colony of Aden and a large number of loosely federated independent sultanates and sheikdoms, known as the Protectorate of South Arabia. Over past decades, occasional small outbreaks of smallpox, usually attributed to cases imported by pilgrims, had been reported from Aden. The last officially notified outbreaks occurred between 1957 and 1961, during which 341 cases with 105 deaths were recorded, primarily in the western part of the country. The outbreaks were said to have resulted from a series of different importations from India, Pakistan and Yemen. They were controlled by mass vaccination. Twenty-four cases of variola minor, which were not officially reported to WHO but were nevertheless recorded in a government document, occurred in 1965 in the eastern part of the country. As in other countries, there were undoubtedly other unreported cases, but in this very sparsely settled area it was difficult for smallpox transmission to be sustained; any importations that may have occurred ceased spontaneously.

Vaccination with liquid vaccine had been fairly extensively practised in the British crown colony of Aden for many decades. In the less populated areas to the east, protection against severe smallpox was more frequently achieved by variolation. The outbreaks of 1957–1961 had occasioned an extensive vaccination campaign in Aden, some 338 000 vaccinations having been recorded between 1957 and 1959. In 1960, freeze-dried vaccine was first made available by UNICEF for a vaccination campaign, but until 1970, it was uncommon for more than 50 000–75 000 persons to be vaccinated each year.

In September 1969, WHO agreed to support an eradication programme, basically a village-by-village campaign to administer smallpox vaccine to all persons and BCG vaccine to those under 15 years of age. WHO supplemented the salary of the national programme director, paid the national staff a per diem, provided vehicles, vaccine and other supplies and equipment, and made funds available for petrol and vehicle repairs. WHO eventually provided about US$206 000 and more than 1.8 million doses of vaccine in support of the programme (Table 21.4).

The national staff comprised 48 persons, including 32 vaccinators who worked in 4 operational groups, each with 4 vaccination teams consisting of 2 men. The vaccination campaign proceeded on a house-to-house basis and was regularly assessed by a special team. Because of security problems, operations were initially restricted to 3 of the country's 6 governorates that were located in the immediate vicinity of Aden. In September 1971, one of the programme vehicles, carrying 10 vaccinators and the driver, was destroyed by a land-mine, which killed 4 of the vaccinators and injured the others. Under-

Table 21.4. Democratic Yemen: WHO support provided to the smallpox eradication programme, 1967–1979

Year	Personnel, supplies and equipment (US$)	Doses of vaccine (thousands)
1967	–	–
1968	–	150
1969	22 941	35
1970	17 801	–
1971	22 297	350
1972	1 100	–
1973	26 174	220
1974	17 000	602

1978	49 584	96
1979	328	62
Total	206 230	1 815

standably, the staff feared to venture too far from the capital. Not until 1973 did civil disorder subside sufficiently to permit the extension of vaccination activities into all governorates.

As is shown in Table 21.5, the number of vaccinations performed annually from 1970 onwards ranged between 169 364 (1971) and 302 296 (1973). Productivity was not high, each vaccinator averaging about 50 smallpox vaccinations and 10–20 BCG vaccinations a day. This was partly attributable to the difficulty of travelling through the generally rugged mountainous country, with few roads. Assessment figures indicated that the coverage achieved was consistently about 90%, but it took 7 years for a total of 1.5 million vaccinations to be performed, a number approximately equivalent to the population. During this time, some 514 000 BCG vaccinations were also administered.

Despite the strategic location of Democratic Yemen and the apparent risk of importations, no cases were confirmed after 1967. A single case in Aden was reported to WHO in 1968 but the report was later retracted in the belief that the illness had been chickenpox. The absence of known importations can be explained in part by diminished maritime traffic associated with the closure of the Suez Canal from 1967 to 1975 and in part by restrictions on travel imposed by the government after independence in November 1967. Conceivably, outbreaks may have been overlooked since neither a surveillance nor a morbidity reporting system was ever developed. However, extensive surveys conducted during the country's programme in 1978 to certify the absence of smallpox failed to detect any person who had been infected with the disease since 1966. These surveys also showed that, in the different governorates, between 76% and 90% of the population had vaccination scars—a high level of vaccinial immunity.

Table 21.5. Democratic Yemen: number of vaccinations performed and number of reported cases of smallpox, 1967–1975

Year	Number of vaccinations	Number of reported cases
1967	10 830	0
1968	46 720	0
1969	26 233[a]	0
1970	302 202	0
1971	169 364	0
1972	245 628	0
1973	302 296	0
1974	181 277	0
1975	242 881	0

[a] Six months only.

Contrary to expectations when the programme began, Democratic Yemen did not experience problems with smallpox; in retrospect, a special vaccination programme may have been unnecessary. However, the combined smallpox and BCG vaccination campaign did provide a basis for the establishment of a national immunization programme.

ETHIOPIA

Ethiopia was 6 times larger in area (1.2 million square kilometres), with a population (25.5 million in 1970) more than 5 times greater than that of Yemen, but the problems of geography and population dispersion were similar. Most of Ethiopia's population was widely distributed in small groups of huts scattered across the central highlands (Fig. 21.3) at 1500–3000 metres above sea level. Rugged mountains and deep ravines made travel extremely difficult throughout this area, and impossible during the rainy season, from June to September. At the periphery of the country were lowland areas in the west and south-west, with a fertile and more populated savanna grassland. Nomads roamed the vast Danakil and Ogaden deserts to the east, moving freely across the unmarked borders with Somalia and the French Territory of the Afars and the Issas (later Djibouti). Less than 10 000 kilometres of all-weather roads connected the few scattered cities and towns. Health facilities and trained health

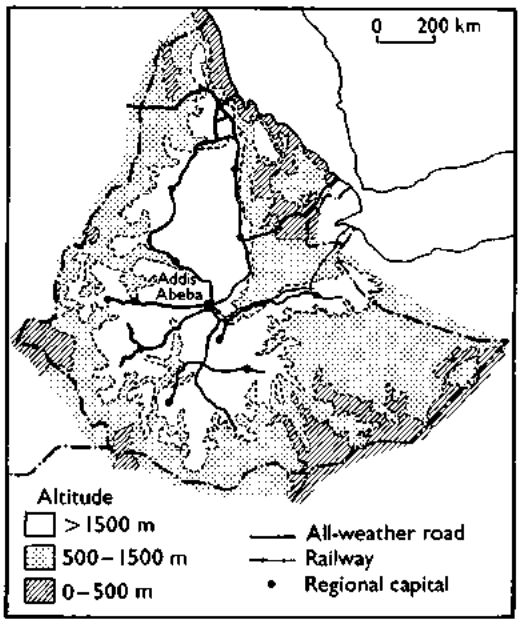

Fig. 21.3. Ethiopia: topography and road system.

staff were few; vaccination was all but unknown to most of the population, but variolation was widespread. Several hundred cases of smallpox were reported each year, but in 1967 it was surmised that thousands of cases must be occurring.

Throughout the world, experience had shown that smallpox transmission was not readily sustained in sparsely settled areas. Elimination of smallpox from urban centres and the accessible, more populated rural areas usually resulted in the disease dying out spontaneously in the more remote parts of a country. In Ethiopia, this did not happen. Here, among a dispersed, thinly settled population, the global eradication of smallpox came nearest to being thwarted, as an unparalleled array of problems and catastrophes continually hampered the programme. Nearly 6 years elapsed after the campaign had begun before the last outbreak was finally discovered and contained, in August 1976.

A detailed account of the programme is presented in the book *Smallpox Eradication in Ethiopia* by Tekeste et al. (1984), from which most of the data in this chapter are drawn.

Background

Ethiopia, in 1967, was one of the world's least developed countries, and until 1974 it was a monarchy with numerous feudal landlords. The infrastructure of services for health, education, transport and communications was rudimentary except in the northern province of Eritrea, in which a number of roads and health centres had been built during the Italian and British administrations.

Administratively, the country was divided into 14 provinces (which, after the 1974 revolution, became 15 regions), each with a governor, who was usually a member of the royal family. Each province was subdivided into *awrajas* (102 in the country as a whole) and these, in turn, into *woredas* (539 all told), each with its appointed governor or administrator. At the local level, the feudal, often absentee, landlord was the acknowledged headman, but he was frequently indifferent and sometimes hostile to higher government authority. To obtain assistance with the programme at each administrative level a special letter requesting cooperation had to be prepared by a superior and taken by messenger to the official concerned.

No census had ever been taken but it was thought that no more than 2 million of the estimated 25.5 million population lived in about 200 towns and villages of 500 or more persons. In the rural areas of the plateau, the houses were widely scattered. There, the smallest traditional unit, sometimes referred to as a village, was the *mender*, consisting of up to 100 houses occupied by one or more related families. Fifty or more *menders* comprised a *deber*, which included the membership of a single church. After the 1974 revolution and nationalization of the land, workers' cooperatives, called "farmers' associations" or "urban dwellers' associations", were created and village areas were defined. The villages, however, were unlike those in most other countries in that they usually extended over large areas, the distance between houses often ranging from a few hundred to a thousand metres. In the extensive eastern and southern scrub desert areas, which comprised half the country, nomadic groups with ethnic ties to the neighbouring French Territory of the Afars and the Issas and Somalia wandered freely, not infrequently crossing open borders between the countries. In the south-west were tribal groups whose way of life was little more advanced than that of a Stone Age culture.

Roads of any type were few; more than 85% of the population lived further than 30 kilometres away from the nearest all-weather road (Ayalew, 1982). Travel from place to

place during the dry season was largely on horse- or muleback or by foot. When torrential rains occurred in the highlands, between June and September, large areas became completely inaccessible. Communications were poor: an unreliable, frequently unusable, telephone service linked the capitals of provinces, and the postal service was deficient.

Language presented a further problem. The people of Ethiopia consisted of 10 major ethnic groups speaking 70 languages and dialects. Frequently, programme staff had to communicate successively through two or three different interpreters to question villagers about the existence of smallpox and to explain the unfamiliar practice of vaccination. Some people were reasonably receptive, but refusal and sometimes active resistance were encountered among many who lived in the highland areas in the north and central parts of the country. Not surprisingly, smallpox proved to be particularly tenacious in those areas.

Health personnel and facilities in 1967 were concentrated in Addis Abeba, the capital, and in Eritrea. The largest proportion of the government's health budget was allocated to curative services, to which not more than 5% of the population had access. Government records for 1967 show a census of 84 hospitals and 64 health centres and a total of 362 physicians and 2800 other health staff. For 40% of the population, a journey of 3 days or more, and for another 30%, a journey of 1–2 days, was required to reach the nearest health unit. Personnel engaged in the administratively separate malaria eradication programme were far more numerous than the national health services staff. In all, 8000 malaria eradication staff were distributed over about one-third of the country. They were concerned only with malaria and were supported under a bilateral assistance programme.

Protection against smallpox was often provided through variolation. This was usually performed by the head of a household among family members after cases began to occur in the vicinity. The Afghan type of professional variolator, who travelled widely and preserved scabs and pustular material over long periods of time, was uncommon. Data on the number of smallpox vaccinations performed annually before 1971 are not available but estimates indicate the total to be less than 500 000. Most of them were performed in hospitals and clinics; a few were given by an "Anti-epidemic Service", a small mobile unit which vaccinated people in and around Addis Abeba when outbreaks were reported. The vaccine, which had been produced at a government laboratory in Addis Abeba since 1953, was of the thermolabile liquid variety. In the mid-1960s, however, the preparation of a freeze-dried vaccine began, but this could not be tested for potency owing to a lack of fertile eggs. When it was eventually examined by a WHO reference laboratory, it was found to be unsatisfactory. In 1970, freeze-dried vaccine was provided by WHO and vaccine production in Addis Abeba ceased.

Little is known about the prevalence, extent and severity of smallpox before 1971. Epidemics with high mortality were said to have occurred every 10–30 years during the 19th century. Annual statistical compilations that date from 1931 show as many as 2832 cases in 1956 but comparatively few in most years. The cases that were reported were among hospitalized patients in the few urban

WHO / T. FARKAS

Plate 21.1. A variolator in Ethiopia obtaining pustular material from a patient (*lying*) and inoculating it into the arm of a healthy recipient (*standing*). Variolation was usually performed by one of the elders in a family and was widely practised throughout Ethiopia. The last known patient in Ethiopia (August 1976) developed illness following variolation. (Detail from a painting by Zerihun Yetmgeta presented to WHO by the Government of Ethiopia.)

Variolation and Receptivity to Vaccination

Smallpox was widely recognized and feared by the different ethnic groups throughout Ethiopia, each of which, in the absence of vaccination, dealt with it in a different manner. Among the Amharas, who largely populated the central zone provinces and Shewa, and among the nomads of the eastern desert areas, protection was obtained through variolation, which was practised widely when outbreaks occurred. Many Amharas resisted vaccination in favour of variolation and religious ceremonies that consisted in decorating the dwelling of a patient with fresh green leaves, grasses and flowers and in burning incense. Sheep, goats and hens of different colours were sacrificed and ritual play-acting and singing were performed to induce the disease to take a mild form. Other groups had other practices and rites. When smallpox occurred, the Nuers, a Nilotic tribe living near the Sudanese border, performed a ceremony in which a prophet would lead the people to a river where goats were sacrificed to the "mother of gods", who was thought to live in the river; in a ceremony of joy, the assembled crowd would then bathe in the river.

For reasons which are unclear, most ethnic groups in the south and east of the country readily accepted, indeed actively sought, vaccination whether or not they performed variolation. Among Galla groups, who inhabited large areas of provinces in the south-west and south-east, people returned many times for vaccination, and many villages reported falsely that outbreaks were occurring in order to induce the teams to visit. In this area, it was not uncommon for teams to discover crudely scribbled notes left along trails requesting visits to villages as distant as 40–50 kilometres.

centres. There is no information on the number of deaths. After 1971, when the eradication programme began and more complete data became available, only the mild variola minor form of smallpox was found. Variola major had disappeared, but it is not known when this occurred. Variola minor was documented as early as 1958, but as recently as 1964 a smallpox outbreak with a high case-fatality rate typical of variola major was reported by a health officer in the central highlands.

Delays in Launching an Eradication Programme

At the inception of the Intensified Smallpox Eradication Programme in 1967, Ethiopia was considered to be strategically important as an endemic country. The neighbouring areas of the French Territory of the Afars and the Issas, Somalia and the Sudan were thought to be free of smallpox. Kenya, with an extensive network of health services and a more complete notification system, was reporting fewer than 200 cases a year. If reinfection of adjacent countries was to be averted, a programme would have to be started in Ethiopia as soon as possible.

Government officials stated, however, that they were not interested in undertaking a smallpox eradication programme and could not do so because so many resources were already committed to malaria eradication. They reasoned that one eradication programme must be as expensive as another, a belief encouraged by expatriate malaria advisers. Given that the Ethiopia malaria eradication programme was then disbursing more than US$8 million a year, primarily from bilateral contributions, and that it employed 8000 workers, their apprehension was understandable. The government authorities did not appreciate that a smallpox eradication programme was far simpler, cost much less and required far fewer personnel than a malaria eradication programme. Moreover, WHO staff believed that smallpox eradication in Ethiopia might be combined successfully with other health activities then being considered, including a BCG vaccination programme in urban areas and a proposed yellow fever vaccination campaign which the Federal Republic of Germany was expected to support. The most extensive resources available were those of the malaria eradication programme itself. It was felt that much could be accomplished if its directors would permit the thousands of malaria workers to serve as smallpox surveillance agents and to vaccinate those encountered during their regular house-to-house visits. In addition, several

projects staffed by United States Peace Corps volunteers were then in operation in Ethiopia and it was understood from United States government officials that they would be receptive to a request to provide manpower to health-related projects.

WHO smallpox eradication staff believed that a suitable, economically feasible and acceptable plan for at least a control programme, if not for eradication, could be developed. To do so would require appraisal and discussion in Addis Abeba of potentially available resources and of the cost and options for the conduct of such a programme. Repeated proposals were made to the government that WHO regional and Headquarters staff should make an exploratory visit, but for nearly 3 years these proposals were firmly declined. Initially, this reaction was difficult to understand because most governments were more than willing to discuss possible options, whether or not they were inclined to undertake a programme. Gradually, however, it became known that the United States malaria eradication programme adviser and his Ethiopian counterpart had persuaded the Minister of Health that a smallpox eradication programme would fatally compromise the malaria eradication campaign, which was then making little progress. They advised that, under the circumstances, his best approach would be to refuse to receive WHO smallpox eradication staff, even for exploratory discussions.

The impasse was not readily resolved. The strategy and the projected order of magnitude of needs for smallpox eradication were discussed in Geneva at the World Health Assembly with Ethiopian government officials and malaria advisers from the USA, with bilateral assistance staff in Washington and with malaria staff at the United States Center for Disease Control—all to no avail. An indirect approach to the government was planned when Dr George Lythcott, senior adviser to the United States-aided western and central African smallpox eradication programme, was invited to speak about that programme at a meeting of the Organization of African States in Addis Abeba. Having been briefed by WHO staff and being prepared to hold informal meetings with Ethiopian government officials, he was about to leave for Addis Abeba when United States officials abruptly and without explanation cancelled his trip.

Nearly 3 years had elapsed when, inexplicably, in October 1969, the government responded favourably to yet another proposal for an exploratory visit. Dr Ehsan Shafa, then Regional Adviser on Smallpox Eradication at the WHO Regional Office for the Eastern Mediterranean, and Henderson flew immediately to Addis Abeba. The response to the proposed visit had been sent by a subordinate when the Minister and Secretary of Health were absent on a trip abroad. They were not pleased, on their return, to find the WHO team awaiting them; they made it clear that Ethiopia's attitude had not changed. They did agree, however, that Henderson and Dr Shafa could devote 2 weeks to the preparation of a plan which the government would consider. In view of WHO's budgetary limitations and the obvious antipathy of the government, it was apparent that whatever programme might be devised would have to be a modest one. The malaria eradication programme's considerable resources in manpower and transport offered a potential building block, but its director declined to cooperate in any way. There were no other immunization programmes and little assistance could be expected from the few existing health units. However, tentative offers to provide volunteers were made by the USA and Japan. Among the many officials to whom Henderson and Dr Shafa spoke was Dr Kurt Weithaler, then serving as director of

BY COURTESY OF D. A. HENDERSON, 1971

Plate 21.2. Kurt L. Weithaler (b. 1919), an experienced health administrator, served as the senior WHO adviser to the Ethiopian smallpox eradication programme from 1970 to 1976.

the hospital for the Emperor's Imperial Guard. Dr Weithaler, an Austrian, had been employed by the government for more than a decade, was widely known in government and medical circles, served as a member of the Health Minister's advisory panel the General Medical Board—and was a friend of the Emperor. He expressed considerable enthusiasm for the programme and intimated that he might be persuaded to serve as WHO's senior adviser. The draft plan of operations was presented to the Minister on a Saturday for consideration that weekend and a decision on Monday. He expressed little interest. Meanwhile, unbeknownst to the WHO team, Dr Weithaler showed the plan to the Emperor, who agreed that it should be initiated and ordered the Minister of Health to support it.

The Programme Begins, 1971

The draft plan of operations envisaged: (1) a search for outbreaks and their containment to the extent possible with the available manpower; (2) the development of a simple surveillance programme for the reporting of cases and vaccination by the staff of existing health facilities; and (3) mass vaccination in Ethiopia's few centres of population. It was hoped that, with the limited personnel and equipment that could be provided, smallpox transmission might be successfully interrupted in the accessible areas. It was to be hoped that the disease would then die out spontaneously in at least some of the rural areas. However, since a relatively small proportion of the population lived in accessible areas and since vaccinial immunity was undoubtedly as low as anywhere in the world, the proposition was uncertain. All the same, a less than fully effective control programme was better than no programme at all.

A staff of about 70 was envisaged. The government requested that a senior WHO medical officer should be appointed as "the responsible executive authority", and the energetic Dr Weithaler was recruited to fill the post. It was exceptional in most countries for a person assigned by WHO to serve in this capacity but, in Ethiopia, in which trained personnel were in short supply, such an appointment was considered essential. A WHO epidemiologist was to be appointed for surveillance, and Dr Ciro de Quadros, who had served previously on the national staff of the Brazilian smallpox eradication programme (see Chapter 12), was selected for this post. The government assigned as the senior national professional Ato Tamiru Debeya, a respected and able person who retained this responsibility through 1975. His title was that of sanitarian but, in Ethiopia at that time, such persons had a broad public health training and served as administrators for many public health programmes. Twelve other workers were to be assigned to the headquarters office—3 drivers, 8 office staff and a most competent locally recruited WHO administrative officer, Ato Tefari Seyoum. For assignment to the field, the government agreed to provide 21 staff, health officers or sanitarians, who would work with volunteers from the USA. The health officers played an exceptionally important role; they were graduates of a recently established 4-year course of study in the health sciences which was designed for students who had completed secondary school.

Ethiopia's financial commitments consisted only in paying salaries of its health officers and sanitarians, all of whom were transferred from other programmes, and meeting the cost of office accommodation. WHO provided all supplies and equipment and covered the cost of transport, as well as

E SHAFA, c. 1973

Plate 21.3. Ciro C. A. de Quadros (b. 1940) worked in the smallpox eradication programme in Brazil before joining WHO and the programme in Ethiopia, 1970–1976. In 1977, he became regional adviser for the Expanded Programme on Immunization in the Americas.

the per diem allowances of Ethiopian staff and the salaries of the central office staff. The salaries and expenses of the volunteers were borne by their respective governments. WHO provided, in all, US$175 562 in 1969–1970, in addition to supplies of vaccine (Table 21.6). Eventually, the Organization was to spend nearly US$13 500 000 from its regular budget and from contributions made by numerous governments to the WHO Voluntary Fund for Health Promotion and to contribute more than 23 million doses of vaccine. The Ethiopian government spent US$1 360 546. Additional support, amounting to about US$1 390 000 was provided, in cash and in kind, through bilateral contributions from Austria, the Federal Republic of Germany, Japan and the USA. The total support to the programme amounted to about US$0.57 per head of population.

During the autumn of 1970, personnel were recruited, the volunteers from the USA arrived, equipment was delivered, a central office was established, training programmes were conducted, and by mid-January 1971, field operations began. At that time, there were only 3 other countries in Africa in which smallpox remained endemic—the Sudan, Zaire and South Africa. The latter 2 succeeded in interrupting transmission in 1971 (see Chapters 18 and 20).

For a programme in one of Africa's last endemic countries—one of its largest and least developed—the available resources were few indeed. Over the first 6 months, the entire field staff consisted of only 39 persons—the 2 WHO advisers, 2 health officers, 19 sanitarians and 16 United States volunteers. They had only 6 Land Rovers between them, although 11 more were scheduled for delivery that summer. In the interim, it was hoped that vehicles might be borrowed from the malaria eradication programme's large reserve pool of vehicles, which were parked at a training centre south of Addis Abeba. A request was made, but the vehicles mysteriously vanished. The request was denied on the grounds that all vehicles were in use. (It was later learned that they had been transferred to a motor pool in a remote desert area.)

It was decided to concentrate personnel and vehicles in the 4 provinces of the south-western zone: Gamo Gofa, Kefa, Ilubabor and Welega (Fig. 21.4; Table 21.7). Besides being epidemiologically important because they bordered on the Sudan, these provinces had a better health service structure than most, and the people's acceptance of vaccination was generally good. Two additional vehicles and teams were assigned for work in Addis Abeba and the surrounding Shewa Province. One sanitarian was assigned to each of the other provinces to establish a smallpox eradication programme office in or near the office of the provincial medical officer. His duties were to report weekly any cases of smallpox that were discovered, to compile a list of health facilities, and to visit them, by bus or mule, in order to provide vaccine and to encourage them to report cases and to vaccinate. In the 4 priority provinces, these functions were to be undertaken by the teams,

which were also expected to carry out an active search for cases and to contain by vaccination any outbreaks that were found.

To provide encouragement and guidance to the smallpox eradication staff and other health personnel throughout the country, Dr de Quadros, in January 1971, inaugurated the publication of a surveillance report which documented smallpox incidence and conveyed important information and instructions. The report was at first distributed monthly to health personnel and relevant government officials throughout the country; late in 1974, weekly publication began. The report proved of inestimable value in securing cooperation and support and also served to sustain morale among the widely distributed smallpox eradication staff, who could contact each other only infrequently.

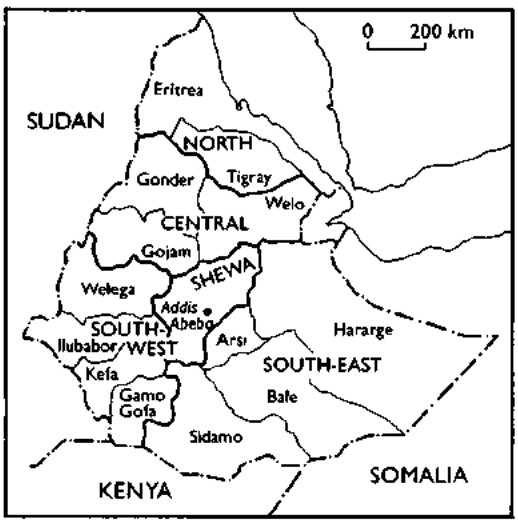

Fig. 21.4. Ethiopia: zones and provinces, 1970.

The number of cases that might be discovered when the teams reached the field was a subject of intense speculation. Ethiopia had reported only 197 cases in 1969 and 722 cases in 1970. It was recognized that smallpox was greatly underreported, but the extent of the underreporting was unknown. Although few vaccinations were being performed, variolation had been extensively practised throughout the country and had undoubtedly rendered many persons immune. To obtain some idea of the possible extent of smallpox, Henderson and Dr Shafa, during their visit in 1969, had questioned many health officers, mission health personnel and others, both in Addis Abeba and on a field visit to Welega Province. Surprisingly, few persons reported having seen many cases of smallpox recently and some reported having seen no cases whatsoever for many years. Although the survey was brief and incomplete, it fostered the hope that smallpox might be uncommon in the sparsely settled rural areas and that continuing endemic transmission might be confined primarily to the comparatively few populous areas.

Whatever the smallpox situation may have been in 1969, it differed greatly in 1971 from

Smallpox Surveillance and Containment in the South-west Zone in 1971

One volunteer, Mr Vincent Radke, has described his own initial surprise at the magnitude of the smallpox problem and the necessary adaptations in procedures which field staff had to make. During the training programme, the surveillance teams had been instructed to undertake a planned series of trips through the province for which they were responsible. They were to visit health centres and schools, where these existed, as well as village leaders and, in showing the WHO smallpox recognition card, were to inquire about possible smallpox cases. Any reports were then to be investigated. In the first classroom Mr Radke visited in Kefa Province, he obtained so many reports of cases in so many different villages that he did not bother to visit the other classrooms but went immediately to investigate. Village after village throughout many parts of this and other south-western provinces were found to be so heavily infected with smallpox that he and his fellow-workers decided that for some areas, even village-by-village containment vaccination was futile. Instead, they began to try to define the outer limits of the spreading epidemic and to concentrate on vaccination in populations at the circumference of the outbreak area, much as one would fight a forest fire.

what had been expected. The teams began work in mid-January and discovered 278 cases in only 2 weeks; 1493 cases were found in February and 3434 cases in March. This amounted to half the cases being reported throughout the world at that time. Henderson was sceptical that so few field staff could discover and investigate so many cases; he therefore cabled Dr Weithaler and Dr de Quadros, cautioning against recording rumoured outbreaks without due investigation. They were justifiably indignant and replied by cable and letter that the only cases reported were those individually confirmed by the smallpox eradication staff. Dr de Quadros had established a reporting system which was similar to that used in Brazil. A form was completed for each household in which a case was discovered. The form included the name, age, sex and past history of smallpox and vaccination of each household member. Only the cases seen by the surveillance teams and recorded on the forms were reported. The Ethiopian programme, in fact, had the most comprehensive data collection system of any national eradication programme and was the only one in which data were collected from the outset.

Since vehicles were available only to the teams in the south-western zone and Shewa during the first 6 months, it was not expected that the health officers and sanitarians assigned to other provinces would undertake much field work. However, most of them exhibited extraordinary ingenuity in getting from place to place by bus and borrowed vehicles, by foot and by mule. They, too, discovered and investigated numerous cases of smallpox.

Up to the end of June 1971, the field staff of only 39 persons documented 13 447 cases, more than had been recorded in the whole of India during the preceding year. Meanwhile, the threat that Ethiopia represented to its smallpox-free neighbours became manifest in March, when an outbreak of 46 cases of smallpox, introduced by an Ethiopian cattle herder, was discovered in Kenya. The now evident epidemic smallpox and the concern shown by neighbouring countries served to alarm the government, and from then on the programme began to receive somewhat greater support.

Seasonal torrential rains began throughout the highlands in June and, until September, forced the surveillance teams to restrict activities to populations living along the few all-weather roads. There, in addition to a search for cases, extensive systematic vaccination campaigns were conducted in the towns and cities. In Addis Abeba itself, smallpox eradication staff, with help from the Anti-epidemic Service and 12 secondary-school students, vaccinated 154 000 people over a 2-month period.

It was apparent that the problem in Ethiopia was a major one, requiring far greater resources than were available. Efforts were intensified to find such support. The government agreed to provide some additional staff but, in fact, had few available who could be mobilized except for personnel

of the malaria eradication programme, but a request for the transfer of some of these staff was refused. Programme funds previously destined for countries in the WHO African Region were transferred to Ethiopia, as well as what little remained for smallpox eradication in the WHO Voluntary Fund for Health Promotion. Other Headquarters funds for 1972 were earmarked for the recruitment of another WHO epidemiologist, Dr P. A. Koswara, formerly the director of Indonesia's successful programme. Continuing discussions with the government of Japan led to its commitment to provide 30 transceivers as well as 5 vehicles and 12 volunteers to serve as radio and automobile mechanics. The Austrian government agreed to provide 4 volunteers, and the USA to increase the number of its volunteers.

The end of the seasonal rains and the return of the teams to the field were eagerly awaited. During the rainy season in other parts of the world, smallpox was transmitted much less easily, and with travel restricted, the disease often died out in large areas. Moreover, the number of susceptible individuals was clearly lower than in the previous year because of the extent of the epidemics and the large-scale vaccination–containment activities that had been conducted in urban areas during the rainy season and in rural areas earlier in the year. Any hope that the smallpox problem might soon become more manageable vanished, however. The number of cases discovered totalled 2113 in September and rose each month, reaching 3322 in December.

In 1971, 26 329 cases were recorded, more than half in Shewa and the 4 provinces of the south-west zone, in which reporting was the best (Table 21.8). Cases were detected in 146 of the country's 539 *woredas* in the first half of the year, and in 160 *woredas* in the latter half (Fig. 21.5). In all, 3.1 million vaccinations

were performed, nearly 15 times the number given during the preceding year; yet this figure represented no more than one-eighth of the population. It was clear that a long and difficult task lay ahead.

The Second Year, 1972

In 1972, more resources became available (Table 21.9). A staff which had grown to 67 by January 1972 rose to 82 by the end of the year as additional volunteers from Austria, Japan and the USA joined the programme. In November 1971, a special meeting was held with the provincial medical officers to explain the programme to them and to solicit their support. Gradually they, as well as staff attached to health centres, took an increasing interest in the programme and made substantial contributions. WHO assigned an additional epidemiologist—Dr G. P. Marchenko, who was transferred from the programme in Pakistan. A fleet of vehicles numbering 27 in January increased to 49 by the end of 1972, making the surveillance staff far more mobile. The transceivers, of which half were based at provincial capitals and the other half mounted on vehicles, greatly facilitated communication. Dr Weithaler and Dr de Quadros sought additional help wherever it could be found. Thus ensued, in successive years, a large number of cooperative undertakings with private and public sector groups, including the personnel of a leprosy control programme, mission groups, scientific expedition staff and emergency relief workers, all of whom were supplied with vaccine and asked to report cases of smallpox and to perform vaccinations. Volunteers were also found among visiting health professionals, a number of whom served the programme for many months without salary, receiving the same per diem as Ethiopian staff.

Major difficulties had, however, become more apparent. Only variola minor was found and mortality was low: in 1971, for example, only 530 deaths were recorded (a case-fatality rate of 2.1%). Even in the acute phase of illness, patients experienced so few symptoms that they were able to travel easily, spreading the disease to contacts. A second problem was widespread resistance to vaccination among the two ethnic groups, the Amhara and the Dorsey, which constituted most of the population of the central zone, northern Shewa and some adjoining areas. A third

[a] Status as at end of each year.

problem was the widespread practice of variolation, to which, in 1971, more than 3000 cases (12% of the total) were attributed. Many more persons than this were known to have been variolated but, as was the practice in Afghanistan (see Chapter 14), only those who developed a generalized rash in addition to a lesion at the site of inoculation were counted as cases. Lastly, it had become apparent that such maps as were available were very incomplete and often erroneous. Accordingly, the teams found it necessary to prepare their own sketch maps of each *awraja* and its subdivisions, the *woredas*, in order to identify the locations of outbreaks.

By the summer of 1972, the control of smallpox had begun to improve. During the first 6 months of 1972, the number of reported cases had remained as high as in 1971, with one-third of the 538 *woredas* notifying cases. During the rainy season, the number of reported cases fell steeply, as it had in the same period of the previous year. Thereafter, the number of cases recorded monthly remained below 1000 despite an increasingly comprehensive surveillance system. The total number of cases reported in 1972 was 16 999—nearly 10 000 fewer than in 1971. Most of this decrease was accounted for by a sharply diminished incidence in the last 4 months of the year, 2363 cases being reported in this period compared with 10 725 in 1971. During 1972, 3.2 million additional persons were vaccinated.

Progress in the 4 provinces of the south-west zone was highly encouraging, although not unexpected because resources had been concentrated there. Containment vaccination throughout this zone had been extensive because of the widespread outbreaks and was readily accepted, indeed actively sought, by most of the population. There were, however, some tribal groups which caused difficulties. As was reported by some of the smallpox eradication staff, "... many workers were suffering at one time from human bites" (WHO/SE/72.48, Tilahun et al.). By the end of 1972, vaccinations equivalent in number to more than half the estimated population had been performed in the 4 provinces and the number of reported cases of smallpox in 1972 fell by nearly two-thirds. In 2 provinces, Ilubabor and Welega, transmission was interrupted by the end of the year.

A rapidly declining incidence in Eritrea and Tigray Provinces was most unexpected, however. These provinces, whose population was nearly as large as that of the 4 provinces in the south-west, had each been assigned only one sanitarian—Ato Tadesse Fissehaye and Ato Worku Gebre Selassie, respectively. Both were dedicated and imaginative workers and proved successful in overcoming extraordinarily difficult problems. Eritrea, although endowed with substantially more extensive health facilities, communications and roads than other provinces of Ethiopia, was torn by civil war. Large areas were periodically cut off so far as road travel was concerned, while other areas were completely inaccessible to government authorities. On assuming responsibility for the programme, Ato Tadesse Fissehaye, contacted all health units to establish a reporting network and to encourage them to vaccinate both patients and nearby inhabitants. As a native Eritrean, he was able to contact dissident groups to explain the programme and obtain their cooperation. Accordingly, he was usually able to travel throughout the province, despite the civil war, to investigate and contain outbreaks. He contained 65 outbreaks with 487 cases in 1971, and 10 outbreaks with 86 cases in 1972. The last endemic case in Eritrea occurred in December 1972. Only 2 importations, resulting in 3 cases, were subsequently discovered in 1973. Tigray, which was more mountainous and had fewer resources, presented a different type of problem. There, Ato Worku Gebre Selassie persuaded the able and widely respected governor to lend his per-

sonal support to induce health and other civil authorities throughout the province to cooperate in a search for cases and their containment. Travel was not then hampered, and by the end of 1972 transmission had been interrupted in this province also. Importations were to occur in 1973 and 1974, resulting in 17 and 30 cases respectively, but both outbreaks were effectively contained. Except for these imported cases, the northern provinces remained free of smallpox after 1972. The early interruption of transmission in Eritrea and Tigray was fortunate because the intensity of civil strife in this area heightened significantly in later years, making it far more difficult to travel freely and to obtain the cooperation of the population.

A Year of Hope, 1973

In only 2 years the smallpox eradication staff, few though they were, had made remarkable progress, and the programme gained such momentum in 1973 that by the end of the year expectations were high that transmission might be interrupted within the next 12 months. The staff had become more experienced and, during twice-yearly seminar training programmes, had steadily modified and improved surveillance techniques. The staff at health centres were increasingly cooperative and participated more actively in reporting and in vaccination campaigns. In fact, 20% of all cases in 1972 were reported by the regular health services. Problems of transport and radio maintenance and repair were fewer, thanks to the Japanese volunteers; adequate supplies were available for camping and the arduous treks on foot or on muleback.

Surveillance methodology had been evaluated in June 1972 in an imaginative study which provided additional confidence in the approaches being adopted. A surveillance officer, Mr James Siemon, accompanied by a vaccinator, undertook a 14-day search in a remote mountainous *awraja* covering an area of 48 000 square kilometres and with a population of 275 000 (Quadros et al., 1973). No cases had been reported for 6 months. The 2-man team travelled extensively through the *awraja*, mainly on foot, making inquiries about smallpox cases among administrative officials and at the sole health centre and 4 health stations, at 8 schools, and at weekly markets. None of the administrative officials, village leaders or health staff knew of any cases. However, 5 different persons, at 3 markets and 2 schools, identified a single small outbreak of 8 cases in 3 households. Mr Siemon investigated the outbreak, which was 2–9 hours' walk from each informant, and discovered it to have been caused by an importation from another province. From follow-up surveys, it was confirmed to be the only outbreak then present in the whole *awraja*.

A description of surveillance activities as practised at this time is helpful to an understanding of the programme and how it functioned. In most provinces, 2 surveillance teams were assigned, each team being responsible for an area with a population of 500 000 to 2 million. The team leader prepared a sketch-map and drafted a rough tour plan so that each *awraja* could be visited regularly. In some provinces, this often meant a walking tour of 3 or 4 weeks in just one *awraja* as the team progressed from valley to valley. A team of 2 workers was found to be the most practical because its members could be more readily accommodated locally. For ease of travel, they carried minimal supplies but were given letters by administrative officials to local leaders requesting that they should be provided with food and accommodation. By staying overnight with local leaders, they became better acquainted with the local people and were often able to obtain assistance from them in searching for cases and performing vaccinations. As the programme gradually began to concentrate on the more mountainous central and northern areas, vehicles were less often used because travel by foot and by mule proved more practical and permitted access to more difficult areas. Accordingly, the vehicles available to the programme staff began to be used primarily for transporting teams and supplies to points accessible by road and picking them up again at an arranged rendezvous point after 2–4 weeks. On arrival in the *awraja*, the team visited the offices of the *awraja* and then the *woreda* administrators to inquire whether they were aware of smallpox cases. Because there was little contact between officials and villagers at that time, this procedure was rarely useful in finding cases. However, official letters from the *awraja* and *woreda* officials helped in making contact with village leaders. The team then visited each market, clinic, school and church. Weekly markets were a feature of both rural and urban Ethiopia, and although most of the people attending lived

within 3 hours' walking distance, some travelled for as long as 3 days. For market surveillance, careful planning of the tour was required because markets were held on different days in different villages. Clinics and schools were comparatively rare but, where present, they were often a helpful source of information. Coptic churches, a prominent feature of the mountainous plateau area, convened adults for Sunday services from distances of up to 15 kilometres. Other persons encountered on tour were also questioned about smallpox.

Because the population was sparsely settled, most of the team's time was devoted to travel. When groups were questioned about possible smallpox cases, vaccination was offered but no attempt was made to persuade those unwilling to be vaccinated or to vaccinate all persons in an area except where there was an outbreak. Outbreak containment consisted only in vaccinating those in geographical proximity. With so few staff, it was impossible for the team to remain at an outbreak site to ensure the isolation of the patient or the vaccination of absent contacts or of visitors who later came to the village. Not surprisingly, some outbreaks persisted for many weeks after the team's departure, and some resulted in the spread of smallpox to other villages.

During the first 6 months of 1973, an average of only 590 cases was discovered each month; 115 *woredas* reported cases—64 fewer than during the same period of 1972. With fewer cases and fewer outbreaks, surveillance staff were able to devote more time to search, and additional manpower could be concentrated in problem areas. From April to September the number of cases decreased steadily, reaching a low of only 71 cases in September. Areas known to be infected were few in number and widely scattered except in the central zone (Fig. 21.6).

In preparation for what was hoped might be the last smallpox season, an international seminar was convened in Addis Abeba at the end of the rainy period to which were invited representatives from the French Territory of the Afars and the Issas, Kenya and the Sudan. All these countries by this time were smallpox-free, the Sudan having been the last to eliminate the disease (at the end of 1972). Plans were coordinated for continuing surveillance along border areas and the possibility was explored for teams from these countries to undertake surveillance

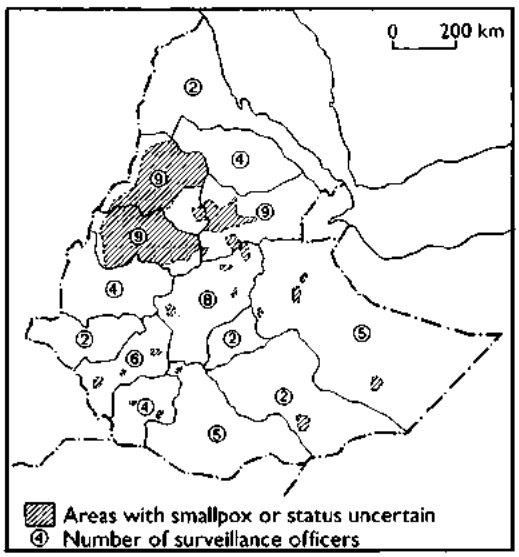

Fig. 21.6. Ethiopia: areas with endemic smallpox and number of surveillance agents assigned to each province, as of 30 September 1973.

programmes within Ethiopia in areas adjacent to their borders.

The remaining endemic areas, principally in Gojam, Gonder and Welo, were comparatively small but they posed enormous problems. The population was predominantly Amhara, many of whom adamantly refused vaccination despite the persuasive efforts of government leaders, village chiefs and priests. Meanwhile, variolation continued to be widely practised, performed by the heads of households when cases occurred in the vicinity. The terrain was the most mountainous and rugged in all of Africa and throughout much of the area security was a problem. In some areas, there was no government presence and smallpox eradication staff were forbidden to enter. It was apparent that helicopters would be invaluable for surveillance, but they were costly; appeals at this time to donor agencies as well as to the Ethiopian army met with no response.

To persuade villagers to accept vaccination sometimes required the teams to remain in an area for extended periods. The overcoming of resistance to vaccination required a somewhat different approach in each village. Some people accepted vaccination only if it was performed on the wrist (the site normally used for variolation); some would accept it only if it was administered by jet injector; in other areas, additional medications had to be

provided first. Not infrequently, weeks of inducement and cajoling were required to vaccinate even half the population of an infected village. Ethiopian and WHO staff showed unusual stamina, courage, imagination and persistence in solving the formidable array of problems, especially notable leadership being provided by 3 Ethiopian health officers—Ato Bono Hora, Ato Wassihun Woldetensie and Ato Zein Ahmed. Time and manpower were required, however, both of which were in short supply. Because of the special problems in these provinces, 2 additional WHO epidemiologists were recruited to permit the assignment of one to each of the 3 provinces, leaving 2 advisers to work with Ethiopian coordinators throughout the remaining 11.

In the autumn of 1973, an unforeseen disaster occurred. The eastern and north-eastern parts of Ethiopia experienced an extremely severe drought, followed by famine, during which an estimated 200 000 persons died. This was accompanied by an unprecedented migration of nomads into the highland areas and by a large-scale migration of the population from the endemic areas of Welo Province into other provinces. Many cases were imported into smallpox-free areas and into the neighbouring country of Somalia and the French Territory of the Afars and the Issas.

Because of the extensive movement of refugees, the number of cases increased to 542 in November and 508 in December, almost as many as had occurred during these same months in 1972. For the year as a whole, however, the 5414 recorded cases represented a decrease of nearly 70% from the 1972 figure of 16 999 cases. Ninety percent of the cases were from only 5 provinces, in which half the smallpox staff were concentrated. During 1973, 2 additional provinces, Gamo Gofa and Arsi, succeeded in interrupting transmission, bringing the number of smallpox-free provinces to 6. Much had been achieved, but it was becoming apparent that the eradication of smallpox from Gonder, Welo and especially Gojam was anything but a certainty. Resistance to vaccination in these areas was reflected by the proportion of the population that had been vaccinated. By the end of 1973, 8.3 million people in Ethiopia as a whole had been vaccinated, a total equivalent to one-third of the population, but in the central zone provinces, the corresponding proportion was only 20%.

A Year of Turmoil, 1974

The optimism and high expectations of early 1973 that a rapid interruption of transmission might be achieved had given way to the recognition that an arduous task lay ahead which would require the utmost persistence and imagination. Greater support from the government and the involvement of more Ethiopian staff were essential in order to cope effectively with uncooperative populations. Increased financial support from international sources was also required but was difficult to obtain. At this time, WHO considered the eradication of the severe variola major in Asia to be of higher priority, and such discretionary funds as were made available to the Organization had to be directed to the programmes in Bangladesh and India. Possible bilateral support for Ethiopia, meanwhile, remained in suspense as increasing civil strife began to envelop a country beset with economic crises, famine and rebellion against the traditional feudal system of government.

The programme's resources were primarily concentrated in the central zone provinces but the working conditions there became increasingly difficult. Because of armed conflict, *woredas* and sometimes entire *awrajas* were declared by the army to be too dangerous to permit work to continue. In other areas, the teams had to travel with a security escort. In Welo and the south-east, in which outbreaks accompanied refugees, the teams sought and obtained assistance in reporting and vaccination from relief workers distributing food supplies.

Special assistance to the programme was provided during the early months of 1974 by health staff from the French Territory of the Afars and the Issas, Kenya and the Sudan in an exceptional display of international cooperation. It was beyond Ethiopia's capacity to contend successfully with the outbreaks among nomads and refugees in the huge eastern desert areas. Here, with the full approval of Ethiopia, the authorities of the French Territory of the Afars and the Issas responded by providing 5 teams, comprising 46 persons supported by 20 vehicles and 3 helicopters for a 6-week programme of search and vaccination. This operation extended up to 300 kilometres inside the Ethiopian border in the eastern part of Welo and Hararge. To support the effort, Ethiopian staff established petrol depots at key points and accompanied

The Sudanese Search in Western Gojam Province

Search and vaccination in the difficult area of western Gojam Province were undertaken by a Sudanese team in a journey characterized by great ingenuity and determination. Travelling in 3 Land Rovers, 12 persons required 2 months to traverse some 250 kilometres through Gojam Province from the Sudanese border to the town of Bahir Dar in Ethiopia. Led by a Sudanese sanitarian, Mr Abdul Gadir El Sid, the team had to carry with it all the petrol and most of the supplies needed. Sudanese pounds were acceptable currency for the purchase of food over half the distance; for the last part of the journey, the team members needed Ethiopian dollars, and to obtain them they sold a supply of blankets which they had brought with them just for this purpose. The "roads" over which they travelled had not been traversed for years. It was necessary for them to construct bridges and in many areas to walk ahead of the vehicles, clearing a path with large knives. In some places, the underbrush was so dense that it had to be burnt (on one occasion the flames nearly consumed one of the vehicles). Mechanical breakdowns, poisonous snakes, wild animals and insects were daily problems. Nevertheless, they persisted in their journey, during which they contacted and vaccinated some 20 000 people but found no smallpox. They were gratefully received in Bahir Dar by Ethiopian staff, provided with Ethiopian dollars and, after a brief rest, returned home by the same route.

the French teams, coordinating the overall work through the transceiver network. Meanwhile, a Sudanese team of 12 persons with 3 vehicles undertook a 2-month programme of search and vaccination throughout the western third of the difficult Gojam Province. In the south, Kenyan teams began a continuing programme of search and vaccination in Ethiopian *awrajas* adjacent to Kenya.

Every possible effort was being made to augment the capacity of the programme through cooperative work with the regular health services staff, relief workers and others. Even the malaria eradication staff began to participate after several cases of smallpox had occurred among the malaria workers themselves. The coordination of such disparate groups and activities was difficult, however; it became even more so when, because of the intensifying civil war, a number of foreign volunteers left the programme. Ethiopian health officers and sanitarians served to fill the gap, their efforts being augmented by students who were hired as temporary staff during an extended holiday from the university, which was closed owing to the civil unrest.

Despite the chaos and obstacles, progress continued to be made. Transmission was interrupted in April in Kefa Province, leaving the entire south-west zone smallpox-free. In the northern zone provinces of Eritrea and Tigray, only one importation occurred and this was contained. In the south-east zone, the outbreaks were contained in the populous areas of northern Hararge by mid-year. Smallpox continued to spread among desert nomads, but few of the staff believed that transmission could be long sustained in this sparsely settled area. Gonder, Gojam and Welo remained the principal areas of concern.

More resources were required for the central zone provinces and, in June, came the welcome announcement that the Surgeon General of the United States Public Health Service had arranged to make available US$220 000 from his domestic health budget allocation specifically for the lease of 2 helicopters. Planning began immediately to mount a special search programme, to commence in late 1974, as soon as the helicopters, pilots and mechanics had arrived. A Canadian company, under contract to WHO, arranged to fly the helicopters to Ethiopia and recruited Canadian pilots and mechanics, under the leadership of Mr Robert Lavack and Mr William Waugh. Meanwhile, it was decided to make intensive efforts to continue the programme throughout the rural areas despite the difficulties of travel created by the advent of the rainy season.

The challenge of keeping the programme in operation was already enormous, but in 1974 the situation was exacerbated by the beginning of a major revolution. The Emperor was deposed and a new government with a different administrative structure began to take shape. An important tenet of the

The Death of Dr Petrus Aswin Koswara

The emotional and physical strain associated with field work in Ethiopia was especially great in 1974; it cost the life of one WHO smallpox eradication programme adviser, Dr Petrus Aswin Koswara. He was the only WHO adviser to die while actively engaged in the programme. After serving brilliantly as the director of the successful programme in Indonesia, Dr Koswara joined the Ethiopian programme in 1972. In 1974, he was working in Welo Province, where he was responsible for the planning and logistics associated with the new helicopter-assisted search programme. On returning from Welo one afternoon after weeks of exhausting strenuous field work, he experienced severe chest pain and died that night of a heart attack. He was only 43 years old. His wife and their two children returned to Jakarta, where Dr Koswara was buried. He was decorated posthumously by the President of Indonesia and given a state funeral.

new government was the abolition of the feudal system of land tenure, an action welcomed in most areas but forcefully resisted in others. At the same time, the long-standing revolt in Eritrea intensified; violence increased among the Amharic peoples of the central zone; and the traditional antagonisms between Ethiopians and ethnic Somalis throughout the Ethiopian portion of the Ogaden desert erupted into sporadic open warfare as armaments began to be supplied to guerrilla forces calling themselves the Western Somalia Liberation Front. These problems persisted over the succeeding years, never completely subsiding. Some of those engaged in hostilities were supportive of the smallpox eradication programme and arranged for the staff to work in areas otherwise inaccessible to government authorities. Others, however, attacked smallpox eradication teams, kidnapped some of them, and on one occasion killed 2 of the Ethiopian vaccinators. Nevertheless, programme staff continued their work, both Ethiopian and international workers often serving in areas in which no other government staff could operate.

The special campaign employing helicopters began, as planned, in mid-November 1974 with the object of searching the more inaccessible highland areas. This took careful preparation as fuel depots had to be established and a scheduled programme of search elaborated for areas of which existing maps, at best, only approximately represented the actual terrain. Camping equipment and food were also necessary because supplies in the drought-stricken areas were scarce. The helicopters, operating from base camps, ferried teams into the most difficult and remote areas.

Plate 21.8. P. A. Koswara (1931–1974) seated (*centre*) with 2 Ethiopian colleagues, Endale Alemayehu and Tedla Tegegn, shortly before his death.

Thereafter, the teams proceeded by foot and on mules to an arranged pick-up point over a period of 7–10 days. The helicopters provided logistic support and were used to transport staff to confirm rumours of outbreaks. The teams searched for cases and performed vaccinations. Where resistance to vaccination was encountered, administrative officials were flown in to help to persuade the villagers. As these operations progressed, the staff were surprised to find that, in many areas, resistance to vaccination was less of a problem than it had been before. This phenomenon was attributed in part to the dramatic appearance of teams by helicopter.

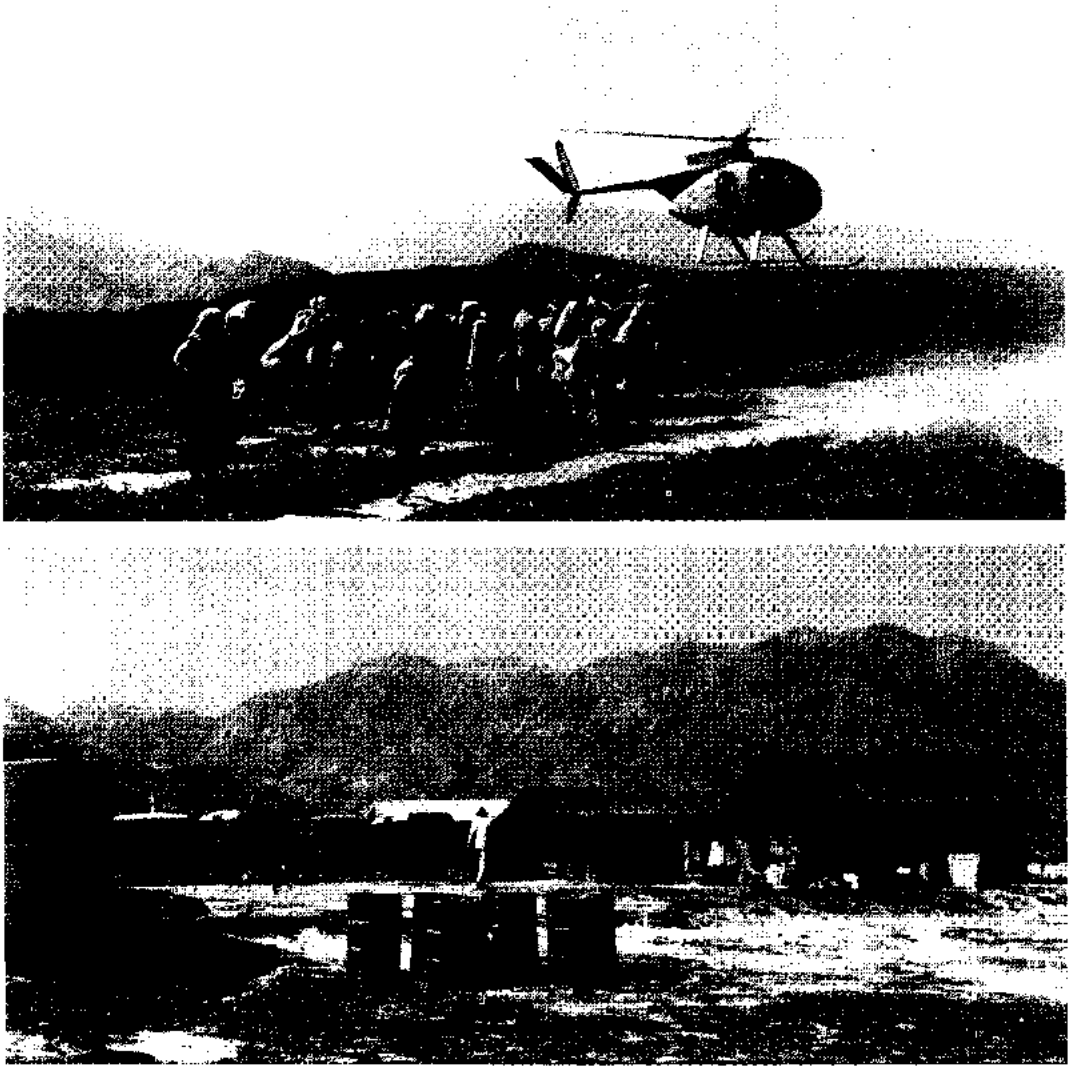

Plate 21.9. **A:** Helicopters were used in the Ethiopian programme from 1974 for smallpox searches in inaccessible areas. Although they could carry 4 passengers at sea level, they could not transport more than 3 persons at the high altitudes of the vast central mountainous area. **B:** The limited flight range made it necessary to establish depots of fuel drums in camps.

The helicopters greatly facilitated efforts but an operation such as this was costly and was attended by other problems. One hour of flying cost about US$250 and thus careful planning of use was mandatory. Moreover, the 4-passenger helicopters did not have a great range and at the high altitudes of the central plateau could not transport heavy loads. Thus, fuel depots had to be carefully sited and accessible by the heavy trucks required to transport the drums of fuel from Addis Abeba. Serious delays in the schedule occurred when helicopters experienced mechanical failures or other events took place. Such incidents included the destruction of one helicopter by a hand grenade shortly after a team's arrival in a village; a second was hit by a bullet which penetrated the fuel line, causing a fire and a forced landing. On another occasion, a helicopter lost its bearings, made a forced landing when fuel ran out, and was not found for 2 days. And on yet another occasion some years later, rebel forces captured a helicopter and pilot and held them to ransom (Plate 21.10). Although nobody was injured or killed as a result of these incidents, some of the pilots returned home within days of arriving in Ethiopia. Most

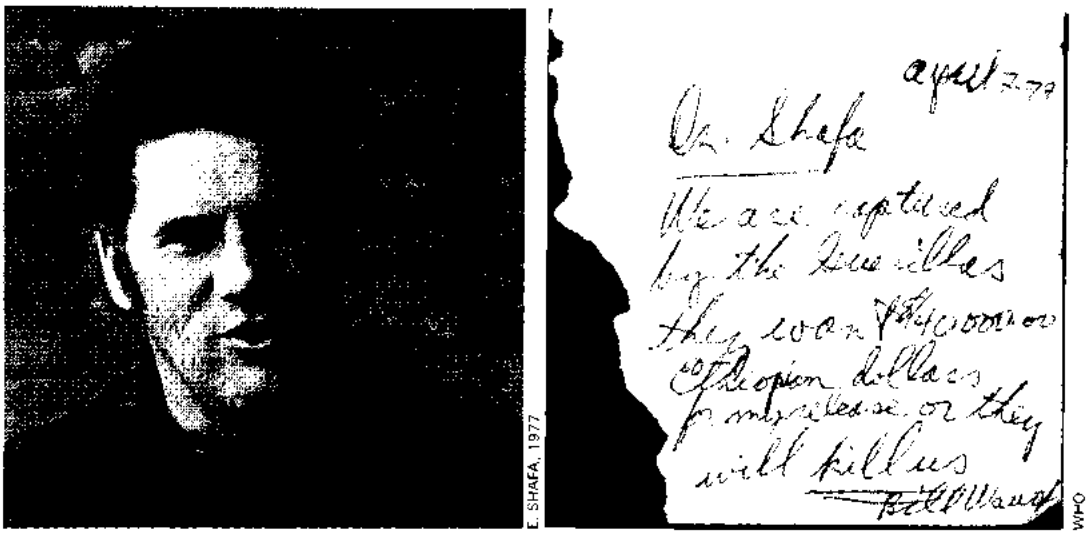

Plate 21.10. William Waugh, a Canadian helicopter pilot, was captured in 1977. He managed to send this message to Ehsan Shafa, of the Smallpox Eradication unit at WHO Headquarters, who was in Ethiopia. It reads: "April 7–77 Dr. Shafa We are captured by the Guerillas they want $40 000.00 Ethiopian dollars for my release or they will kill us, Bill Waugh". He was released 4 days later when this picture was taken, without the ransom having been paid.

were undaunted and became as expert in the diagnosis of smallpox and the strategy of the programme as the senior programme staff.

The helicopter-supported operation detected fewer smallpox outbreaks than had been expected; most of those discovered were rapidly contained. In Gonder, few cases were found and by December the persistent focus in one *awraja*, which was responsible for 60% of cases in the area, had been eliminated, leaving only one seriously affected *awraja*. In Welo, fewer smallpox cases were discovered in the northern area than had been expected, although continuing transmission in the south remained a problem. In Gojam, by the end of the year, smallpox appeared to be limited to only 24 of the province's 1800 *debers*.

By the end of 1974, 4439 cases had been discovered, 20% fewer than during the previous year; the number of provinces in which transmission had been interrupted had risen from 6 to 8 as both Kefa and Sidamo in south-western Ethiopia became smallpox-free. Search continued in both of these provinces but the few cases that were found could be identified as importations and were quickly contained.

The Final Phase, 1975–1976

At the beginning of 1975, with mounting civil disorder and with increasingly large areas in the endemic provinces inaccessible to the programme staff for long periods of time, it seemed more and more questionable whether adequate resources could be deployed sufficiently quickly and effectively to interrupt transmission. In fact, it seemed possible that the degree of control that had been achieved was at risk of being lost, which would permit smallpox to spread widely through Ethiopia and into other countries. If additional resources were to be made available, however, they would have to be drawn from other programmes. But eradication of the severe variola major in Asia continued to have priority, and although excellent progress was being made in India and Nepal, in the early months of 1975 Bangladesh experienced major epidemics (see Chapter 16) associated with famine and extensive movements of refugees. Not until the summer of 1975 was it reasonably certain that smallpox could be eliminated from Asia. When smallpox transmission was interrupted in India in May 1975 and in Bangladesh a few months later, it was possible to divert resources and energies to Ethiopia—then the world's last remaining country with smallpox. At this favourable turn of events, Ethiopian and international staff alike renewed their endeavours to attain what had once seemed such a distant target—"Smallpox Zero".

Surveillance of Smallpox in a Hostile Area

A special problem faced by the smallpox eradication staff was surveillance among a population living in the Blue Nile gorge, a ravine which formed the southern border of Gojam and was one of the widest and deepest in the world. At least 2 days were required to travel from one edge of the gorge to the other. Large numbers of people inhabiting the gorge were hostile to the intrusion of strangers; when the teams visited, they often had to be accompanied by armed security forces. During much of 1974–1975, the teams were unable to enter the gorge at all and thus were limited to conducting surveillance–vaccination activities around its rim. On one occasion, rumours were received about the existence of smallpox in one of the villages, whose inhabitants were thought to have been responsible for killing the members of a German Blue Nile expedition. A young schoolboy who was a native of the area and had relatives in the village volunteered to investigate. He went to the village and, while playing with other children, succeeded in obtaining scabs from a child who had experienced a disease with rash. Laboratory investigation confirmed it to be smallpox.

It was not until 1977 that the fighting subsided sufficiently to permit search teams, accompanied by civil guards, to travel widely through this area. Fortunately, transmission had ceased by then even though few persons had been vaccinated.

Throughout the summer of 1975, the staff, still numbering less than 100, continued the struggle with smallpox in the highlands of the central zone and adjacent areas of Shewa, as well as in the Ogaden desert area of Hararge (Fig. 21.7). Unexpectedly, additional manpower became available when the authorities decided to send 60 000 students into villages throughout the country in a special campaign to improve literacy. The government agreed that some could also work with the smallpox eradication teams, and thus many were trained in techniques of case search and vaccination. The students proved to be especially valuable, since they were natives of the area in which they were working and could both identify persons with political influence and induce the villagers to accept vaccination.

Progress in Asia eventually came to be measured in terms of the number of currently "active outbreaks" in a village or sector of a town—i.e., those in which a case had occurred during the preceding 6 weeks. This system of measurement was introduced into the Ethiopian programme in 1975 but it was difficult to apply. An epidemiologist was required to revisit the site of an outbreak after 6 weeks to confirm that transmission had ceased and that the site could be removed from the list of "active outbreaks". Because of the paucity of staff and the periodic prohibitions on travel in large areas, such visits were sometimes unavoidably delayed. Moreover, it

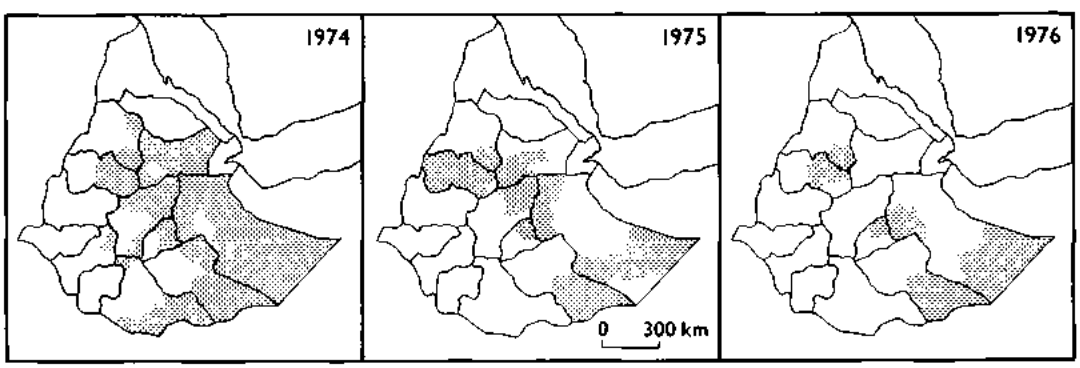

Fig. 21.7. Ethiopia: *Awraja* areas (shaded) in which cases of smallpox were reported, 1974–1976.

was no easy matter to deal with an Ethiopian "village", a collection of houses often dispersed over many square kilometres. Nevertheless, the staff began to define the smallpox problem in this way and by mid-year had evolved a reasonably effective data collection system. By the end of July 1975, there were only 131 known active outbreaks occurring in 13 clusters. The clusters were spread over about 15 360 square kilometres, little more than 1% of the country's total area (Table 21.10). Many of the outbreaks in Gojam, Shewa and Gonder, however, had occurred in areas which the teams had been forced to leave because of civil strife, thus precluding their removal from the list of active outbreaks.

As civil disorder was so widespread, some enbassies decided that effective work in the countryside was impossible and too dangerous and so terminated the assistance of their countries; the remaining volunteers from Austria and the USA were withdrawn, although those from Japan continued to work. The smallpox eradication staff, however, believed that they might yet be successful if conditions did not deteriorate further. In fact, the problems became more acute. Petrol for vehicles, which had been in short supply, was brought to the capital by truck in an armed convoy from the coast. In June, because of the destruction of a major road bridge, the supply line was interrupted and rationing was imposed in Addis Abeba. In many parts of the country, no petrol at all was available. However, the Acting Resident Representative of the United Nations Development Programme, Mr John Phillips, who in 1971–1972 had been instrumental in initiating the smallpox programme in Botswana (see Chapter 20), worked out an imaginative scheme with the French government and an oil company to ship petrol by train from the city of Djibouti to Addis Abeba.

Table 21.10. Ethiopia: status of smallpox as at 23 July 1975

Regions	Number of clusters	Number of active outbreaks	Approximate area (km²)
Hararge	3	6	2 517
Shewa	1	24	3 600
Welo	2	6	234
Gonder	2	15	2 450
Gojam	4	79	6 550
Bale	1	1	9
Total	13	131	15 360

From there it was distributed to the regions by truck and by a chartered DC-3 fixed-wing aircraft. Fortunately, there remained a large residual stockpile of aviation fuel in Addis Abeba which the government made available to the programme, thus permitting continued helicopter operations.

In July 1975, Henderson held meetings with Ethiopian and WHO staff to plan an intensified programme extending to the end of 1976. It was hoped to utilize monetary contributions from Canada, the Netherlands and the USA, vaccine from the USSR and additional support from the WHO regular budget. The revolutionary government agreed to issue a proclamation declaring the programme to be of the highest priority. The new plan provided for 85 Ethiopian surveillance officers, 16 WHO advisers and as many as 1200 temporary field staff; the number of helicopters was increased from 2 to 4; additional vehicles and considerable quantities of camping equipment were also provided.

In October, more ample facilities were made available for the programme's headquarters, including an automotive repair shop. At the end of the year, an exceptionally able Ethiopian health officer, Ato Yemane Tekeste, was named director of the programme; Dr Weithaler continued to serve as its senior WHO adviser.

Activities steadily intensified, especially in the highland plateau areas, to which the most able Ethiopian and WHO staff were assigned. With additional locally recruited staff available, it became possible to assign teams to search for cases more widely and more frequently and to remain in outbreak areas until transmission had ceased. However, areas in which organized operations could not be undertaken because of the lack of security continued to be a problem. In many of these areas, locally recruited staff who were known to the dissidents opposing the government were sometimes able to travel quite extensively to search for cases and to vaccinate, although not without risk. It was during this period, in Gojam, that one worker was killed and a second captured and presumably killed by dissident groups.

By the end of 1975, smallpox transmission had been interrupted in 2 more regions, Shewa and Welo. No cases were detected in Gonder between July and December 1975, but because of the extent of the areas that could not be searched, the staff remained

uncertain as to the true situation in the province. The main problem was presented by Gojam, in which 4 contiguous *woredas* in and adjacent to the Blue Nile gorge, all heavily infected, could not be entered, and from this source cases were repeatedly exported to other areas. The teams sought to contain this focus through the surveillance and vaccination of the population of adjoining areas, but many individuals resisted vaccination.

The other principal focus of smallpox was in the vast Ogaden desert. Smallpox among the nomads had spread slowly but steadily from the highlands of the north-west into the Ogaden desert area of south-eastern Hararge, with occasional spread into Bale and Arsi Regions. From the initial reports of smallpox eradication staff in the area, there appeared to be few problems in containing this focus. They guessed that the affected population was not more than 300 000, of whom a third lived along a river, readily accessible by vehicle. As a result of the vaccination of people settled along the river, of refugees receiving food at shelters, of nomads when they stopped at water-holes and of other individuals contacted during search operations, the WHO epidemiologist estimated that at least 60% of the population had been protected. In a population so sparse and scattered, and so well vaccinated as this, everyone agreed that continuing transmission should cease quickly. However, the possible spread of smallpox into the part of the Ogaden desert that lay within Somalia was also a source of concern. Accordingly, periodic border meetings were arranged between Ethiopian and Somali staff. The Somali programme director reported at one of these border meetings in August 1975 that 85% of the nomads in Somalia had been vaccinated and assured everyone that surveillance in Somalia was most thorough. Only much later did it become evident that both Somali and Ethiopian staff assigned to the Ogaden area had greatly overestimated their achievements and underestimated the size of the population and the severity of the problem.

The early months of 1976 were characterized by far more intensive efforts but increasing organizational turmoil. The arrival of additional WHO epidemiologists and the acquisition of more vehicles, 2 more helicopters and a small fixed-wing aircraft, as well as the employment of many more local staff, overtaxed the capacity of the administrative structure. The helicopters began to be scheduled for as many as 8–10 flying hours a day, which exceeded safety limits and created difficulties in providing the requisite maintenance. Close field supervision of the increased staff became more difficult; the provision of field supplies was increasingly delayed; and the effective management of funds for the field payment of temporary staff and the purchase of supplies deteriorated. On a field visit in late February 1976, Henderson found a well-organized operation in progress throughout Gojam, Welo and Gonder under the overall supervision of Dr de Quadros and directed at regional level, respectively, by Ato Bono Hora and the WHO epidemiologists, Dr P. R. Arbani from Indonesia and Mr Gary Urquhart from the USA. In other areas the situation was less satisfactory. In northern Hararge, Henderson discovered that 5 outbreaks of chickenpox had been misdiagnosed as smallpox by inexperienced field staff. The most disturbing observations were made in the Ogaden, where supervision and organization were seriously deficient. At a watering-place only 20 kilometres from the Somali border, a smallpox isolation hut, located in the middle of a nomad camp, had no watchguard and was frequently visited by people from the camp; many unvaccinated persons were found in the area. At another camp, 2 individuals were encountered who had been

Plate 21.11. Poerwokoesoemo R. Arbani (b. 1941) was a WHO epidemiologist in Ethiopia, 1975–1979, having previously served in the same capacity in Pakistan since 1973. Before that, he had played an active role in the eradication of smallpox from Indonesia.

infected in the office of the camp physician by patients summoned for examination from the smallpox isolation facility. It was apparent that the optimism of the field staff in the Ogaden was unfounded.

The management of the programme was reorganized on 5 March 1976, and from then on rapid progress was made. A special task force for the endemic regions was created, with Ato Yemane Tekeste as programme director, Dr de Quadros as chairman, Mr Lavack as director of helicopter support operations, and Mr John Copland, administrative officer for smallpox at WHO Headquarters, as finance officer. Dr Weithaler was assigned to coordinate activities in the non-endemic areas; Ato Tesfaye Temelso and the WHO epidemiologist Dr Bert van Ramshorst assumed responsibility, under the direction of the task force, for operations in the Ogaden.

The tempo of activities increased in 1976 as both government authorities and WHO staff sought desperately to contain the world's only remaining focus of smallpox. It was possible to employ additional local staff through the use of funds made available by a special contribution from the USA of US$3 million in May of that year. New outbreaks continued to occur, however, until August (Fig. 21.8). The focus in Gojam was eventually contained by using armed civil guards who accompanied teams moving through the area; the last case occurred at the end of March. In Gonder, however, in January, after nearly 6 months without any cases having been detected, search teams were able to penetrate an *awraja* in the Blue Nile gorge which had been inaccessible for nearly a year, but in which fighting had recently diminished. There the teams discovered that smallpox had continued to spread (Table 21.11). Although this focus was near the outbreak area in Gojam, the two were unrelated. An intensive surveillance–containment programme was conducted, again employing civil guards, but transmission was stopped only with difficulty. As the search was extended around this area, another focus of 24 outbreaks with 140 cases was discovered 120 kilometres to the north. An itinerant musician had introduced the disease in December 1975 from the Blue Nile gorge. Fortunately, the population in the infected area proved to be receptive to vaccination, and on 29 June the last outbreak in the central zone provinces was discovered and contained.

Meanwhile in the Ogaden desert areas of Hararge and Bale, smallpox outbreaks continued to occur among the nomads, but the sources could rarely be traced because of the frequent movements of the different nomadic bands. Additional resources were deployed there in March and a better organized, more systematic pattern of search was developed employing more than 200 locally recruited staff.

In addition to helicopters, fixed-wing aircraft were chartered by WHO, and others were provided by the Netherlands and the Norwegian Save the Children Foundation. Search activities were compromised by sporadic fighting and the occasional kidnapping of staff and WHO advisers, who were taken to Somalia but eventually released through the intervention of United Nations officials. In addition, during this period 9 of the programme's vehicles were seized and taken across the border. The Somali guerrilla forces sometimes hampered operations, but more often than not took steps to protect the teams. In one town, to which a team had been brought by helicopter, notice was given by guerrilla forces that an attack had been planned and that the team should leave. As the helicopter took off, fighting immediately broke out. On other occasions, guerrilla forces attacked government buildings, killing the occupants, but did not molest the personnel of

BY COURTESY OF Y. TEKESTE, 1978

smallpox camps in the same town. For Ethiopian and WHO staff alike, working in the Ogaden was a trying experience. Many participated in the operation but special credit must go to the dedicated Ethiopian staff, to the helicopter pilots, and to Ato Tesfaye Temelso, Dr van Ramshorst (Netherlands), Dr do Amaral (Brazil), Dr M. N. El Naggar (Egypt), Dr Alexander Gromyko (USSR), Mr Carl Hasselblad (USA) and Dr J.-P. Ryst (France).

Gradually, it became apparent that in the Ogaden desert, smallpox was persisting primarily as a result of transmission back and forth between desert nomads and agriculturalists settled along the Shebele river, which divided Hararge and Bale. Efforts to control the spread, however, were severely hampered in the summer by the most serious flood in decades, which destroyed roads and river crossings and displaced numerous villagers. Across the river in the southern half of Bale, fighting between Ethiopian and guerrilla forces had greatly intensified and not until the middle of July was it possible for teams to enter this area. On 22 July, one of the teams discovered an outbreak in the small nomad village of Dimo in Bale, the first case having occurred on 5 June. Containment vaccination was immediately

A Missing Team—Chronology of Events

Work in the Ogaden was difficult enough. Guerrilla forces made it even more problematic.

Events as experienced by Ethiopian staff:

4 June 1977

Early morning—Surveillance Officer Ato Metiku reported to Addis Abeba by radio from Warder (a town in the Ogaden) that the WHO epidemiologist Dr Claudio do Amaral and a team comprising an assistant surveillance officer, 2 interpreters and a driver had not returned as expected on the previous evening. They had gone by Land Rover some 120 kilometres away to check on a rumoured smallpox case.

07.00 hours—The helicopter with Ato Metiku searched without success and returned to base.

10.00 hours—A fixed-wing aircraft joined in a second unsuccessful search.

15.00 hours—The two planes began a third search and at 17.50 hours, the vehicle was sighted. Because dusk had fallen it was decided to send the helicopter the following morning.

5 June 1977

06.00 hours—The helicopter flew to the site and many people were seen gathered around the vehicle waving white cloths. Fearing gunfire, the helicopter had to remain at a distance. From there, no team members could be identified.

12.00 hours—The helicopter returned to the site; this time a truck was observed parked next to the vehicle, again with many people surrounding it but no one waving.

15.00 hours—Two locally recruited Ethiopian staff volunteered to be dropped near the site (about 3 kilometres away) to obtain information. Special signals were arranged for them to identify themselves to the helicopter, which would keep watch from a distance and pick them up on 6 June at a site 30 kilometres away, on signal.

16.00 hours—The helicopter returned to the site but the vehicle was gone and the volunteers could not be seen. On returning to base, the truck seen previously was spotted. As the helicopter flew closer 2 individuals jumped from the truck and began firing at it.

Evening—At a special meeting, it was decided to bring in a second helicopter for search; 2 additional Ethiopian staff volunteered to be dropped at the site on the following morning hoping to learn something of the fate of their colleagues and of the team.

6 June 1977

07.30 hours—The volunteers were dropped at the site; helicopter search continued over a widening area.

14.00 hours—A flight over the original area revealed no sign of the volunteers.

16.00 hours—The helicopters flew to the pick-up site; one volunteer was seen but did not signal. The pilot returned to base at 19.15 hours.

Evening—Ato Metiku arranged in secret with the town-dwellers' association for a group of villagers to walk to the site.

7 June 1977

It was decided that all the aircraft should undertake a final area-wide search and then await instructions. Arrangements were made for a DC-3 fixed-wing aircraft to fly additional fuel to the area. The volunteers were located and retrieved by the helicopter; they had been unable to obtain any information.

8 June 1977

The Director-General of WHO sent a telex from Geneva to the Minister of Health of Somalia requesting assistance from the Somali border guards. Daily telex and telephone contact was established by Geneva with Addis Abeba and Mogadishu.

9 June 1977

A surveillance officer from Warder reported that a villager had told him that he had seen Dr do Amaral and the team on 6 June being taken by guerrilla forces to Deghbur, another area in the Ogaden.

Ato Yemane Tekeste and another high-ranking Ethiopian official left for Deghbur to be available to participate in negotiations should the captors make contact with the government.

11 June 1977

A telex was received in Geneva from the WHO Representative in Mogadishu with the message that the team was in Hargeisa, Somalia.

Events as related by Dr Claudio do Amaral:

3 June 1977

We left Warder at 07.00 hours to investigate a rumoured smallpox case 120 kilometres to the north. About 80 kilometres from Warder, 2 men with sub-machine-guns started shooting at us and ordered us to stop. Within minutes, they were joined by many others who ordered us out of the car, took everything we had and made us lie on our backs with our arms up. At that moment, I thought it was the last day of my life! Suddenly, one of their leaders appeared and took us to a village 300 metres from where we had been captured. He identified the group as being soldiers of the Western Somalia Liberation Front. We talked about the smallpox eradication programme and what we were doing, but he said that we had no right to be in the area, and emphasized that they could release us or kill us as they chose. We were given Somali dress and provided with goat meat and camel milk. We slept that night in the open air guarded by 2 men with sub-machine-guns.

4 June 1977

At about 15.00 or 16.00 hours we heard the helicopter and saw the fixed-wing plane but I hid, fearing they might land and be captured. That night we slept in the same place.

5 June 1977

In the morning, we again saw the helicopter and with a gun at my head, I was told to contact the pilot by radio to request him to land. I convinced our captors, however, that radio contact was not possible. The leader then ordered me to take off my shirt so that they would see my white skin and be persuaded to land. Again, I refused, persuading him that the pilot could not recognize colour from such a great distance. Fortunately, neither plane tried to land. Surprisingly, in the late afternoon, a vaccinator appeared who was from the village to which we had intended to go. He reported that the case we had intended to see was chickenpox, not smallpox! We were then driven to another village, where, we were told, we should be informed as to what would be done with us.

8 June 1977

After 2 days when nothing appeared to be happening, we were driven to yet another village, 120 kilometres further away, where we met a more senior leader. Once again, I showed my passport, explained I was Brazilian and described the smallpox eradication programme. To my great surprise, he knew all about our movements as well as the names of all the epidemiologists and where they were stationed. The leader said they would hand us over to the Somali authorities. That night they gave us a small hut and blankets for sleeping.

11 June 1977

We were handed over to the National Somalia Security authorities and arrangements were made for me to fly to Mogadishu on 18 June and to Addis Abeba on 22 June. The vehicle, after repair, was to be returned to Ethiopia.

instituted. In all, 16 cases occurred, 9 of the persons concerned having been variolated. The Dimo outbreak proved to be the last in Ethiopia, (Table 21.11) and for many weeks it was thought to have harboured the world's last case of smallpox—that of a 3-year-old girl who had become ill on 9 August. She had been variolated as well as vaccinated during the incubation period of the disease.

Active search continued and intensified throughout the country, on the assumption that in a country so large and with so many inaccessible areas, smallpox must be present somewhere. In many areas, especially in the south, the task of search was greatly facilitated by the new farmers' cooperatives and urban dwellers' associations. Through contact with the leaders of such organizations, it was possible to explain the objectives of the programme and to enlist the assistance of the population in reporting suspected cases. To encourage such reports, a reward was offered, a practice first initiated in January 1975 in Gonder.

Surprisingly, week after week passed with no additional smallpox foci found anywhere in Ethiopia. Except for the cases found in late July and early August in the nomad village at Dimo, none occurred in the Ogaden with an onset of illness after July; in the highlands the last case had occurred on 5 July. Search teams, posted in each *awraja*, were able to intensify their efforts in September and October as the seasonal rains ended, but still no cases were found.

Plans were made to hold a press conference at the end of October 1976 in the expectation that an announcement could be made that 10 weeks had elapsed since the onset of what was believed to be the world's last case of smallpox. Confirmation of eradication would require 2 full years of search, but week by week it appeared increasingly certain that no further cases would be discovered. Television crews flew to Dimo to take pictures of the village and of the last known patient, Amina Salat.

In late September plans were abruptly changed when cases of smallpox were reported from Mogadishu, the capital of Somalia. Initial disappointment that a few last imported cases had necessitated delay of the announcement turned to despair as it gradually became apparent that Somalia had endemic smallpox. Despite assurances to the contrary, neither surveillance nor vaccination activities had been well conducted. It had been anticipated that the last chapter of the global eradication of smallpox would be written in Ethiopia—but it was not to be.

Morbidity and Mortality Data

From the time the programme began, data collected from all households in which cases occurred included the name, age and sex of all residents and their past experience with regard to smallpox, vaccination and variolation. Data from Ethiopia are, in fact, more

Plate 21.13. National and international staff planning search strategy around last foci of smallpox in Ethiopia. *Left to right:* Zewde Besha, Muchie Kidanu, Mitiku Haile, C. do Amaral.

complete than those from any other country which experienced extensive endemic smallpox. Information on the age and outcome of illness are available for 54 991 of the 58 031 cases reported from 1971 to 1976 (Table 21.12). One-fourth of all cases (26%) occurred among persons aged 15 years and over who comprised 57% of the population. The large proportion of cases among adults is characteristic of an area in which the presence of smallpox was infrequent among much of the population. The proportion of cases among those less than 1 year of age (2%) is almost certainly understated because, in many areas, very young children with smallpox were often hidden from investigators.

Only variola minor was observed. No outbreaks were discovered with case-fatality rates comparable to those in Asia or western Africa. The overall case-fatality rate was calculated at 1.5%. The true figure may, however, be somewhat higher because outbreaks that occurred in the early years of the programme were not observed throughout their course and the deaths of some patients during the second or third week of illness may have been missed. Nevertheless, it is doubtful that the actual rate was much higher than 2%, a rate characteristic of variola minor.

Cases occurred almost exclusively among the "never vaccinated" group, only 961 of 49 106 persons of known vaccination status having previously been vaccinated. Even some of those listed as "vaccinated" had been vaccinated too late in the incubation period of the disease to be protected. Of the total number of cases, 7.3% occurred among persons who had been variolated.

Secondary attack rates among susceptible individuals within families were comparable to those measured elsewhere. Nearly 80% of children under 15 years of age who were exposed in households contracted the disease. Lower secondary attack rates among adults (43.6%) may reflect diminished levels of exposure, but they may, in part, be understated because of the failure of adults to recall past infection (Table 21.13).

Comparatively few children under 15 years of age were immune because of previous smallpox, which suggests that the disease had not been widely prevalent for a number of years. Among household contacts of cases as a whole, approximately equal numbers were immune as a result of variolation and vaccination. Three times as many had previously experienced smallpox.

Finally, data regarding the source of infection of outbreaks (if known) revealed that the

disease rarely spread over long distances. Of 6957 outbreaks analysed, a source of infection was ascertained for 4565. Of these, the source of 3956 (87%) was from contact in the same *woreda* and of another 362 (8%) in the same *awraja*. Only 1 in 20 originated in another *awraja*.

Exportation of Cases

Ethiopia, as had been feared, was a source of infection for neighbouring countries. The Sudan, which had been smallpox-free in 1967 (see Chapter 18), was reinfected by cases from Ethiopia in 1967–1968 and the disease subsequently became endemic there. One additional importation occurred in the Sudan in December 1972 but was quickly contained. Kenya experienced 2 imported cases in 1970–1971 with 44 secondary cases; 2 imported cases and 2 further cases in 1973; and 1 imported case with 5 further cases in 1976 (see Chapter 19, Fig. 19.4).

The French Territory of the Afars and the Issas and Somalia were the most subject to importations. The former, in December 1971, recorded an outbreak of 104 cases following an importation; in 1973, 10 separate importations occurred with 4 secondary cases; and in March 1974, 12 cases were reported following 1 or possibly 2 importations. Somalia, from 1962 to 1972, recorded only 2 cases of smallpox (1966); the origin of these was unknown. However, from December 1972 to the end of August 1976, when Ethiopia detected its last case, 42 cases were reported, of which 38 were said to have been importations, the last of these occurring in March 1976, 5 months before Ethiopia interrupted transmission. No further cases were reported from Somalia until October. Those cases were said to have originated in Ethiopia but in fact, as was later discovered, endemic smallpox had by then become re-established in Somalia and the official reports of field investigations, at least during the latter part of 1976, were unreliable.

CONCLUSIONS

Ethiopia proved to be as formidable a challenge to the Intensified Smallpox Eradication Programme as any country in the world, and at every stage. For nearly 3 years, the government not only declined to discuss a possible eradication programme, but actively opposed it. The idea of a national programme was eventually accepted, with reluctance, and, when it was launched in 1971—the fifth year of the Intensified Programme—little support was given by the government either in resources or in commitment. For more than 3 years, a staff proportionately smaller in number than in any other endemic country struggled valiantly, but with remarkable success, to contain the disease in one of the most rugged and difficult terrains in the world and among hostile populations to whom vaccination was all but unknown. Escalating civil war and famine further confounded the endeavour. The fact that the disease was of the mild variola minor variety increased the difficulty, because the population was not particularly eager to be vaccinated; many who were ill with smallpox were able to travel widely, spreading the disease as they went. Adequate resources could not be made available until late in 1975, but with much of the country then smallpox-free, less than a year elapsed before transmission was interrupted. Subsequently, search activities to certify the absence of smallpox were well supported by the government and resources for the task became available. But less than a year later, in 1977, the Somali-Ethiopian war broke out, rendering inaccessible a large portion of the area in which the last cases had occurred. Only through a surveillance programme conducted from bases in Somalia was it possible to continue activities in the troubled Ogaden desert and to confirm the absence of smallpox.

It is a tribute to a dedicated WHO staff and a small band of extraordinarily capable Ethiopian health officers and sanitarians that programme activities were continued at all during several years in many parts of the country. For many years and in many areas, smallpox eradication was virtually the only health programme in operation in the field, and WHO smallpox staff were almost the only expatriate workers who ventured outside the major cities.

Global smallpox eradication was in jeopardy on numerous occasions and in many countries, but nowhere was the outcome so greatly in doubt, and for so long, as in Ethiopia.

Prospects for the successful interruption of smallpox transmission in Yemen had not originally appeared to be much more encour-

aging than in Ethiopia, and indeed the programme, such as it was, was reasonably well executed only during its first year. Yemen, however, was far smaller in size and population; variola major, rather than variola minor, had predominated but apparently had spontaneously died out before the programme began. In Democratic Yemen, whose population was even smaller than that of Yemen, the WHO-supported programme was better executed, but its achievement primarily consisted in confirming the absence of smallpox.

In retrospect, it would have paid rich dividends strategically if, in Ethiopia, greater attention had been paid to smallpox in the Ogaden desert area at an earlier stage. The most competent staff and the larger proportion of resources were initially assigned to the difficult mountainous plateau areas of the north in the expectation that smallpox transmission would soon terminate—for the most part spontaneously—among the desert nomads. Until March 1976 the programme in the Ogaden was modest and, as became evident, not well organized. When a fully effective programme did take shape, it was soon discovered that vaccinial immunity was far lower than had been recorded, reporting was poor and containment ineffective. Smallpox continued to spread among nomads, but in August 1976 the last known outbreak was finally contained. This would have marked the end of smallpox if the WHO-supported programme in Somalia had been conducted as well as it was reported to have been. However, uncontained importations into Somalia set the stage for yet one more major programme in a country that had previously been free of smallpox. These events are the subject of the next chapter.

INTRODUCTION

Unexpectedly, the final episode in the global eradication of smallpox did not take place in one of the countries which had recently been so heavily infected, but in Somalia, whose first endemic cases in 14 years were reported in late September 1976. The reports were received 7 weeks after the last outbreak in Ethiopia, at a time when WHO was preparing to announce that, subject to confirmatory search, the world was free of smallpox. It was a bitterly disappointing setback, coming as it did at the end of a 12-month period that had witnessed the occurrence of the last case of variola major in Asia and the conclusion of a difficult but successful campaign in Ethiopia, then thought to be the world's only remaining endemic country. For Somalia to be identified as the last country with endemic smallpox was an embarrassment to its government. It was especially distressing to Somalia's health services, which for years had been sharply, and sometimes justifiably, critical of the programme conducted in adjacent areas of the Ogaden desert by the Ethiopians.

Since 1969 Somalia had been engaged in a WHO-assisted programme of smallpox vaccination and surveillance which national programme staff believed to be highly successful. As late as August 1975, the national programme director, in a meeting with Ethiopian staff at the border of the two countries, reported that 85% of the population had been successfully vaccinated. Although importations of smallpox had been frequent, most of the cases were said to have been detected within a few days of onset. They had occurred among nomads, who roamed freely across the vast Ogaden desert. Between 1972 and February 1976, 38 imported cases were acknowledged but only 4 secondary cases were said to have occurred. No cases were reported between February and September 1976, although later evidence suggests that it was during these months that endemic smallpox became re-established. In September, Somalia's report of smallpox cases brought the prompt assistance of experienced WHO epi-

demiologists. These staff members were handicapped by not being permitted to visit the sites of outbreaks or to travel widely in search of cases, but with their Somali counterparts they struggled to interrupt what seemed to be a few tenuous chains of transmission in Mogadishu, the capital. By January 1977, it appeared that they had succeeded. However, a country-wide search for cases was called for, and in March the government agreed to cooperate fully in making this possible. The search soon revealed that endemic smallpox extended throughout southern Somalia. Major epidemics followed, and in May the government declared an emergency.

An intensive operation was therefore started which brought support from many countries and agencies and assistance from WHO epidemiologists who had worked in other endemic countries. The government gave its full support, and on 26 October 1977, only 141 days after the emergency had been declared, the world's last case of endemic smallpox occurred. Meanwhile, more than 3000 cases had been recorded.

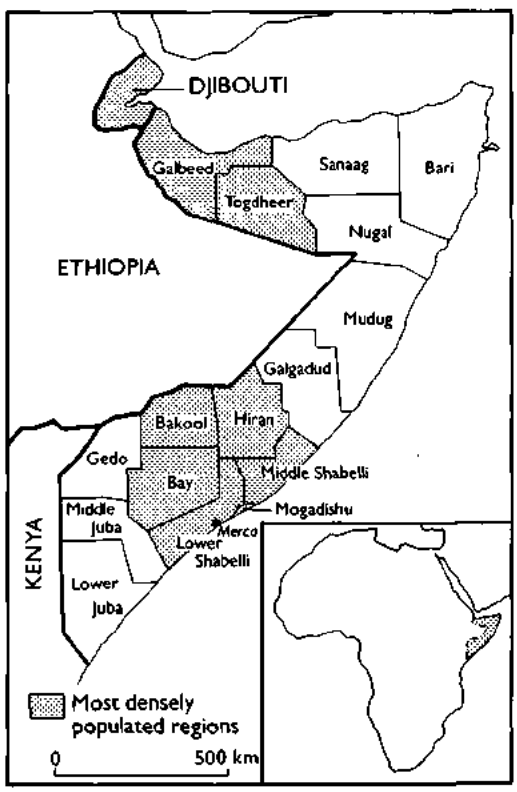

Fig. 22.1. Somalia: Regions and adjacent countries. Before attaining independence in 1977, Djibouti had been the French Territory of the Afars and the Issas.

This chapter deals with events in Somalia and, briefly, with the situation in the adjacent French Territory of the Afars and the Issas, which became the independent state of Djibouti in 1977 (Fig. 22.1). The latter country, with a population (1977) of 240 000, experienced periodic importations of smallpox from Ethiopia but the disease never became endemic. Outbreaks were controlled by containment vaccination; mass campaigns were conducted every 3 years.

For a detailed account of the Somalia programme, the reader is referred to the book *Smallpox Eradication in Somalia* (Ježek et al., 1981), from which much of the information in this chapter is derived.

BACKGROUND

The Somali people, who were predominantly nomadic and semi-nomadic pastoralists, roamed across the largely open and unmarked borders of the Horn of Africa in areas that included Somalia, parts of Djibouti, Ethiopia and Kenya. In 1960, when the country became independent, Somalia comprised the former British Somaliland Protectorate and the United Nations Trust Territory of Somalia, once an Italian colony. Thus, English was widely understood in the north and Italian in the south. Following a military coup in 1969, the country was administered by a Supreme Revolutionary Council and renamed the Somali Democratic Republic. The Somali Revolutionary Socialist Party was founded in July 1976 and provided political and administrative leadership throughout the country's 16 regions and 83 districts. The government's idea of uniting all the Somali peoples in one nation, regardless of existing political boundaries, was a source of contention with neighbouring countries throughout the course of the Intensified Smallpox Eradication Programme. This controversy was manifested in the continuing tension between Somalia and Ethiopia and in guerrilla warfare in areas of Ethiopia adjacent to Somalia in which Somali nomads lived.

Population Movements and Health Facilities

Nomadic pastoralists, who constituted about half Somalia's population (3.1 million

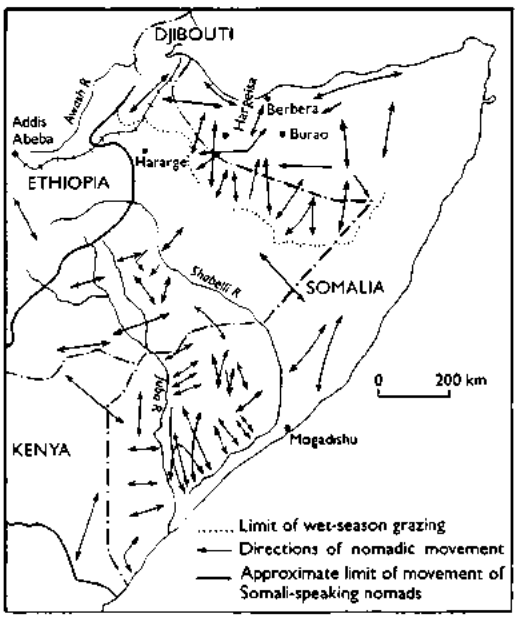

Fig. 22.2. Horn of Africa: approximate area covered by movements of Somali-speaking nomadic pastoralists.

persons in 1975), played an important role in sustaining smallpox transmission, carrying it from one area to another, where it spread among settled populations. An indication of the extent of pastoralism is provided by estimates (1975) of the numbers of livestock -3.5 million camels, 15 million goats and sheep, and 4.5 million head of cattle. A large proportion of the settled population was located along the coast in some 60 towns and cities, which were designated as municipal centres. Fewer than 25 of these, however, had more than 5000 inhabitants; by far the largest was Mogadishu (population, 450 000). Small settlements were also found along roads and in an agricultural area in southern Somalia. It was the south that was afflicted by the 1977 epidemic.

The population of Somalia was most heavily concentrated between the Juba and Shabelli rivers in the south and in areas to the south-east of the French Territory of the Afars and the Issas in the north. About 1.5 million people lived in the most heavily populated areas in the south and about 900 000 in the north. The rest were widely scattered over a vast, arid scrub desert in which population densities seldom exceeded 1 or 2 persons per square kilometre. Travel between the northern and southern areas was infrequent. During the dry season, the nomadic population in the north congregated near deep wells, primarily within Somalia; during the March June rainy season, they travelled south and settled widely over a grassy well-watered plateau area in Ethiopia (Fig. 22.2). In the south, the pattern of movement was more complex. Nomads

Plate 22.1. The unpredictable movements of Somali nomads made the search for cases difficult. Their huts were easily carried on camel-back (**A**) and quickly erected (**B**).

located west of the Juba river travelled to more westerly districts and into Kenya in the rainy season. During this period, those living between the two rivers dispersed widely throughout the area because of the hordes of insects, especially the riverine species of tsetse flies, which infested the river banks and localities with standing water. The nomads whose herds consisted only of camels or cattle moved more or less constantly throughout the year. Others, termed "semi-nomads," had mixed herds of camels, cattle, sheep and goats and settled during the crop-growing season to cultivate arable land.

The movements of nomads, particularly in the south, were unpredictable, even from one day to the next. This made it exceptionally difficult to conduct any sort of systematic programme, either of case detection or of vaccination, especially during the rainy season, when roads became all but impassable. The rains fell irregularly, sometimes consisting of scattered localized downpours extending over only a few square kilometres. The different nomadic groups competed for the scarce vegetation and each had several searchers who roamed extensively. When rains fell in an area, the report of a searcher might cause an entire group to dismantle its camp, pack up its belongings and move 50 kilometres or more over a period lasting several days. Moreover, the nomadic groups, often consisting of only 3 or 4 families, frequently broke up into smaller subgroups for the sake of mobility, and families often shifted from one group to another. Although the women, girls and small children stayed in the camps, the men and older boys accompanied the herds; the younger men, who herded the camels, frequently ranged over great distances.

During the time of the smallpox eradication programme in Somalia, there were 4 other factors which led to substantial movements of population. The first was the seasonal need in the south for large numbers of agricultural labourers, which brought nomads and others from sparsely settled areas to the banana and sugar-cane plantations. The second was severe drought, which occurred throughout the Ogaden desert in 1974–1975 and led to the migration from the Ethiopian portion of the Ogaden of an estimated 200 000–300 000 persons, many of whom were accommodated and fed in refugee camps (Plate 22.2) in Somalia and the French Territory of the Afars and the Issas. The third was the Somali–Ethiopian war, which began

UNHCR / W. GAPTUNG

Plate 22.2. Laas Dhurre camp, Hargeisa District, Somalia. War and famine drove thousands of refugees out of Ethiopia.

in 1977 and resulted in tens of thousands of refugees fleeing into border areas of Somalia and Djibouti. The fourth was a programme, launched in 1975, to resettle upwards of 100 000 nomads in southern agricultural areas.

Health services in the two countries were much more extensive than in Ethiopia. In Somalia in 1968, there were 21 hospitals and 187 health posts and dispensaries with more than 1300 trained health personnel. In the French Territory of the Afars and the Issas, there were 6 hospitals and 16 dispensaries and a health staff of 450 persons, including 41 physicians. The Somali road network—also more extensive than in Ethiopia—consisted of 2000 kilometres of asphalt-surfaced roads and 4000 kilometres of gravel and earth roads.

Smallpox and its Control before 1969

As was the case in most countries, reporting systems in Somalia and the French Territory of the Afars and the Issas were poor and data on smallpox are incomplete. Variola minor was said to have been the predominant form during recent decades and, in some areas, health staff differentiated between the more severe cases, which they called "true smallpox", and the less severe, which they called "alastrim". Because cases of variola minor were often not reported as smallpox, this distinction undoubtedly contributed to underreporting. From the available data, it appears that endemic transmission in Somalia ceased in about 1962 (Table 22.1). The French Territory of the Afars and the Issas—at least since 1930—experienced only rare sporadic outbreaks following importations, but 2 outbreaks, in 1959 and 1966, are of special interest. Both resulted from importations from Ethiopia and occurred over a 2-month period. The first consisted of 110 cases with 13 deaths (11.8%), and the second of 52 cases with 6 deaths (11.5%). The two outbreaks and the report of a single outbreak in Ethiopia in 1964 (Teclemariam, 1965) provide the only documentary evidence of the persistence of variola major in Ethiopia or the Horn of Africa after about 1955. Apart from the 1966 outbreak in the French Territory of the Afars and the Issas, during which the disease was imported into Somalia, no cases of smallpox were recorded in either country between 1963 and 1971.

[a] .. = data not available.

The infrequent occurrence of smallpox in the French Territory of the Afars and the Issas and the cessation of transmission in Somalia in 1962 could not be attributed to national vaccination campaigns. Both countries offered vaccination for those travelling abroad and conducted localized vaccination campaigns when outbreaks occurred. The French Territory of the Afars and the Issas carried out its first country-wide campaign in 1966, during which 115 000 people were vaccinated; thereafter, campaigns using freeze-dried vaccine were conducted every 3 years, each resulting in the vaccination of 100 000–120 000 persons. Somalia, using a locally produced liquid vaccine until 1966, vaccinated only 20 000–50 000 persons a year, primarily the inhabitants of major towns who required vaccination certificates for travel. In addition, because of outbreaks, special vaccination campaigns were conducted in 1962 near the Kenyan frontier and in 1966 near the border of the French Territory of the Afars and the Issas and in Mogadishu. During the latter campaign, 194 000 persons were vaccinated, but with vaccine of dubious quality; a study carried out in 1967 revealed that only 14% of those given primary vaccination had had successful takes.

Special vaccination scar surveys (Table 22.2) conducted in 1967 by a WHO medical

Table 22.2. Somalia: results of vaccination scar surveys, by age group, 1967 and 1968

officer and in 1968 by United States Peace Corps volunteers showed that vaccinial immunity was poor even among the rural settled population of Somalia. It was undoubtedly much lower among the nomads.

Until the early 1960s variolation had been widely practised when outbreaks of smallpox occurred. However, no evidence of active variolation was discovered in either country during the 1970s, although as recently as August 1976, Ethiopian staff observed the practice in a Somali-speaking nomad group in the Ogaden desert in Ethiopia (see Chapter 21).

Despite the low level of vaccinial immunity and the proximity of these countries to Ethiopia, which was heavily endemic, the continuing transmission of smallpox had apparently ceased. Imported cases were few, although, because notification systems were poor, it is likely that more occurred than were reported. Long-sustained endemic spread did not, however, develop, the only reasonable explanation for this being that the susceptible population was too widely dispersed for transmission to be sustained. The long absence of endemic smallpox bred an unwarranted confidence among national and WHO staff alike that the disease would not re-establish itself even if it were imported. Similarly, Ethiopian staff were comparatively unconcerned about smallpox among Somali-speaking nomads in Ethiopia and until 1976 gave little priority to their programme in the Ogaden desert.

THE COMMENCEMENT OF THE SMALLPOX ERADICATION PROGRAMME, 1969

Because of the smallpox situation in the neighbouring country of Ethiopia, the development of an eradication programme in Somalia was considered important. The government expressed interest, and a WHO consultant visited the country in January 1968 to formulate a plan of operations. This called for a 3-year national vaccination campaign, from 1969 to 1971, coupled with routine assessment of vaccination coverage, as well as the development of a reporting system and surveillance activities. WHO agreed to provide an adviser, vehicles, equipment and vaccine; to meet the necessary operating costs; and to pay a supplementary per diem allowance for all Somali staff when they travelled in the field. Up to the end of 1976, WHO's annual contribution to the programme was modest (Table 22.3) but adequate, in view of the country's small population.

The plan of operations was similar to many other such plans in the Intensified Programme. It called for vaccination to be performed by mobile teams moving in groups from village to village and from house to house. This would serve to protect the settled population, although little thought was given in the plan to the vaccination of nomads, who comprised half the total population. It was decided simply to vaccinate those who were found at water-holes or encountered by chance when the teams were on their travels. From later observation, it was apparent that only a small proportion of the nomads could have been vaccinated by this approach, a deficiency in the campaign which might have been discovered and corrected if the assessment of coverage had been well conducted. The problem was not pursued until 1977.

The vaccination campaign was slow in starting and never functioned well (Table

Table 22.3. Somalia: expenditure by WHO for smallpox eradication and number of doses of vaccine supplied, 1967–1979

Year	Expenditure (US$)	Number of doses of vaccine

22.4). A WHO smallpox adviser arrived in June 1968 to assist with operations, but the campaign was not launched until August 1969. It began in Mogadishu, where 6 teams with 33 workers took nearly 6 months to vaccinate the city's population. Thereafter, 20 vaccinators began work along the Kenyan border, and in May 1970 a group of 12 workers started to vaccinate people in the north of the country. However, the campaign was suspended in November 1970, when cholera began to occur and the teams were directed to administer cholera vaccine. In June 1971 the smallpox vaccination campaign was resumed and by the beginning of 1974, the teams had completed 2 tours of the country. By the end of that year nearly 3.5 million smallpox vaccinations had been recorded, a number which was approximately equivalent to the population.

The number of vaccinations in relation to population would suggest that a reasonably high degree of vaccinial immunity must have been attained by the end of 1974. However, attempts to confirm this by assessment were never diligently pursued. From information that became available in 1977, it would appear that the coverage in settled populations was at best 60–80%; among nomads in the south, it ranged from 10% to 20%.

During 1974 the smallpox vaccination teams were disbanded and their members dispersed throughout the country initially to participate in a national literacy campaign, and then, after a severe drought in 1974–1975, to help in refugee and relief camps. Finally, at the end of 1975 some of the staff returned to full-time duties with the smallpox eradication programme. At that time, 2 teams of 4 persons began a campaign of both smallpox and BCG vaccination, one team working near border areas in the north and the other in the south. While vaccinating, they searched for cases. With so few personnel engaged, less than one-third of the country could be visited in the course of a year.

No cases were reported in either the French Territory of the Afars and the Issas or Somalia from 1967 until late 1971. However, between November 1971 and July 1976, the two countries together reported 173 cases, the former reporting 131 cases, of which 16 were believed to have been importations from Ethiopia, and Somalia 42 cases, of which 38 were said also to have been imported from Ethiopia. It is probable that there were other cases, since neither country had an organized notification system or an active programme of case detection. Reporting was further compromised because the cases were of the mild variola minor type and some nomadic groups concealed infected persons to avoid being ostracized by other groups, as was the custom when variola major was present.

The first case to be reported for more than 4 years in either country was detected in mid-November 1971 in Djibouti City in a recent arrival from the north of the Territory (Fig. 22.3). Later investigation suggested that smallpox had been introduced from Welo Province, Ethiopia. Other cases soon followed and by the time the outbreak had ended, on 29 February 1972, 104 cases had been documented. Most of them (79) were found in the city itself; the remainder occurred in 4 smaller rural outbreaks. A triennial mass vaccination campaign, scheduled to commence in January 1972, actually began some weeks earlier, and in a matter of a few months, 117 000 vaccinations had been performed.

In October 1972, another imported case from Ethiopia was detected in the French Territory of the Afars and the Issas, but this time secondary spread did not occur. Also in October—for the first time in 6 years—Somalia reported cases; the 5 patients concerned were said to have been infected in Hararge Province in Ethiopia. No secondary cases were reported.

During 1973, cases were imported into both countries. The French Territory of the Afars and the Issas reported 14 cases: 10 represented importations and 4 were among contacts, 3 of whom were infected while hospitalized. Somalia reported 7 cases, of which 6 occurred in the southern part of the country. Their place of origin in Ethiopia was unknown. As in 1972, all were said to have

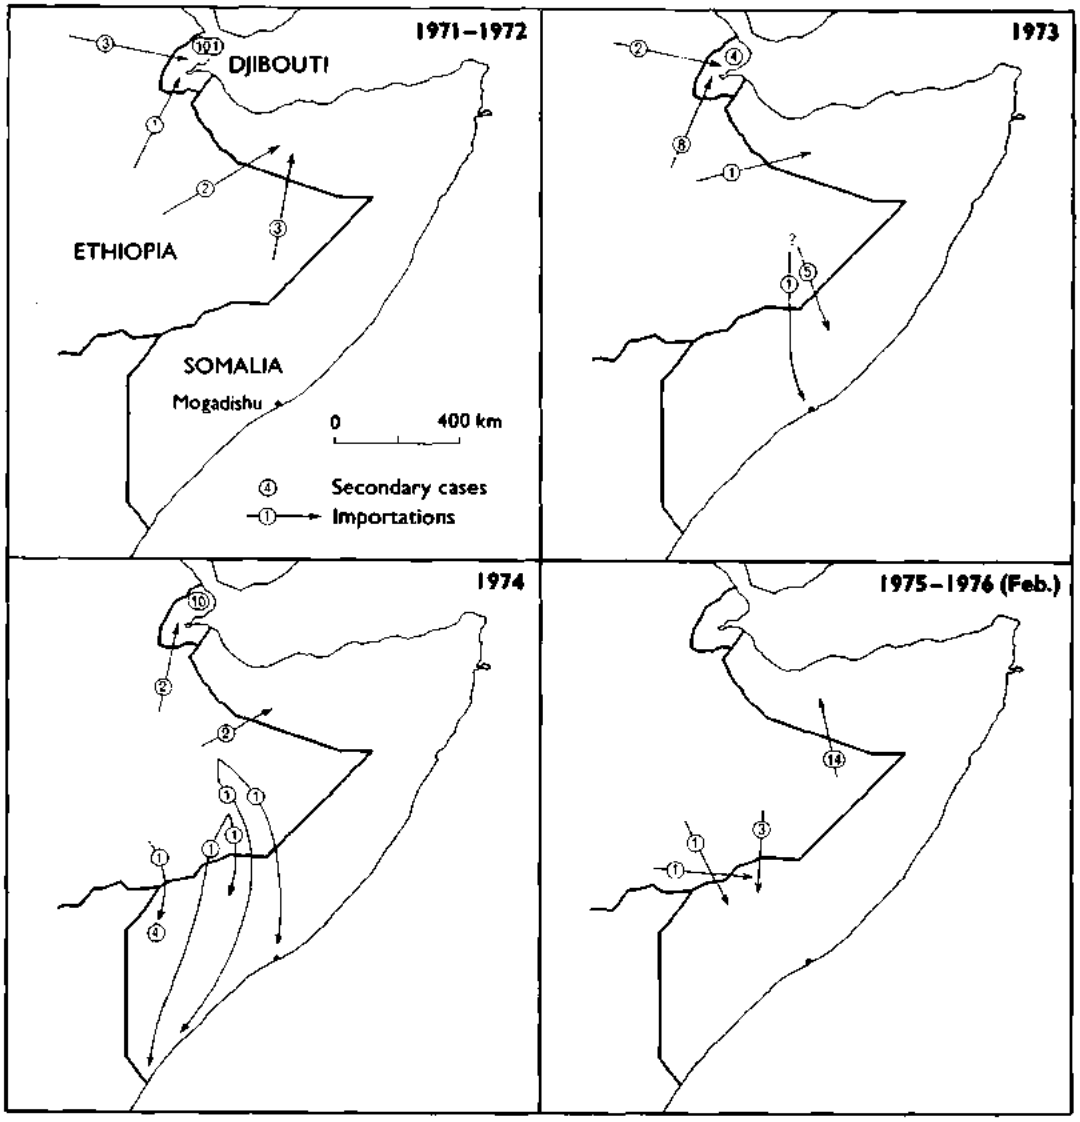

Fig. 22.3. Somalia and Djibouti: reported importations of smallpox, November 1971–February 1976.

been detected within a few days after the onset of rash and no secondary cases were reported.

In 1974 the French Territory of the Afars and the Issas reported another 12 cases, of which 2 were importations, the remainder resulting from the subsequent spread of infection. These were the last known cases in the Territory. Nine of the 11 cases in Somalia that year occurred in the southern part of the country, in parallel with a spread of smallpox in Ethiopia from the northern mountainous plateau into the southern Ogaden desert. For the first and only time Somalia reported 4 secondary cases, all close contacts in a single household.

From January 1975 to the end of February 1976, Somalia reported an additional 19 imported cases, many of which were in refugees in drought-relief camps, but no secondary cases were said to have occurred.

In 1975–1976, the Smallpox Eradication unit at WHO Headquarters became increasingly sceptical that the reports submitted to WHO from Somalia were complete or fully accurate. It seemed unbelievable that, between October 1972 and February 1976, Somalia could so quickly detect and contain

38 importations, with secondary spread occurring on only one occasion, given the paucity of staff and the lack of an organized surveillance programme. No other country had been so successful in the rapid detection and containment of imported cases. Moreover, data submitted to WHO regarding the dates of onset and dates of detection for 30 of the cases indicated that 20 were supposed to have been detected within 3 days after the onset of rash; yet even the most experienced clinicians had difficulty in identifying cases of smallpox so early in the course of the disease. Even in countries with an adequate surveillance system, cases were rarely detected and diagnosed until a week or more after onset. The reports from Somalia seemed too good to be true. The fact that some of the cases were first reported to WHO in Geneva through one of the embassies in Mogadishu but were not notified officially to the Organization until questions had been raised with the Somali government did nothing to increase confidence in the official reports.

Meanwhile, in letters from Henderson to the WHO regional smallpox adviser, copies of which were sent to the WHO smallpox adviser in Somalia, repeated attempts were made to obtain additional information about the status of the programme and the occurrence of cases, and advice was offered as to the methods that should be adopted in the investigation, containment and notification of outbreaks. One letter, dated 23 February 1976, is of special interest in view of subsequent events:

"The occurrence of 4 importations into Somalia during the course of only a few weeks is both surprising and alarming. It suggests indeed that many more may occur and unless due care is taken, I believe there is a very real risk that Somalia might become epidemic... I am very concerned that Somalia should not become an endemic area just at that point when we believe the problem in Ethiopia is coming under control. The memory of Botswana becoming reinfected just at that point when the last cases in South Africa were occurring is too fresh!"

Somalia reported a case in February 1976 but no others were notified during the next 6 months. No reports were received from embassy sources, which had, in the past, been reasonably prompt and accurate in forwarding information. In retrospect, greater efforts should have been made during this period to assess the problem through personal visits but because of the complex logistics of the final phase of the Intensified Programme in Ethiopia and a range of activities concerned with the certification of eradication in many different countries, the attention of WHO Headquarters and regional smallpox eradication staff was diverted from a country which was apparently free of the disease.

At some point in 1976 smallpox became reestablished in Somalia. It could not be determined exactly when this occurred, and information about the cases could not be obtained. Political problems played a role in inhibiting surveillance and the reporting of cases. In the Ethiopian portion of the Ogaden desert, the Western Somalia Liberation Front had been formed in the early 1970s and a liaison office set up in Mogadishu. Training camps were established in Somalia near the border with Ethiopia, and guerrilla forces as well as nomads began moving back and forth across the border in larger numbers. In 1976–1977, guerrilla warfare steadily intensified, eventually culminating in the occupation of the Ethiopian portion of the Ogaden desert by the Somali army in July 1977.

THE SMALLPOX OUTBREAK IN MOGADISHU, SEPTEMBER 1976

After the last known case of smallpox occurred in Ethiopia, on 9 August 1976, 7 weeks passed during which no case was reported from anywhere in the world. Specimens from patients with rash and fever in many countries were received daily by the WHO Smallpox Eradication unit in Geneva and dispatched to the reference laboratories in Atlanta and Moscow. None of them showed evidence of poxvirus until 27 September, when the Atlanta reference laboratory reported the presence of poxvirus in 2 specimens from Somalia. Henderson immediately sent the following cable to Mogadishu:

"POXVIRUS PARTICLES PRESENT BOTH SPECIMENS STOP DIAGNOSIS OF SMALLPOX VIRTUALLY CERTAIN STOP URGENT THAT EVERY CONTACT SINCE RASH ONSET BE FOUND AND VACCINATED INCLUDING ALL HOSPITAL PATIENTS STOP SITUATION MOST CRITICAL SINCE NO SMALLPOX SINCE 9 AUGUST IN ETHIOPIA STOP ESSENTIAL DETERMINE WHERE BOTH PATIENTS WERE EACH DAY FROM SEVEN TO SEVENTEEN DAYS BEFORE ONSET STOP SUSPECT BOTH EXPOSED SAME LOCATION

STOP HIDDEN FOCUS MUST BE PRESENT NEAR BORDER OR POSSIBLY ELSEWHERE STOP THIS COULD BE WORLDS LAST FOCUS STOP ESSENTIAL THIS BE FOUND AND CONTAINED URGENTLY STOP ARITA DEPARTING EARLIEST POSSIBLE FLIGHT TO ASSIST."

Arita departed for Somalia forthwith to help in the investigation, and telephone and telex messages between Geneva and Mogadishu began to be exchanged daily.

By the end of September, 5 patients who had experienced the onset of smallpox between 30 August and 23 September had been placed in an isolation hospital in Mogadishu. The first 2 entered hospital on 1 and 14 September respectively; these were the patients from whom the first specimens had been taken. The remaining 3 were hospitalized between 20 and 25 September.

The 5 patients, ranging in age from 16 to 70 years, were questioned repeatedly by Arita and Somali staff in an effort to determine where they might have contracted the infection. They all claimed to have been living in one or the other of two areas in Ethiopia and said that 8–10 days before the onset of illness they had travelled to the Somali border on foot and thence had taken a bus to Mogadishu, a distance of 400 kilometres (Fig. 22.4). Two patients were said to have reported seeing other people with a similar type of rash in areas of Ethiopia from which they said they had come. The two areas thus identified were situated in the desert, one lying south-west of Dimo, the site of the last known outbreak in Ethiopia, and the other further to the south-east, near the border. The reports were plausible. Ethiopian teams had been actively searching for many months throughout most of the Ogaden except in the province in which the two suspect areas were located. There, search operations had been delayed until August 1976 by guerrilla warfare and were somewhat hampered thereafter.

Arita immediately travelled to the Somali–Ethiopian border to contact WHO epidemiologists working in the Ethiopian part of the Ogaden desert. By conveying to them in detail the information obtained from the 5 patients, he hoped that the focus in Ethiopia might be quickly located and contained. An extensive search in Ethiopia was promptly undertaken by a staff which included 8 Ethiopian sanitarians, 5 WHO epidemiologists and 150 search workers using vehicles, helicopters and a fixed-wing aircraft. The entire area was searched repeatedly over a 6-month period, but no evidence that smallpox had been present after July 1976 could be found.

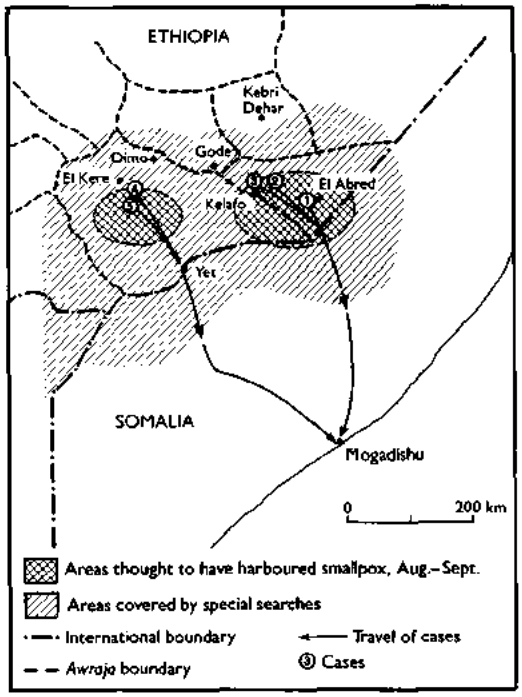

Fig. 22.4. Ethiopia and Somalia: areas thought to have harboured smallpox and areas searched, 1976.

A more accurate, although still incomplete, account of what had actually happened did not become available for many months, indeed years. The search for a source of infection in Ethiopia had, in fact, been futile because, by then, endemic smallpox had already become established in Somalia, a fact known both to Somali staff and to the WHO smallpox adviser.

For Somalia at that time to admit to the existence of cases was awkward for both the political leaders and the national health staff. With tension mounting between Somalia and Ethiopia, the periodic meetings of national smallpox eradication staff from the two countries at border posts had become increasingly acrimonious, as each expressed doubts about the quality of the other's programme. In September, Somali programme staff simply did not believe that Ethiopia had become smallpox-free. A letter dated 11 November 1976 from the WHO representative in Somalia to the Director of the WHO Re-

gional Office for the Eastern Mediterranean, reflected the prevailing emotional climate:

"Government authorities have resented the fact that Ethiopia has been declared free from smallpox, almost at the same time as Somalia was declared as the last known infected focus in the world. This is viewed as some kind of international conspiracy and the influx of WHO smallpox experts as adverse publicity for Somalia."

Reports later received by WHO field staff indicated that other suspected cases of smallpox had been hospitalized as early as June 1976, and less definite information suggested that there had been other unreported cases, indeed sizeable outbreaks, earlier in the year. Somali staff had hoped that containment could be achieved without publicizing the outbreaks, thus avoiding the stigma of Somalia's being identified as the last infected country. As in other countries that sought to contain outbreaks while suppressing information about their existence, the outcome was disastrous.

With smallpox known to have been prevalent in Somalia for many months, it is curious that a decision was made, on 14 September 1976, to obtain specimens from 2 patients and to submit them to WHO for laboratory examination. Three events appear to have been responsible: first, the receipt of a letter from Henderson informing Somali programme staff about a projected news conference to announce that the world's last case of smallpox might now have occurred; secondly, the arrival in Mogadishu of Dr Bert van Ramshorst, a WHO smallpox adviser with the Ethiopian programme who had been seized by the Somali border police; and thirdly, the first occurrence of smallpox cases in the capital city. Henderson's letter, dated 30 August, was addressed to the regional smallpox adviser at the WHO Regional Office for the Eastern Mediterranean in Alexandria, and a copy was sent to Mogadishu:

"As the days go by, it seems increasingly possible that the Bale [Ethiopia] case with onset on 9 August 1976 could be the world's last case of smallpox ... my guess would be that it will be difficult to have reasonable confidence about this until late October. When we do reach [that] point, the Director-General would like to make a major announcement with maximum possible news coverage... Such an announcement conceivably could be made jointly with the Secretary-General at the [United Nations] General Assembly ... one would not wish to make an announcement that there are no known smallpox foci without having reasonable confidence that another outbreak would not emerge one or two weeks later. We know, of course, that we cannot have full confidence until at least two years have elapsed... [but] the provisional announcement, which would be highly newsworthy, could come, I believe, as early as late October."

That the programme in Ethiopia might be better than Somali officials had believed was confirmed by Dr van Ramshorst. The report of the WHO smallpox adviser in Somalia, dated 16 September 1976, to the regional director is of interest:

"Dr van Ramshorst crossed into the Somali territory on the afternoon of 8 September 1976 near Abu Duaaq. He was detained by border police and handed over to security authorities who brought him to Mogadishu the same night. He was in Mogadishu from 9 to 13 September before RR UNDP [Resident Representative, United Nations Development Programme] was informed about his detention ... During Dr van Ramshorst's stay in Mogadishu, we have made some useful exchange of information ... I was able to arrange a meeting with the Minister. The Minister was favourably impressed with the zeal and enthusiasm demonstrated by Dr van Ramshorst in the pursuance of the objectives of the programme ... for the first time the Somali health authorities have now appreciated the effort that is being put into the programme on the other side of the border."

The possibility that Ethiopia might be free of smallpox could no longer be discounted. The discovery of smallpox cases in Somalia after an announcement by the Director-General of WHO that smallpox appeared to have been eradicated would have been most embarrassing. The concealment of the outbreak in Somalia could continue no longer.

Initial Containment Measures

Somali programme teams assisted by 2 WHO advisers endeavoured to find the source of infection of the 5 cases and, still believing that it was in Ethiopia or along the Somali side of the border, undertook a 3-day search in border areas in Somalia, from 3 to 6 October 1976, but discovered no cases. They reported that 80–90% of the villagers whom they saw had vaccination scars. A more intensive search was deemed necessary, and 32 staff and a WHO epidemiologist, provided with 4 vehicles, were assigned to the task. The

Plate 22.3. The WHO smallpox recognition card was abundantly used by the Somali search teams inquiring about possible cases of smallpox.

search began on 9 October and was completed on 2 November. It ranged over an area about 500 kilometres long by 100 kilometres wide but revealed no cases. In all, some 12 000 persons were seen in approximately 30 different villages; 74% had vaccination scars. Of 1200 nomads seen at watering-places, 68% had previously been vaccinated. All denied having seen cases of smallpox for 2 years or more.

Meanwhile, house-to-house night-time searches were conducted in Mogadishu on 18 and 25 October (Fig. 22.5) utilizing 60 programme staff in the northern part of the city, in which the cases had been discovered, and 2000 other staff, including police, to search the other areas.

Cases continued to be admitted to hospital and by the end of October, 20 had been officially reported (Fig. 22.6). The sources of infection of only 10 cases could be documented. Careful investigation, search and vaccination in and immediately around the dwelling of each patient were urgently required. The WHO epidemiologists were skilled in this approach but were not permitted to accompany Somali health staff in visits to houses in the city or in questioning patients at the hospital. Containment was less than optimum because vaccination was conducted only during the daylight hours, when most adults were away from home. To help in detecting cases, WHO staff proposed that a reward should be offered to anyone reporting a case, but this proposal was not accepted.

The persistence of cases led to a city-wide vaccination campaign extending from 28 October to 15 November, and this was followed on 16 November by yet another night search. Only 9 cases of smallpox were reported in November, and for 8 of them the source of infection could be clearly identified. It was hoped that the outbreak might be coming to an end but, as it was later learned, the notification of cases continued to be suppressed. Smallpox patients were then being admitted to two different parts of the hospital, one in which cases were officially reported and another in which they were not. Officially 34 cases were registered as having been hospitalized in 1976; the unofficial hospital register, not made available until 1978, showed the actual number to have been more than 500.

The continuing failure to discover the source of infection of what was thought to

have been the first 5 importations into Mogadishu was most disturbing at the time. It was claimed that the foci had been in Ethiopia but no evidence of smallpox had been found there since early August. The most reasonable explanation, seemingly, was that the cases had occurred among nomadic groups which had moved elsewhere before the search. With the passage of time, it was thought that such groups might well have penetrated far into Somalia. Search of the border regions in Somalia had failed to detect cases and none had been reported subsequently by 5 Somali mobile teams then working outside Mogadishu. However, no systematic search had yet been conducted in the 5 other administrative regions of southern Somalia. Accordingly, WHO proposed to the health authorities that such a search should be undertaken, with support from 2 additional experienced WHO epidemiologists who had recently arrived in Mogadishu. A plan was elaborated by Somali and WHO staff which called on WHO to provide 10 more vehicles, to be obtained through emergency local purchase in Kenya, and to cover the necessary local costs. An expenditure of US$350 000 was envisaged. On 11 November the Director-General of WHO, in a telegram to the Minister of Health, approved the expenditure, ending on the encouraging note that it was to be hoped that the concerted effort over the next 2 months would be sufficiently intensive to identify clearly and to interrupt the links in the chain of transmission. If this proved successful and it could be asserted with confidence that no hidden foci existed, he would plan to make a formal announcement at the January 1977 meeting of the WHO Executive Board that the world's last smallpox foci had been eliminated. The Minister, in his reply three days later, affirmed the government's commitment: "... we shall spare no efforts to mobilize all available resources...", but he pointed out that Somalia would not have had the problem if Ethiopia

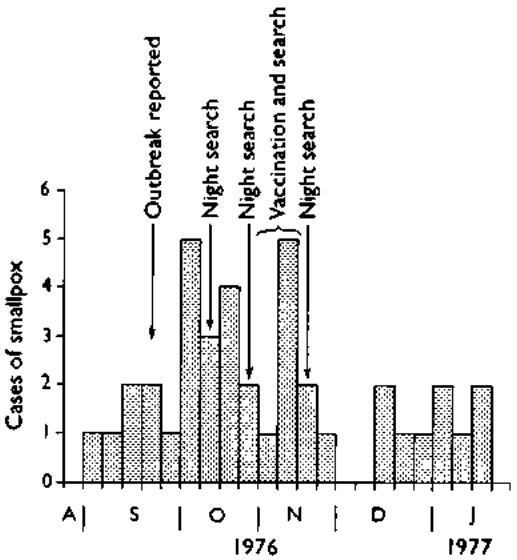

Fig. 22.5. Mogadishu: number of reported cases of smallpox, by week of onset, September 1976–January 1977.

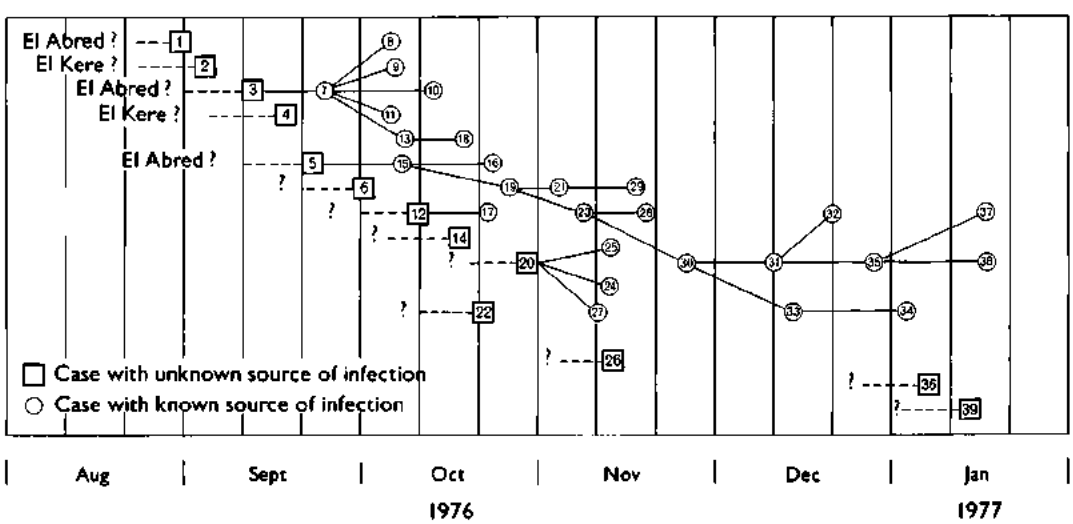

Fig. 22.6. Mogadishu: ostensible chain of transmission of smallpox, September 1976–January 1977.

had acted prudently; he requested that US$2 000 000 should be made available.

Permission to search in the 5 regions was not, however, forthcoming. It was therefore proposed that Ladnyi, at that time an Assistant Director-General of WHO, should visit Somalia early in December to discuss the problem. With Ladnyi's impending visit, permission was given for the WHO epidemiologists to make 1-day visits to each of the regions in the south; later, on 15 December, they were allowed to make such visits in the northern regions. Little could be done in the way of search during such brief visits but at least the WHO staff were thus enabled to make personal contact with the regional health authorities and to discuss the need for case detection—though everyone they spoke to denied that smallpox was present.

As a consequence of Ladnyi's visit, permission was given for WHO staff to visit the hospital regularly with Somali counterparts and to undertake investigations throughout the city. Thereafter, the transmission of smallpox in Mogadishu subsided rapidly. However, despite the visit, WHO staff were not allowed to participate in a search in other parts of the country. The Minister insisted that not less than US$2 000 000 would have to be provided before a search could begin. WHO staff considered this to be an exorbitant sum; moreover, it far exceeded the amount of money WHO then had at its disposal for smallpox eradication.

Although a national search for cases could not be undertaken, the situation appeared to improve from January to mid-March 1977. In Mogadishu, the vaccination of contacts and close neighbours of patients began to be conducted at night as well as during the day, and on 17 January 1977, the last case was reported. Repeated night searches of the entire city in January and again in February failed to detect further cases. Sanction for an organized national search was finally given on 21 January, during the fifty-ninth session of the WHO Executive Board, when the Director-General, the Director of the WHO Regional Office for the Eastern Mediterranean, Ladnyi and staff of the Smallpox Eradication unit held a private meeting with a member of the Board from Somalia. He agreed that 6 more experienced epidemiologists should be recruited immediately by WHO to serve as advisers in each of 6 regional administrative areas in southern Somalia and to help in conducting an intensive search commencing late in March. WHO agreed to provide the proposed US$350 000 in additional funds to cover expenditure on transport and supplies and local costs. It was also agreed that a special meeting would be convened in March to coordinate what was hoped would be final search activities throughout Ethiopia, Kenya, Somalia and the Sudan to confirm that eradication had been achieved.

The development of the programme in Somalia at this time was greatly facilitated by the appointment in February of a new national Smallpox Eradication Programme Manager for Somalia, the knowledgeable Dr Abdullahi Deria, who had just returned to the country from a course of study in tropical medicine. With Dr Ehsan Shafa, of the WHO Smallpox Eradication unit, he immediately set to work to draw up a search plan. So far as WHO staff then knew, only 39 cases of smallpox had been admitted to the hospital in Mogadishu, and although everyone was aware that some additional cases had occurred, it seemed unlikely that a national search would turn up large numbers of outbreaks. To facilitate the detection of cases, Dr Deria and Dr Shafa decided that, beginning in March, a reward of 200 Somali shillings (US$32) would be offered to anyone reporting a case.

WHO / E SHAFA

Plate 22.4. This man reported a case that proved to be smallpox and received the reward of 200 Somali shillings.

A disturbing event during this period was the discovery on 30 January 1977 of an outbreak in Kenya. The first case had occurred on 26 December 1976 in a Kenyan village near the Somali border, introduced by a young man returning from a religious school in Mogadishu. Shortly after becoming ill, he had returned to Somalia but no one knew where he had gone. Meanwhile, he had infected 4 other persons—his sister and her 3 children. Possible areas in and around Mogadishu were searched, but to no avail. In February, when it was learned that he might have gone to a town 80 kilometres north of the city, a Somali–WHO team investigated this area, but again, neither the patient nor any evidence of smallpox was found. It is not known what relationship, if any, the index case bore to outbreaks which were found subsequently. In part, this was because the government asked that when the 6-month national search was undertaken, cases and outbreaks which had occurred previously should not be documented.

First Coordination Meeting, March 1977

To coordinate the forthcoming intercountry search programme, Arita, with assistance from Dr Wilfred Koinange, Director of Health Services of Kenya, convened a meeting in Nairobi on 15 March 1977 of health staff from Ethiopia, Kenya, Somalia, and the Sudan. At that time, more than 2 months had elapsed since a case had last been notified. Each of the delegates reported on the nature and extent of his country's surveillance programme and expressed hope that smallpox transmission had been interrupted. Dr A. I. Idris from the Sudan, who was still sceptical, pointed out that, however satisfactory surveillance appeared to be, no link had been discovered between the outbreak in Kenya and the last outbreaks in Mogadishu. To him this indicated that other undetected cases must have occurred, and until the chains of transmission had been clearly identified efforts could not be relaxed. It was a prophetic observation.

The participants all agreed to undertake similar types of search programmes over the succeeding 6 months, involving house-to-house searches for cases and special searches among nomads, the collection of specimens from cases both of chickenpox and of suspected smallpox, and notification through WHO Headquarters in Geneva of rumours of outbreaks in other countries. Priority would be given to the Ogaden desert area. In Ethiopia a thorough search of the area would be carried out every 4–6 weeks employing 224 search workers, 16 supervisors and 4 WHO epidemiologists, provided with 18 vehicles and 2 helicopters. Kenya planned to utilize 320 public health staff and 64 locally recruited workers with 16 vehicles. In Somalia 300 search workers, 10 Somali supervisors and 7 WHO advisers with 19 vehicles would be deployed. The group agreed to meet again 6 months later to assess the situation and to decide on future action. Staff from Djibouti would also be invited to that meeting to ensure full coordination of all activities throughout the entire area.

EPIDEMIC SMALLPOX IN SOMALIA, MARCH 1977

Shortly after the Somali smallpox eradication staff returned from the Nairobi meeting, Dr Deria reported to the WHO advisers that 2 cases of smallpox had been discovered in Bakool Region, near the Ethiopian border—the first outbreak to be officially reported outside Mogadishu. A joint Somali–WHO team visited the area and was told that the first patient had been in an Ethiopian village 2 weeks earlier. Ethiopia was immediately notified but investigation revealed no evidence of smallpox in the designated village either at that time or in the past. A few days later, another case was reported from a village much further south but no source of infection could be identified. On 24 March, yet another case was reported. By mid-April there were 29 cases, and more were being discovered daily as the search programme was gradually intensified. Villagers revealed the disturbing information that smallpox outbreaks had occurred outside Mogadishu in 1976, but these had never been notified. Indeed, an outbreak of 17 cases in November and December 1976 was found to have been verified by both the regional medical officer and the WHO smallpox adviser but not officially reported.

Meanwhile, experienced WHO staff members working in India, including Dr M. K. Al Aghbari, Dr W. Hardjotanojo and Mr R. J. Hatfield, were mobilized and sent to Mogadishu in March. However, they were too few to cope with the situation. In April, Arita

A Unique Approach to Case Detection

In March 1977, the suppression of information and the concealment of cases continued to be widespread despite the new instructions of the Ministry of Health. One of the first to break this barrier was an ingenious Sudanese sanitarian, Mr Abdul Gadir El Sid, who was serving as a WHO consultant. On entering a village for the purpose of investigating suspected cases, he saw several persons with facial pockmarks suggestive of recent smallpox but was confronted with unanimous denial by the villagers that cases had recently occurred. Taking over the vehicle from his driver, he deliberately drove it into deep mud. A large crowd came from the village to help to extricate the car, and among them were 4 persons with active smallpox.

hurriedly flew from Geneva to Mogadishu, and with the agreement of the government immediately took measures to recruit 8 additional WHO epidemiologists to complement the 7 provided by the Organization who were already working there. It was the first step towards a greatly intensified effort (Table 22.5). In April alone, 157 cases were documented in more then 40 outbreaks (Table 22.6). However, the discovery of cases and the containment of outbreaks among nomads were proving to be extremely difficult. The encampments were often hard to locate in the high scrub; the groups were small, averaging no more than 30–40 persons; and less than 25% remained in a given location for more than a week. Meanwhile, search in Ethiopia was increasingly hampered by guerrilla warfare and border hostilities. The final goal of global smallpox eradication, which only weeks before had seemed imminent, was once again in doubt.

[a] No cases were reported in Bari, Galbeed, Mudug, Nugal or Sanaag Regions.
[b] Although reported in November, all 3 cases experienced the onset of illness before 27 October.

The Emergency Programme, May 1977

In May 1977, delegates attending the Thirtieth World Health Assembly heard reports on the smallpox situation in Ethiopia, Kenya and Somalia and expressed considerable apprehension. The number of cases in Somalia was increasing each week, and with hostilities between Ethiopia and Somalia escalating, the prospects for control, let alone eradication, were not encouraging. Not only were Kenya and Ethiopia at risk of reinfection, but in the autumn, during the annual pilgrimage to Mecca, other countries would be at similar risk. Since variola minor—the predominant form—was clinically so mild, concern was expressed that pilgrims might travel to Mecca even though they were ill, and while there would spread it to other pilgrims, coming from Asia and other parts of Africa. The Health Assembly accordingly adopted a resolution (WHA30.52), which stated:

"Recognizing that, while smallpox is now reported from only a single country in north-eastern Africa, continuing smallpox transmission in that area represents considerable danger for adjacent countries owing to nomadic population movements...

"REQUESTS all Member States to continue to give financial support to the smallpox eradication programme, either through the Special Account for Smallpox Eradication of the Voluntary Fund for Health Promotion or on a bilateral basis, in order that the last known smallpox foci can be eliminated as rapidly as possible...

"URGES all governments to make full use of the expertise of international and national personnel with experience in smallpox surveillance and in containment measures as may be required effectively to interrupt transmission of the disease..."

Additional resources were urgently required but voluntary contributions from governments would inevitably take some time to become available, and WHO's funds for smallpox eradication were running low. Moreover, at least a year would elapse before vitally needed vehicles could be delivered from the factory. On 16 May WHO telephoned the Office of the United Nations Disaster Relief Co-ordinator (UNDRO) in Geneva to seek help. UNDRO indicated that it would be willing to make a world-wide emergency appeal if Somalia would officially declare the epidemic a disaster requiring the expenditure of resources beyond the country's means (WHO/SE/77.99, Hauge & Wickett). The agreement of the United Nations Development Programme's Resident Representative in Somalia that the resources requested were appropriate to the emergency was also necessary. A telex was immediately sent to Mogadishu, and on 18 May the government officially declared the situation to be a disaster and appealed for assistance. After a detailed list of urgently needed supplies had been prepared, UNDRO endorsed the request, and on 27 May issued an appeal to possible donors. Within the week, cash donations and contributions in kind amounting to some US$400 000 were received from Canada, the Netherlands, Norway, Sweden, the United Kingdom and the League of Red Cross and Red Crescent Societies. The total amount provided eventually reached US$459 750. In addition, Dr William Foege, Director of the United States Center for Disease Control, who was attending the Thirtieth World Health Assembly, offered to assign 5 epidemiologists forthwith to provide assistance over the following 3 months.

To procure and deliver 16 vehicles and tons of camping equipment, transceivers and other supplies, such as tires and spare parts, posed another problem. Two airlines which normally provided a service to Somalia suspended shipments in May because of fear of the outbreak of war. An emergency airlift was required and this was provided by Canada, Sweden and the United Kingdom. Vehicles which had already been delivered to UNICEF for an emergency reserve, plus others in the possession of the United Kingdom government and the League of Red Cross and Red Crescent Societies, were earmarked for use. Procurement and supply staff from UNDRO and WHO, working with their counterparts in various countries, hurriedly assembled materials, and in 4 special flights over the period 4–14 June the whole consignment was delivered. On 8 June the 5 epidemiologists from the USA arrived, and on 9 June the French government delivered by air 3 teams with 2 vehicles and supplies. Four persons from OXFAM, the British private charitable organization, arrived later that month. By mid-June more than 3000 national staff, primarily locally recruited workers, assisted by 23 epidemiologists working for WHO and 52 vehicles, were in the field.

Ježek and Dr B. Kříž had arrived in Mogadishu on 10 May. The former assumed the senior leadership role for WHO and the latter took immediate responsibility for the

emergency operation in Bay Region, the most affected area. On 21 May, the Somali government agreed on a detailed emergency programme to be conducted throughout the 10 regions in the south (later, as additional resources became available, the programme was extended to the northern regions). Sixteen health assistants were trained and designated as regional epidemiologists, operational offices were established in each affected district and all possible health staff were assigned on an emergency basis to search systematically for cases and to vaccinate all persons within a radius of 5–10 kilometres from the site of an outbreak. One or more WHO epidemiologists worked in each region. Regional party secretaries worked with them to mobilize party workers and assistance was offered by the Somali Women's Democratic Organization, the Somali Workers' Organization, and the Somali Youth League.

In Mogadishu the central programme office was reorganized and reinforced with a WHO administrative officer from the Bangladesh programme, a transport and supply officer and, later, a finance officer. In April, the publication of a weekly surveillance report began. Training programmes, launched in May in Mogadishu, were conducted thereafter in every region. Monthly meetings of all senior staff throughout Somalia began in June; they were attended by the Minister of Health and by Arita, who travelled every month from Geneva for the purpose.

Operations were initially concentrated in southern Somalia. Most of the outbreaks were centred in the area between the Juba and Shabelli rivers, the most fertile and heavily populated area in the country. The area was criss-crossed by watercourses which flowed briefly during the seasonal rains, only occasionally reaching the sea. The rains, from March to June, were heavy in 1977, creating large marshy areas and washing away roads. Searching the areas was difficult because of the lack of maps and the fact that half the population consisted of nomadic peoples who moved frequently over long distances through the dense scrub. Work in the field was further complicated by the need to provide tents to accommodate all but the locally hired nomads and to obtain food to supplement the limited available supplies of milk and goat meat as well as jerrycans for drinking-water. Moreover, because of the prevalence of wild animals, at least 2 persons had to travel together and construct a thorn barricade around their campsite each night. Communication between personnel in the field and the staff in Mogadishu was difficult at best, a problem which could have partly been resolved by employing transceivers. However, with the invasion of the Ethiopian part of the Ogaden desert by the Somali army only a few months away, the use of transceivers was forbidden. Except for this

Plate 22.5. **A:** Rodney J. Hatfield (b. 1949), a WHO administrative officer, established critically needed motor vehicle maintenance and repair workshops in Somalia and Bangladesh. **B:** Bohumír Kříž (b. 1936), a veteran WHO epidemiologist from the smallpox eradication programmes in Asia, assumed responsibility in May 1977 for emergency operations in Bay Region, the epicentre of the smallpox epidemic in Somalia.

Vehicle Maintenance in Somalia

The availability of serviceable vehicles was especially vital in Somalia, in which the population was sparse and distances were great. When the emergency programme began in May, only 19 vehicles were in use, 11 of which were more than 5 years old. By July, a fleet of 50 4-wheel-drive vehicles was in operation. To oversee their maintenance and repair, Mr Rodney Hatfield, a veteran of smallpox eradication programmes in India and Bangladesh, was brought to Mogadishu. A valuable paper (WHO/SE/80.155, Hatfield) documents the problems of transport operation and the solutions adopted.

An initial difficulty consisted in obtaining spare parts. This was partially alleviated when substantial stocks, consigned to WHO programmes, were found in the Mogadishu customs office; some had been left in the stores for as long as 3 years. Additional orders were placed for delivery by sea and air. They included special 10-ply truck tires which were required because of the thorn scrub and the frequency of punctures.

Until February 1978, commercial garages had repaired and maintained vehicles for a negotiated price. The expenses were reduced when a WHO workshop was established in February, but even then it proved more costly than had been expected to keep the vehicles on the road. Mr Hatfield found that the servicing of a vehicle cost US$70 per 1000 kilometres for the first 48 000 kilometres and US$120 per 1000 kilometres for the next 42 000 kilometres. Over 100 000 kilometres, the total costs of labour and spare parts began to approach the cost of the vehicle. By the time vehicles had logged 150 000 kilometres, the cost of maintenance and repair was prohibitively high, making them unacceptable for unrestricted service.

restriction, government staff supported the programme, permitted travel to any area and made adequate supplies of petrol available.

A complete search was planned to take place twice a month from May to December in all high-incidence areas, once a month in low-incidence areas, and every other month in areas thought to be free of smallpox. The search programme required ingenuity in planning if all or even most nomadic groups were to be found. Gradually, a routine was established which required, first, the preparation of a sketch-map so that specific areas with landmarks could be identified and assigned to each search group. In settled areas, conventional approaches were adopted in which workers displayed the WHO smallpox recognition card and asked about possible cases at each house and in schools, markets, health units and tea-shops. In such areas, one worker could visit from 50 to 100 houses per day. For the nomadic areas, other methods were required. The initial, and simplest, approach consisted in assigning to each area of 10–15 square kilometres a literate health worker from the region and a nomad familiar with the surroundings. By inquiring in settled villages and by sighting smoke from morning camp-fires and finding the fresh faeces of domestic animals and other tracking signs, they endeavoured to locate each nomadic group within the area. Supervision of this type of search proved difficult, however, and even for nomads who knew the area, it was not easy to locate the groups because of the high scrub and the unpredictable nomadic movements. A second approach, termed the "drop and move" method (Fig. 22.7), consisted in transporting 2-person teams to points along a road and instructing them to identify and question all groups of nomads encountered during a journey of 50–150 kilometres on foot across the desert to a known landmark. This method provided greater certainty that a geographical area had been covered, but the workers were almost as difficult to supervise. As the programme progressed, and larger numbers of staff became available, a technique called the "criss-cross" search evolved. This required teams to move each day from one landmark to another across a defined area during a 3–5-day period. The search was designed in such a way that the teams would cross each other's paths at different times. Landmark check-points (usually villages) were visited by more than one team on different days, thus permitting each team to check on the work of others.

Vaccinial immunity among nomads was often found to be as low as 10%; therefore, to

Plate 22.6. Vladimir Zikmund (b. 1925) worked as a WHO epidemiologist in many southern Indian states from 1971 to 1975 before joining the emergency effort in Somalia.

diminish the probability of continuing transmission should smallpox cases recur, vaccination was initially offered by all search teams. In most areas, it was readily accepted, but in others the nomads fled into the bush, thus precluding their being examined for possible smallpox. For this reason vaccination was suspended in some areas except when outbreaks were found. Among both Somali and WHO staff, the efficacy of combining vaccination with the search for cases was frequently debated, and the practice differed somewhat from area to area. It soon became apparent, however, that the epidemiology of variola minor in Somalia was different from that observed in other parts of the world and differed significantly from that of variola major. Outbreaks in small groups did not terminate quickly but, rather, persisted for long periods among comparatively small nomadic bands. On 5 occasions, smallpox was found to have persisted for 3 months or longer in groups of less than 100 persons

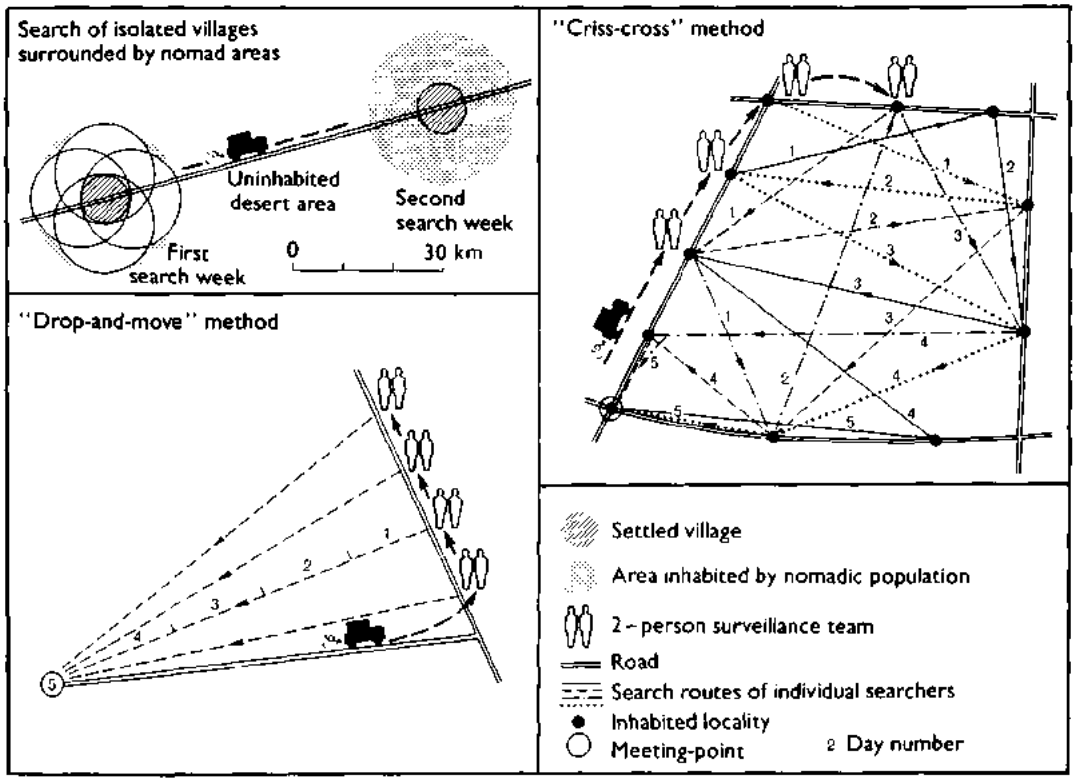

Fig. 22.7. Somalia: smallpox search methods. Surveillance workers were expected to walk 15–20 kilometres a day.

Table 22.7. Somalia: prolonged transmission of smallpox among groups of nomads

Outbreak	Population of nomadic group	Number of cases	Number of days between first and last cases
1	55	14	163
2	44	19	155
3[a]	35	24	152
4[a]	98	20	106
5	75	23	95

[a] Outbreaks 3 and 4 were interrupted by containment.

(Table 22.7). Because of the difficulties of locating such groups and keeping them under surveillance, the decision was made to vaccinate wherever a search was conducted so as to increase the overall levels of vaccinial immunity. This, it was hoped, might serve to retard or stop transmission more quickly. Vaccination scar surveys performed in the south showed levels of vaccinial immunity of 70% or higher by August 1977 and 90% or higher by September. Only 141 days after the emergency programme began, the last known case of smallpox occurred.

Outbreak-containment practices in settled areas were similar to those which had evolved during the programme in Asia. The patient was isolated, a list of village residents was compiled and all were vaccinated, and a team was posted to the village until the patient recovered in order to vaccinate visitors and to conduct continuing search and vaccination within a radius of 5–10 kilometres. Major differences of opinion arose, however, among both Somali and WHO staff as to where the patient should be isolated. Traditionally, patients in Somalia had been isolated in camps situated, in some instances, as far as 100 kilometres from their homes. Adult patients and their families, especially among the nomads, often objected to this practice; in consequence, cases went unreported and sometimes were hidden from search teams. During the early phases of the emergency programme, few of the isolation camps were well organized or provided adequate food or shelter. Accordingly, many patients who suffered from the mild illness characteristic of variola minor decided to leave the camps before recovery and, because they were inadequately guarded, did so with ease. Moreover, procedures to ensure the vaccination of family members who accompanied patients with smallpox or other skin infections were lax. As a result, the isolation camps, like hospitals in other countries, initially played an important role in disseminating smallpox.

Observations on Surveillance among Nomads

Dr B. Kříž, an epidemiologist from Czechoslovakia who had worked previously in Asia, made a number of interesting observations regarding surveillance techniques among nomads.

In bush areas in which nomads were semi-permanently settled, he discovered that they were usually easily located. Inhabitants of the nearest villages were generally well informed as to where and how many nomads were settled nearby. Village headmen, members of the village political committee and shopkeepers could provide this information. Because even relatively small areas of the bush—say, 10 square kilometres—had their own names, the nomads could be located if a map were prepared which showed the names of such places, water-holes, tall trees and roads.

In areas only temporarily inhabited during the dry season, the problem was different because the nomads were constantly on the move and there were few settled inhabitants. In places where water-holes were scarce, a well-motivated "government water-hole watchguard" was extremely useful. In some regions, however, water-holes were so numerous that water-hole surveillance was neither practicable nor useful. Market searches were also of limited value. Frequently, only female nomads visited the market but they were not easy to converse with and usually avoided giving information. In such areas, the so-called "criss-cross" technique of search (see Fig. 22.7) was essential.

To monitor nomadic movement and surveillance, it was found useful to give to the headman of a group a small WHO smallpox recognition card with the name of the place and the date when the card was given. This was widely accepted, and as its value in assessing search activities became apparent a specially designed durable card was prepared.

The alternative to isolating the patient in a special camp was to isolate him in his house, as had been the practice in Asia. In settled areas, this could be done using vaccinators as watchguards to ensure that the patient remained in the house and that all visitors were vaccinated. The task was much more difficult with nomads, who moved their camps every week or two. Moreover, the custom of visiting the sick contributed to the spread of smallpox. Hence, a special study was conducted in nomadic areas to determine what procedure would be the most culturally acceptable (Foster & Deria, 1983). It was decided that the best solution would be to construct a *haro*—a circular barrier of thorn bushes normally used to hold and protect animals at night. Accordingly, in most areas patients were isolated in a *haro*, 10–20 metres in diameter, containing a lean-to shelter and latrine. From funds provided by WHO, each patient was given 5 Somali shillings (US$0.80) a day as an incentive to remain in the shelter, and 2–4 members of the nomadic group were paid 5 Somali shillings a day to build the *haro*, to enforce isolation, to provide food and water and to vaccinate those at the encampment. When the nomads decided to move, a surveillance agent travelled with them in order to detect any additional cases and to ensure that any persons with whom they came in contact were vaccinated.

In some areas, isolation camps continued to be used but conditions in them were improved and supervision was strengthened. Patients were found to cooperate more readily if, on discharge, they were given new clothes—a practical public health measure because it permitted the old clothes to be burned, thus averting the risk of the spread of infection by fomites. Morever, as one observer noted, the new clothes served as "a moving poster" which promoted the use of the isolation camps.

The Epidemic, March to October 1977

The epidemic, first recognized in mid-March, rose to a peak in June (Fig. 22.8). Although reports had been suppressed until March, it did not appear that the smallpox

T. S. JONES

Plate 22.7. A Somali guards the entrance to a hut in which a nomad with smallpox is isolated. These huts were built away from the encampments and enclosed by a thorn-bush barrier to keep out wild animals as well as visitors.

incidence in January and February had been high. The rise in incidence coincided with the beginning of the March rains, when nomadic movement greatly increased. A 15-day religious festival in March held in southern Bakool Region, which was attended by more than 15 000 persons, contributed to the spread. This area, with the adjacent Baidoa District in Bay Region, became the epicentre of the epidemic (Fig. 22.9) and 4% of the population contracted smallpox. The number of reported cases increased sharply in April and May, when the information spread rapidly that a reward was being given to anyone reporting an outbreak of which the authorities were unaware. In many areas, two-thirds of the outbreaks came to light in this manner, the remainder being discovered by teams during search or being reported by government officials.

The number of new outbreaks occurring during April and May far exceeded the capacity of the few advisers and an as yet untrained staff to cope with them. With the declaration of the emergency in May and the influx of personnel and resources in June, the epidemic began to come rapidly under control. As political leaders and numerous volunteers actively participated, the interval between the onset of the first case and the detection of outbreaks decreased, as did the interval between the first and last cases in the outbreaks (Table 22.8). The outbreaks were more effectively contained, and, in consequence, became smaller (Table 22.9) and

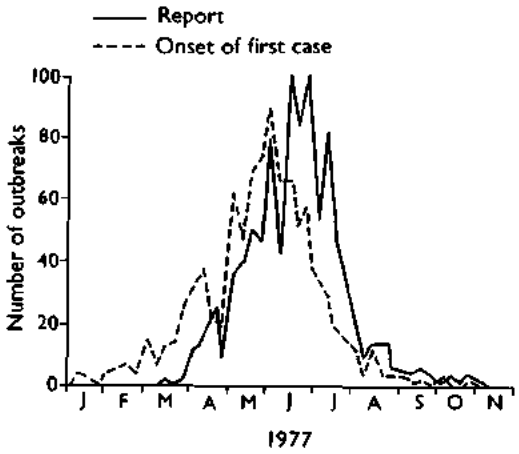

Fig. 22.8. Somalia: number of newly detected outbreaks, by week of report and by week in which the first case had onset of rash.

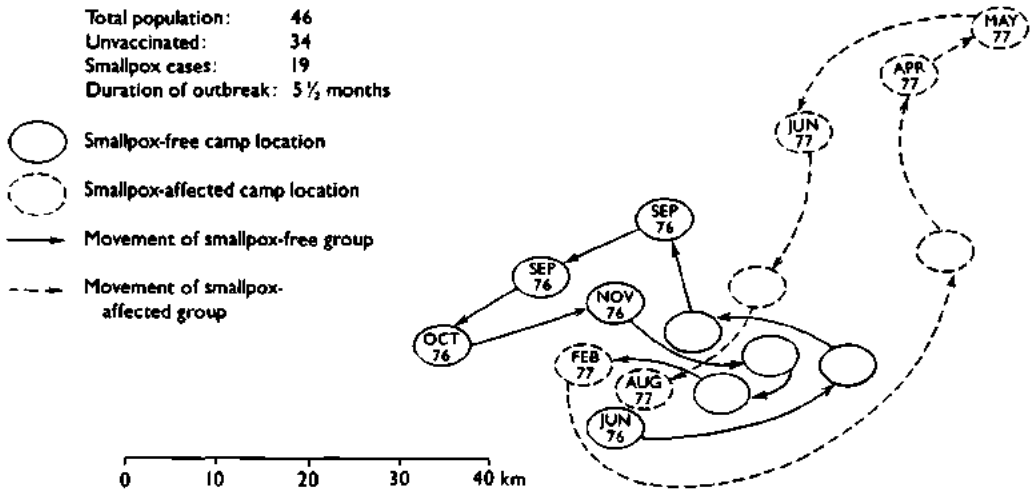
Persistent Transmission among Nomads

Dr Stanley Foster, formerly a senior WHO smallpox adviser in Bangladesh, with Mr Abdul Gadir El Sid, previously with the eradication programme in the Sudan, painstakingly documented the movements of one group of 44 nomads from June 1976 to the end of August 1977 (Foster et al., 1978). During this period, the nomads ranged over an area of about 70 kilometres by 35 kilometres (see illustration below). Only 7 members of the group had previously been vaccinated. In February 1977, the first case of smallpox occurred. The disease spread slowly among the group with only 1 or 2 cases in a generation of transmission. In all, 19 cases occurred over a 5-month period.

Somalia: Mandeelo group migration, Bakool Region, June 1976–August 1977



soon disappeared from the larger towns and villages (Table 22.10). In April 50% of the outbreaks occurred among nomads, a proportion which rose to 75% in June and to more than 90% in July. In all, 570 out of 843 outbreaks for which data are available were among nomads.

Table 22.10. Somalia: number of smallpox-affected localities, by population size and month, 1977

Month[a]	Population					Total
	<50	50–99	100–499	500–999	⩾1000

[a] When locality was first affected.

By late August surveys showed that 77% of the settled population and 70% of the nomads knew of the reward for reporting a case, and the epidemic had subsided to very low levels. At the end of October the last outbreak was contained. In all, 3229 cases had occurred in 947 different outbreaks. All except 5 of the cases during 1977 were outside Mogadishu. Most cases occurred in the Bay Region; few were detected outside the area between the Juba and Shabelli rivers or along their banks. Only 1 outbreak, a documented importation from southern Somalia, was discovered in the country's 6 northern regions (Fig. 22.9).

Surveillance among Nomads in Adjacent Areas of Ethiopia

With outbreaks occurring so close to the border with Ethiopia, and nomads moving freely from one country to another, surveil-

lance in Ethiopia became vitally important. Despite heightening tension between Somalia and Ethiopia and increased guerrilla warfare, Ethiopian staff continued work in the Ethiopian part of the Ogaden desert up to the end of June 1977. Between April and June, they investigated 32 rumours of cases reported by Somali staff and 136 rumours emanating from within Ethiopia. Most of these rumoured cases (96), on investigation, proved to be obvious cases of chickenpox or other skin infections. Numerous specimens were obtained but none contained variola virus. In July the Somali army occupied most of the Ogaden, and at this time surveillance by Ethiopian health staff ceased.

Surveillance in the Somali-occupied areas of the Ethiopian Ogaden provided a new challenge. Neither Somali health staff nor WHO epidemiologists were permitted into this area by the military. No surveillance was carried out for almost 2 months, but late in August an innovative "across the border" surveillance programme began. Five headquarters posts were established at different points along the border, each with Somali staff and an experienced WHO adviser: Dr M. N. El Naggar (Egypt), Mr Carl Hasselblad (USA), Dr Bert van Ramshorst (Netherlands), Dr J.-P. Ryst (France) and Dr J. S. Weisfeld (USA). Because some of the WHO staff had worked in this area previously as advisers to the Ethiopian programme, it was comparatively easy for them to recruit as supervisors and searchers the people who had previously been employed in the Ethiopian programme. With maps already available to them, it was possible to design a systematic search programme which was conducted largely on foot. Specimens were collected from all persons experiencing fever with rash and the specimens were brought back to the border posts. Between August 1977 and February 1978, 410 rumours were investigated and 151 laboratory specimens were obtained.

Independent assessment of the extent of activity of the search workers required different methods. One approach was to require each supervisor and search worker to keep a daily log-book in which he listed all the places visited and entered the full details of each person with fever and rash. The validity of the entries was then checked by other staff. On other occasions, workers were instructed to leave in each village coded WHO smallpox recognition cards. A second group visited the villages at a later date and retrieved them.

Most of the local staff in this programme performed well but some of them believed that their employment had to be justified by the discovery of rumours of smallpox cases which they would then have to investigate. Thus, throughout this period, there was a continuing and alarming flow of reports of possible cases of smallpox. Fortunately, however, an independent check could be made through an examination of the specimens obtained. None revealed the presence of smallpox.

Towards the end of 1977, concern about military security eased, but diplomatic restrictions prevented WHO staff from officially entering the areas of the Ogaden occupied by the Somali army. However, the group engaged was more concerned about smallpox than about diplomatic protocol and took it upon themselves to travel extensively throughout the Ogaden, beginning in November 1977. Areas in which outbreaks had been reported by the search workers were revisited and confirmed to be free of smallpox. This activity ceased in March 1978, when fighting again increased, causing large numbers of refugees to cross into the border areas of Somalia, many being housed in refugee camps. In a thorough investigation of these camps no one was encountered who had seen cases of smallpox since 1974 (Table 22.11).

The report describing in detail the extent of surveillance activities in the Ethiopian Ogaden during the period of occupation by the Somali army was to prove invaluable to the International Commission for the Certification of Smallpox Eradication in Ethiopia. However, even as late as October 1979, the report was considered politically sensitive and its distribution was restricted to only a few people. This caused some individuals, who had access only to publicly available

Table 22.11. Somalia: results of survey of refugee camps, February 1978

information, to question the Commission's ability to be certain of the status of the Ogaden.

The Last Smallpox Outbreak, October 1977

By the end of September 1977, the optimistic view prevailed that the discovery and containment of the world's last smallpox outbreak were at hand. On 26 September, the second intercountry coordination meeting was convened in Nairobi with representatives from Djibouti, Ethiopia, Kenya, Somalia and the Sudan. All these countries pledged a continuing intensive effort to achieve the elusive goal of eradication. At that time there were only 29 villages in Somalia known to be infected, of which 21 had active cases. Heavy rains again prohibited the use of vehicles throughout much of the area, but with large numbers of staff available it was possible to travel by foot or on camels and donkeys in carrying out the work of search and containment. Meanwhile, search in Ethiopia and Kenya continued but no cases were found.

Between 1 and 23 October, 5 more outbreaks were discovered in southern Somalia, of which 3 consisted of only a single case; the date of onset of illness in the last patient was 18 October. With a growing recognition that each outbreak contained might be the last, staff worked with an intensity never before attained. A special team arrived to make a documentary film of the programme, later released by WHO and entitled "The Search". Finally, on 31 October, yet one more case was discovered, not among nomads but in the busy regional port of Merca, a town of 30 000 inhabitants (Deria et al., 1980). The patient should have been protected by vaccination long before; after becoming ill he was in face-to-face contact with tens, perhaps hundreds, of people.

As in many other countries, the last outbreak was unusual. The patient, Ali Maow Maalin, was a 23-year-old cook who had become ill with fever on 22 October and developed a rash on 26 October. Although previously employed as a temporary vaccinator in the smallpox eradication programme and more recently as a cook in a hospital in Merca, he had never been successfully vaccinated.

On 12 October, 2 smallpox patients from a nomad encampment, some 90 kilometres from Merca, had been sent at night by vehicle to an isolation camp near the town. The vehicle stopped at the Merca hospital to seek

directions and Mr Maalin volunteered to accompany its occupants to the smallpox office, some 100 metres away. One of the 2 patients, a 6-year-old girl, was severely ill and died 2 days later. Mr Maalin was exposed for only a few minutes.

On 22 October he felt feverish and left the hospital for his home, about 200 metres away, in a densely populated area of Merca. During the next 3 days he was visited by many friends and neighbours as well as by hospital employees. He was admitted to the hospital on 25 October with a presumptive diagnosis of malaria, and received numerous visitors, walked freely through the hospital and even went outside the compound to obtain his salary payment. On the following evening he developed a rash which was diagnosed as chickenpox, and on 27 October he was discharged. Feeling ill, he remained at home although, again, he received many visitors. By 29 October he suspected that he had smallpox but, fearing to be sent to the isolation camp, did not inform the authorities. On 30 October, a male nurse at the hospital reported Mr Maalin to the regional health superintendent and to the smallpox eradication staff, who confirmed the diagnosis and sent Mr Maalin to the isolation camp. Unlike the cases of recent months, almost all of which had occurred among small isolated groups of nomads with few close contacts, Mr Maalin had been in contact with numerous people, only some of whom could be identified by name.

The hospital was immediately closed to new admissions, all patients were vaccinated and quarantined at the hospital, all health staff were vaccinated, warning signs were placed around the compound, and a 24-hour police guard was posted. Vaccination teams, consisting of 2 smallpox eradication staff, a policeman and a local political leader, listed by name and vaccinated everyone in the 50 houses surrounding Mr Maalin's home and later in the 792 houses comprising the ward in which he lived. Teams then undertook a search of the entire town each week during the succeeding 6 weeks. With police assistance, a check-point was established on the road into Merca and 3 check-points were set up on footpaths also leading into it so that all persons leaving or entering the town could be stopped and vaccinated. In all, 54 777 persons were vaccinated during the 2-week period from 31 October to 14 November. Meanwhile, meetings were held throughout Merca to inform the general public of the outbreak and to stress the need to report cases with rash and fever. The reward of 200 Somali shillings for reporting a case was widely publicized.

Efforts were made to identify all the personal contacts of Mr Maalin as well as those who had been in the same building with him at any time during his illness. In all, 91 face-to-face contacts were identified; 58 had been successfully vaccinated within the preceding 3 years; 21 had been successfully vaccinated more than 3 years earlier; and 12 had no vaccination scar. Of these 12, 6 were hospital employees, 5 were hospital patients or visitors and 1 was a personal friend. It was possible to get in touch with virtually all these people within 24 hours, although some lived as far as 120 kilometres away. They were vaccinated and placed under surveillance for 18 days, and their temperatures were taken daily in order to detect any illness as quickly as possible. Five persons under surveillance developed fever during this period and were isolated in their homes but none developed rash. Seventy other persons were identified who had been in the hospital at the same time as Mr Maalin but did not recall seeing him. All had been vaccinated previously; none developed fever during the surveillance period.

Subsequently, a house-to-house search was conducted each month for 5 months throughout the entire Lower Shabelli Region, in which Merca is situated. No further cases were found.

Finally, on 29 December 1977, 2 months after Mr Maalin had first become ill and a country-wide search for cases had been completed, it was decided that the Merca outbreak—the last one remaining on the list of pending outbreaks—could be removed from the list. Then began a 2-year period of intensive surveillance throughout the countries in the Horn of Africa to confirm that eradication had been achieved. Because of the discovery of 2 hitherto unknown foci following apparently smallpox-free intervals of 7 weeks or more (late in September 1976 and in March 1977), the surveillance was diligent. However, the Merca outbreak proved to be the last naturally occurring outbreak and Ali Maow Maalin's illness the last case.

MORBIDITY AND MORTALITY DATA, 1977

Data on the age of onset and outcome of illness are available for 3022 of the 3229 cases

that occurred in Somalia in 1977. The age distribution of cases is especially interesting in that it parallels closely the age distribution of the population at large (Table 22.12). This finding might be expected in a population with little immunity either from smallpox or from vaccination. As has been noted previously, most cases occurred among nomads whose vaccinial immunity was not more than 10–20% when the epidemic began, and although the level of vaccinial immunity rose to more than 90% by September 1977, most cases had already occurred by then. Facial pockmark surveys conducted in 1978 revealed that for most southern Somali nomads smallpox was a new experience, the last large outbreaks having occurred in 1938, nearly 40 years earlier.

Only 13 deaths were recorded—a case-fatality rate of 0.4%, characteristic of variola minor. Six of the 13 individuals who died were infants less than 1 month old, 1 was a case of fetal variola, 4 were children between 1 and 6 years of age, 1 was a 49-year-old man, and 1 was a 90-year-old woman. None of them had ever been vaccinated.

CONCLUSIONS

From the time the Intensified Programme began, smallpox eradication staff had speculated as to where the last case might occur—no one had expected that it would be Somalia. Rugged, mountainous areas with a paucity of health services, such as Afghanistan or Ethiopia, or densely populated areas, such as Bangladesh or India, in which smallpox spread very rapidly, appeared to be far more likely possibilities. Somalia, with its sparse population and a more extensive network of health services than many other endemic countries, was an improbable candidate. This opinion was reinforced in 1974, when programme staff reported that the second country-wide vaccination campaign had been completed and that the total number of vaccinations performed during the two campaigns was equivalent to the population of the country.

In retrospect, the epidemic in Somalia could and should have been prevented. The first mistake was the assumption by both national and WHO smallpox eradication staff that continuing transmission of smallpox would be difficult, if not impossible, among pastoral nomads in the sparsely populated Ogaden desert. At the time, the assumption seemed reasonable. Somalia, after all, had become free of smallpox in 1962, in the absence of any national vaccination campaign, and at a time when the health services were using a poor-quality thermolabile vaccine and the numbers of people vaccinated were comparatively few. Because of this, the Ethiopian programme had concentrated its best staff and the bulk of its resources in highland areas rather than in the Ogaden. However, because of natural population growth, an augmentation of the normal nomadic population by refugees, and an increased concentration of people at feeding-camps and water-holes on account of warfare, drought and famine, the potential for continuing transmission of the virus was greater than it had been before. The second mistake was the failure to provide better WHO support to Somalia in strengthening its surveillance programme, at least after 1972, when importations began to be reported. Other activities were assigned a higher priority, in part because of the belief that transmission in Somalia could not be long sustained, especially after its extensive vaccination campaign, and in part because of the need to devote all possible resources to the intensified programmes that had begun in Asia in 1973 and in Ethiopia in 1975. The third mistake was the suppression of notifications by Somali programme staff and even the WHO smallpox adviser on the grounds that they were facing only a minor problem, which could be contained without officially acknowledging it. The staff's lack of experience in the investigation and control of outbreaks because of the long absence of

endemic smallpox, coupled with its inability to request assistance in a situation that had not been reported, permitted a localized problem to grow into a major epidemic. The outbreak was centred in an area which, through resettlement and agricultural development, had become steadily more populated. Few cases of smallpox had occurred in the area for perhaps 40 years and an ineffective vaccination campaign, inadequately assessed, had reached only a small proportion of the inhabitants.

When the problem was finally acknowledged and an emergency declared, only 141 days were to elapse until the last case was detected and the outbreak contained. The emergency programme, conducted under the most difficult conditions, was as well executed as any national plan of operations in the Intensified Programme. A determined Somali staff aided by experienced WHO advisers worked day and night, drawing on the experience of 10 years of field activities and motivated by the imminence of the ultimate goal of global eradication. And so the final chapter was written: Ali Maow Maalin represented the last case of smallpox in a continuing chain of transmission extending back at least 3000 years.

INTRODUCTION

In the preceding 11 chapters we have systematically reviewed the elimination of smallpox from the 31 countries in which it was endemic in 1967 and 2 other countries (Botswana and the Sudan) in which endemicity was re-established after 1967. Because smallpox was endemic in many parts of the world in the 1960s and early 1970s, cases continued to be imported into smallpox-free countries. The annual numbers of smallpox cases in most of the larger countries between 1920 and 1958 are tabulated in Chapter 8. The year in which smallpox was last endemic in each of these countries is indicated in the tables; cases occurring after that year were due to importations. This chapter is con-

cerned with a more detailed description and analysis of outbreaks of smallpox that occurred in industrialized non-endemic countries after 1958, and in non-endemic countries of Africa, South America and Asia after 1966, when reasonably complete information first began to be compiled.

In the industrialized countries a total of 37 outbreaks due to importations from endemic areas were reported between 1959 and 1974: 34 occurred in 13 countries of Europe, 1 in Canada, and 2 in Japan (Table 23.1). In addition to importations by infected persons, there were 3 laboratory-associated outbreaks in the United Kingdom between 1966 and 1978. These are comparable to importations from endemic countries in that they were introductions of smallpox infection into a smallpox-free country; they are described in the last section of this chapter.

A notable feature of this period, compared with earlier times (see Chapters 5 and 8), was the absence of transfers of smallpox between the Eastern and Western Hemispheres, and the rarity of intercontinental importations other than from the Indian subcontinent to Europe (Fig. 23.1). This is surprising, in view of the vast volume of international traffic (4 million air passengers in 1948, 46 million in 1966, and over 400 million in 1975) and the much greater speed of travel by air than by sea.

As the Intensified Smallpox Eradication Programme proceeded, more detailed information was collected about cases throughout Africa, South America and Asia, and as a result of this effort, many outbreaks were recognized which were due to transfers across national boundaries in each of those continents. Most of these importations were contained, but some had serious consequences, leading to the re-establishment of endemic smallpox in the Sudan (1968), Botswana (1971), Bangladesh (1972) and Somalia (1976). An importation from Afghanistan into Iran in 1970 led to a large epidemic which was not terminated until 1972, and spread from Iran to Iraq, then to the Syrian Arab Republic, and from Iraq to Yugoslavia.

Excluding the laboratory-associated incidents, the 34 outbreaks in Europe produced 573 cases, of which 90 were fatal. Although the number of cases was extremely small compared with the number occurring in the endemic countries (perhaps some 50 million cases annually in the mid-1950s), health officers and the general public in the industrialized countries feared smallpox more than any other of the diseases then primarily indigenous to the developing countries.

Importations into Europe and Japan did not cease until 1974, when smallpox had been eliminated from most countries of Africa, from Indonesia, and from large areas of India and Pakistan, including most of the larger cities.

CRITERIA FOR DEFINING NON-ENDEMIC COUNTRIES

Apart from the industrialized countries, in which importations had been recognized as such from the 1940s or earlier, few efforts were made until 1967 to classify countries as having endemic smallpox or as being smallpox-free. All countries, by international convention, were supposed to report the occurrence of cases of smallpox promptly to WHO, but not all did so, nor were the reports that were received investigated to determine their validity. With the establishment of the Intensified Smallpox Eradication Programme, a deliberate attempt was made to distinguish countries in which smallpox was endemic from those that were free of the disease. Many

errors in reporting the existence of smallpox, and many instances of failure to report the disease, were discovered. After considerable inquiry, 31 countries or territories were eventually categorized as harbouring endemic smallpox in 1967 (see Chapter 10).

Between 1959, when the global smallpox eradication programme began, and 1967, a number of countries of Africa, South America and Asia which were thought to be non-endemic reported a few cases each year—too few to represent accurately an endemic situation with continuing transmission. Before 1967 few of these outbreaks had been further investigated, and it was impossible to determine whether they were due to occasional importations or represented underreported endemic smallpox, or, indeed, whether they were fictitious events reported as a result of clerical or diagnostic error.

Because of uncertainty as to whether countries in Africa, South America and Asia were indeed free of smallpox, and because reporting had been unsatisfactory and importations had rarely been fully documented, discussion of importations into these countries will be brief, and restricted, for the most part, to the period after 1967.

THE SIGNIFICANCE OF SMALLPOX IN NON-ENDEMIC COUNTRIES

Two aspects of smallpox in non-endemic countries were relevant to the global strategy of smallpox eradication: the actions taken by the countries themselves and those taken by WHO.

Actions Taken by the Non-endemic Countries

Before about 1970, almost all industrialized countries regularly vaccinated a large proportion of their population and enforced the requirement stipulated in the International Health Regulations that international travellers should hold valid certificates of vaccination. These measures were pursued with varying degrees of diligence in different countries. In the USA, for example, most children were required to show evidence of vaccination at school entry and the vaccination rate in the population as a whole exceeded 95%. In the United Kingdom vaccination was encouraged but not enforced, except for international travellers, and only about 60% of the population were vaccinated.

Vaccination certificates

Many countries placed considerable reliance on the examination of certificates of vaccination, spending much money on checking them and complaining about falsified certificates. However, there were several deficiencies in the certification system. For example, vaccination certificates were regularly examined at most—but not all—European airports. This was less of a problem in Canada and the USA, in which airport health officials were rather more rigorous in asking all arriving passengers where they had been in the preceding 14 days and requiring a valid vaccination certificate from all those who had been in a smallpox-endemic country during this period.

With regard to vaccination certificates, there was much discussion of the need to examine the results of vaccinations 7–9 days later to confirm whether these had been successful, and to require a repeat vaccination if they had not. Few appreciated that much of the vaccine used, especially in endemic countries, was of low potency, and that the failure of a first attempt often resulted in a second vaccination with equally poor vaccine. However, certificates did not require that the results of a second primary vaccination should be examined.

The principal value of vaccination certificates probably lay in encouraging most travellers to be vaccinated before they left their own country. Most intercontinental travellers were from non-endemic countries, and although they were in fact responsible for the majority of importations into European countries (see the next section), the number of incidents might have been much higher had there been no requirement for vaccination certificates.

Control of outbreaks

In accordance with the philosophy of smallpox control then prevalent (see Chapter 9), industrialized countries in the 1950s and early 1960s usually responded to the discovery of an importation of smallpox by mounting a large vaccination campaign, in parallel with efforts to identify contacts and vaccinate and isolate them. For example, in the outbreak

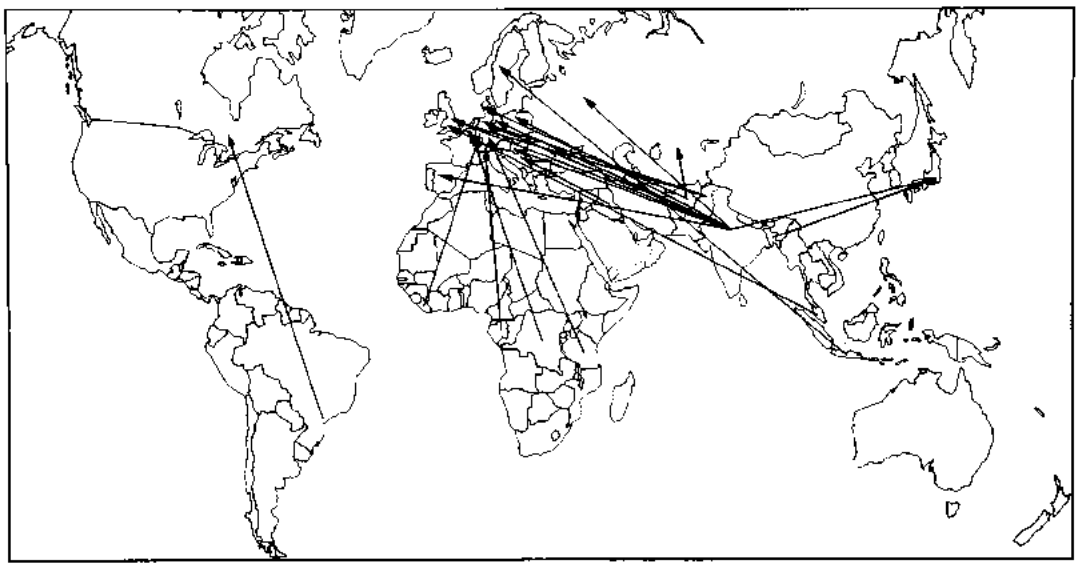

Fig. 23.1. International transfers of smallpox from Africa and Asia to Europe and Japan, 1959–1974, and from Brazil to Canada in 1962. In several cases one arrow represents several transfers, e.g., between India and the Federal Republic of Germany and between Pakistan and the United Kingdom.

which followed an importation into Stockholm, Sweden, in 1963 and caused 27 cases of smallpox and 4 deaths, some 300 000 persons were vaccinated in a period of a few weeks, with 1076 reported complications, of which 77 were serious (Ström & Zetterberg, 1966).

In the late 1960s and 1970s, when surveillance and containment were accepted as the best method of smallpox control, mass vaccination campaigns were rarely undertaken. One exception was the mass vaccination programme undertaken during the large outbreak in Yugoslavia in 1972. Earlier, in 1970, the Federal Republic of Germany had considered mass vaccination when an outbreak occurred at Meschede Hospital, but had been persuaded by WHO not to implement this operation, on the grounds that it was unnecessary and would be costly and likely to result in many complications.

The two countries in Europe with the most importations, the Federal Republic of Germany and the United Kingdom (see Table 23.2), maintained special hospitals for the isolation of smallpox patients, which were held on stand-by in case of a possible outbreak of the disease. The last of these hospitals in the United Kingdom, the Catherine-de-Barnes Isolation Hospital near Birmingham, was not closed until 1985. At the 1976 Winter Olympic Games in Austria, a special building with 8 beds was set aside for use as a smallpox hospital in the event of an outbreak and was identified as such.

Clearly, the health authorities of the industrialized countries remained highly apprehensive of the danger of smallpox, a view shared by the general public. This was evident in the Meschede outbreak, during which motor vehicles bearing a Meschede numberplate sometimes had difficulty in obtaining petrol from garages in other parts of the Federal Republic. As late as 1978, after the laboratory-associated outbreak in Birmingham, England, health authorities in 8 countries demanded valid vaccination certificates for a period of many weeks from all passengers arriving from the United Kingdom, and the authorities in another 6 countries required them from passengers who had been in Birmingham in the previous 14 days.

The attitude to importations in developing countries was not so rigorous, except in those in which a recent campaign had led to the eradication of the disease and thus to a heightened sense of the risk of importation. In the developing countries, many importations resulted in substantial outbreaks and on several occasions to the re-establishment of endemicity.

Actions Taken by WHO

Although the health authorities of the industrialized countries were responsible for controlling any importations, after the establishment of the Intensified Smallpox Eradication Programme WHO took several steps to assist them. An emergency supply of vaccine was held in Geneva, and the health authorities of all countries were notified that members of the WHO Smallpox Eradication unit were prepared to travel at short notice to any country requesting assistance. This rarely proved necessary, but the Smallpox Eradication unit maintained close telephone contact with the relevant health authorities until the emergency was over. However, Henderson and a WHO consultant, Dr Paul Wehrle, assisted in the investigation of the unusual outbreak at Meschede (see Chapter 4); vaccine and WHO technical assistance were supplied to Yugoslavia in 1972; and in 1978 Dr Joel Breman, then a member of the unit, visited the United Kingdom to take part in the inquiry into the laboratory-associated outbreak in Birmingham.

Assistance was also provided by WHO after importations of smallpox into Bangladesh, Botswana, the Gulf states, and the Sudan. Finally, reports of smallpox in non-endemic countries which reached WHO through the reporting system were always investigated to ascertain whether or not they were due to misdiagnosis or to clerical error. Such investigations had been conducted throughout the programme and even after eradication, during the operation of the international rumour register (see Chapter 28).

The *Weekly epidemiological record* was a very useful means for the prompt dissemination of information about smallpox (see Chapter 10); it was widely distributed by WHO to Member States, particularly to their epidemiologists and port and airport health services. In 1968, a large number of reprints of an article by Dumbell (1968), "Laboratory aids to the control of smallpox in countries where the disease is not endemic", was given special distribution to Member States. Also in 1968, the Smallpox Eradication unit invited Dr Thomas M. Mack, then an epidemiologist at the United States Communicable Disease Center, to WHO Headquarters, where he reviewed importations of smallpox into Europe; his paper, "Smallpox in Europe, 1951–1971" (Mack, 1972), was the first comprehensive analysis of the epidemiological pattern of smallpox importations into non-endemic countries.

SMALLPOX IN EUROPE, 1959–1978

Over a period of 20 years, from 1959 to 1978, 13 European countries—about half the larger countries of the continent—reported the occurrence of cases of smallpox. Excluding laboratory-associated outbreaks, which are discussed at the end of this chapter, there were 34 importations from endemic countries, and on 4 occasions the disease spread to neighbouring countries (Table 23.2).

Outbreaks occurred in Europe each year from 1959 to 1973, except 1964, 1966 and 1971, with the largest numbers in 1961, 1962 and 1963. In all, 573 cases were recorded, including the imported (index) cases. The largest outbreaks consisted of 175 cases in Yugoslavia and an associated case in the Federal Republic of Germany (1972), 99 cases in Poland and an associated case in the German Democratic Republic (1963), 47 cases in the United Kingdom (1962), and 46 cases in the USSR (1959–1960). The other 30 introductions caused single-case outbreaks on 14 occasions and outbreaks of 2–33 cases on 16 occasions. Although two-thirds of the outbreaks led to no more than 5 cases, their impact on the communities in which they occurred was out of proportion to the real risk; cases always made the headlines in the newspapers, many persons sought vaccination, and in the larger outbreaks mass vaccination campaigns were urged or undertaken.

The Federal Republic of Germany and the United Kingdom, which together accounted for 19 of the importations from the endemic countries during this period, were the most frequently affected, in part because of the more frequent travel between them and the Indian subcontinent.

Sources of Importations

Asian countries were the source of infection for 28 of the 34 introductions from outside Europe; in only 5 instances was infection brought from Africa, once each from Gabon, Liberia and the United Republic of Tanzania, and twice from Zaire. The Indian subcontinent was the principal source of importations, 14 coming from India and 8 from Pakistan.

As the smallpox eradication programmes progressed in the endemic countries, introductions of smallpox into Europe became less and less frequent—23 in 1959–1963, 7 in 1964–1968 and 4 in 1969–1973—in spite of the increase in the volume of air travel over this period.

Twenty-seven of the 29 importations from overseas for which data are available were associated with air travel, but none resulted from transmission on an aeroplane; all the infected persons were in the incubation period or the prodromal phase of the disease, when virus was not transmitted. The 2 outbreaks in 1962 in which the index case travelled by ship were recognized during the voyage or when the ship docked, as the patients arrived with fully developed signs and symptoms. On one occasion only (No. 33 in Table 23.2) was the index case known to have travelled by bus, and the prodromal symptoms of smallpox, which were taken to be due to fatigue from the long journey, did not develop until after the arrival of the person concerned in Yugoslavia.

In 4 instances, cases were imported from one European country into another. A single case that occurred in Schaffhausen in Switzerland in January 1962 was probably infected in Düsseldorf, in the Federal Republic of Germany, at the end of December 1961 (No. 12 in Table 23.2). In 1970, a case in Tromsö in Norway had been exposed to one in Denmark (No. 32), and a case occurred in the Federal Republic of Germany in a man who had been exposed during the epidemic in Yugoslavia in

1972 (No. 33). The large outbreak in Poland in 1963 (No. 22) was probably responsible for a single case in the German Democratic Republic later that year.

Nature of Index Cases

The index case in importation No. 4 (Table 23.2) was said to have been infected with virus transmitted from Afghanistan on a carpet, but little additional information is available; all other outbreaks were known to be due to the entry of infected persons. Of the other 31 importations into Europe (details are lacking for No. 2 and No. 11), 20 of the index cases occurred in Europeans who had recently visited smallpox-endemic areas. Their occupations varied; among them were 4 physicians and 4 engineers or electricians. Only 11 index cases (7 adults and 4 children) were nationals of an endemic country: 7 were Pakistanis and 4 were Indians and all of them were visiting relatives or friends in the United Kingdom, except for an Indian visiting the Federal Republic of Germany.

Among those importing smallpox, the proportion of males to females was 26 to 5. Twenty-four were adults; the youngest was a 6-month-old baby infected in Zaire (No. 30 in Table 23.2) and the oldest a Swiss nurse aged 70 years who was infected in Gabon (No. 23).

Only one-third of the index cases gave histories of apparently satisfactory smallpox vaccination. In spite of the availability of potent vaccine and the concern of health officers in European countries regarding importations of smallpox, case histories revealed that most of the Europeans responsible for importations were not well protected when visiting endemic countries. It was estimated that about 70% of the importations resulted from unsatisfactory revaccinations, for which poorly kept liquid vaccine seemed mainly responsible. Throughout the global eradication programme health officials expressed great concern about forged vaccination certificates and focused much of their attention on this matter, but it probably played a fairly marginal role, only a few migrants from the Indian subcontinent being implicated.

Of 28 index cases who arrived from abroad by plane, only 5 had signs of disease on arrival, including an acne-like rash and lesions on the lips. Six arrived in the prodromal, influenza-like stage and the remaining 16 landed apparently healthy; it was impossible to identify any of these cases on arrival. One-third of those who were incubating smallpox

Table 23.3 Delays in notification and the extent of spread of smallpox in 30 outbreaks in Europe, 1959–1973

Time-lag[a] (days)	Number of importations	Total number of cases	Average number of cases per importation
0–7	16	87	5.4
8–14	5	44	8.8
15–21	4	63	15.8
≥ 22	5	339	67.8
Total	30	533	17.7

[a] Interval between the date of onset of fever in the first case and date of notification to the health service.

fell ill within 3 days of their arrival and the other two-thirds by the end of the first or the second week after arrival. Recognition of the disease and its notification were often delayed, since the doctors who saw the cases often did not suspect smallpox and were usually unfamiliar with its clinical picture.

Delays in Notification

Of 30 importations for which data are available, 21 were recognized as smallpox within 2 weeks of the arrival of the index cases, indicating that the importations were discovered within one incubation period of the first generation of the cases (Table 23.3). On 5 occasions (No. 12, No. 13, No. 21, No.22 and No. 33 in Table 23.2), delays of more than 3 weeks (range, 22–42 days) occurred before the recognition of smallpox. All these outbreaks resulted in serial transmission for 3 or more generations (see Table 23.4). Clearly, the longer the delay in discovery, the greater was the number of cases that occurred. Sometimes, however, the index case was promptly recognized but a first generation case was missed, as in importation No. 18, in Cardiff, Wales, in which the index case was correctly diagnosed within 4 days of the onset of fever, but a female first-generation patient was not discovered for 20 days; 47 cases occurred in this outbreak, despite early detection of the index case.

Transmission from Imported Cases

In 14 of the 34 importations into Europe there were no secondary cases (Table 23.4). Of 20 importations in which transmission occurred, 12 resulted in 1 or 2 indigenous generations and 5 in 3 or 4 generations; in only 3 importations were there more than 5 generations of transmission. Except for the last-mentioned outbreaks, containment measures were successful in interrupting transmission within about 2 months.

Seasonal effects

Although importations occurred at all times of the year, they were more numerous in the winter and spring (Table 23.5), the usual periods of seasonal increase in smallpox incidence in the endemic areas of the Northern Hemisphere from which most importations originated. The importations at this time of the year usually caused considerably larger outbreaks than those in the summer and autumn, showing that the temperate countries of Europe were also subject to seasonal influences.

Cases infected in Europe

Of the 573 known cases, 35 were index cases infected outside Europe, including 3 cases on board ship in outbreak No. 19. Of the 537 indigenous cases, 277 (52%) were infected in health establishments or during the course of medical or nursing duties (Table 23.4); 57 (21%) of them were fatal. The other 261 cases resulted from intimate contact with cases in affected households or from casual contacts in institutions such as schools or factories. Although most cases in Europe were cared for in well-equipped hospitals, these institutions played an important role in the further dissemination of smallpox and posed a real risk for other patients as well as staff. The routine vaccination of hospital staff was recommended in Europe and North America, but it was rarely carried out satisfactorily. Most cases occurred among young medical professionals, nearly 20% of whom had never been successfully vaccinated. In contrast, cases among hospital patients and visitors occurred most frequently in young children and aged persons. A few cases were reported in seamen and port employees, as in outbreak No. 19. A Czechoslovak Airlines navigator who contracted smallpox (No. 26) was infected during his stay in Bombay, not on his plane.

Case-fatality rates

There had been several importations of variola minor into Europe during the first half of the 20th century, but all importations

[a] Infection said to have been transmitted on a carpet.

after 1959 were of variola major. The overall case-fatality rate of 16% (see Table 23.2) was of about the same magnitude as that in endemic countries, the deaths occurring primarily in unvaccinated infants, in persons with contraindications to routine vaccination, and in older patients who had been vaccinated many years earlier.

The extent of individual outbreaks in Europe

Except for a few outbreaks, smallpox importations into Europe did not produce large numbers of cases, reaching double figures in only 11 outbreaks, even though some outbreaks were not discovered for as long as 3 weeks after the onset of illness in the first case (Table 23.3). Forty per cent of the importations caused no further transmission. After 1963, only 2 outbreaks occurred in which there were more than 2 cases, and both were associated with unusual circumstances: severe cough and the aerosol spread of virus in outbreak No. 31 (Meschede), and spread in Yugoslavia in one of the country's least developed areas, involving an unrecognized case in a man who was moved from hospital to hospital (No. 33). The fact that there was not greater spread can be attributed in part to the prompt isolation of patients at home or in hospital and to the generally rapid and effective application of control measures.

Especially after 1967, however, smallpox importations into Europe received extensive press, radio and television coverage. Despite the prompt measures usually taken by the public health authorities, the deep-rooted if sometimes unfounded fears of the population were difficult to quell. Several countries suffered considerably in consequence. For

example, in the first few days after the recognition of the large outbreak in Yugoslavia, the country was in turmoil: people were afraid to visit public places until they and their families had been protected by vaccination; trucks carrying market products from affected areas were turned back; tourist bookings were cancelled; and some countries closed their borders and advised their nationals not to visit Yugoslavia. Only after a steady flow of epidemiological information and surveillance data had reassured neighbouring countries were the last of the restrictions on trade and travel dropped, some 12 weeks after the beginning of the outbreak.

Table 23.5 Europe: seasonal influence on the numbers of importations of smallpox and the size of outbreaks following importations

[b] Outbreak No. 22; one exceptionally large outbreak occurred at the end of the epidemic season.

Case Studies of Importations into Europe

Detailed accounts of 2 outbreaks following importations into Europe are given elsewhere: outbreak No. 31 in Chapter 4, as an example of the airborne transmission of smallpox, and outbreak No. 33 later in this chapter, as part of the epidemic that spread across south-western Asia into Europe in 1970–1972.

Two other examples illustrate different aspects of smallpox outbreaks after importations into Europe: an outbreak (No. 16) in Bradford, England, in 1961, in which

BY COURTESY OF MESCHEDE HOSPITAL

Plate 23.3. The airborne spread of virus from this 20-year-old electrician, infected in Pakistan, caused smallpox in 17 other patients in the 1970 outbreak in Meschede Hospital, Federal Republic of Germany, described in Chapter 4. He had had no direct contact with any of them.

transmission occurred in 3 hospitals; and an episode (No. 32) in Denmark and Norway in 1970 that led to only 1 further case despite the original patient's having had numerous contacts.

The Bradford outbreak

The outbreak in Bradford started with a 9-year-old Pakistani girl, who developed smallpox in December 1961. She had travelled with her family from Karachi to London by air on 16 December 1961, and then by train to Bradford on 17 December (England and Wales, Ministry of Health, 1963). On 5 December, she had been vaccinated against smallpox and issued with an international certificate of vaccination. On 23 December she was admitted to Bradford Children's Hospital with symptoms of malaria, and the presence of *Plasmodium vivax* was confirmed by blood examination. She responded to antimalarial drugs and was afebrile from 24 to 26 December. On 27 December she developed a low-grade fever and became apathetic and listless. Two days later her temperature rose to 40 °C. On 30 December she developed petechiae on her face and neck and died. A post-mortem examination on 1 January 1962 attributed death to staphylococcal septicaemia and malaria. She was flown to Pakistan to be buried. Smallpox was not suspected; even the physical evidence of recent vaccination was not noted.

Between 11 and 13 January 1962, 10 first-generation cases of smallpox were discovered in the Bradford area (Fig. 23.2) and virologically confirmed. All were unvaccinated before this episode, except case No. 2, in a 40-year-old visitor to an affected ward at Bradford Children's Hospital—a man who had been vaccinated while a member of the armed services during the Second World War—and case No. 3, a resident cook at the Bradford Children's Hospital, who became ill on 6 January. The cook was admitted on 11 January to the Leeds Road Hospital, where a diagnosis of smallpox was made; she died the next day. The other cases were in 6 unvaccinated child inpatients (cases No. 4–No. 9), an 18-year old nurse (case No. 10), and the 37-year-old pathologist (case No. 11) who had performed the post-mortem on the index case; 5 died.

The patients were promptly isolated and vaccinated; only 3 second-generation cases were recognized. The first 2 of these were in elderly male patients (cases No. 12 and No. 13) in the ward of another hospital (St Luke's) to which case No. 2 had been admitted just prior to his death. The third was a boy (case No. 14) who had been in contact with case No. 6, a child who had been transferred to the Wharfedale Children's Hospital. All 3 second-generation cases were confirmed virologically; 2 recovered and 1 died, apparently from a heart attack.

To sum up, the Bradford outbreak comprised 14 cases; 7 of the patients died, 6 of them from smallpox. All the indigenous infections were contracted in hospital, and 4 hospitals were involved, with transmission in 3 of them. The outbreak was already rather large by the time it was recognized as being caused by smallpox, and there had been numerous opportunities for transmission, both within hospitals and in the general community. The task of identifying, tracing and vaccinating more than 1400 contacts and keeping them under surveillance was expensive, difficult and time-consuming. Although mass vaccination was never contemplated, vaccination clinics were opened because so many people had been already exposed by the time the outbreak was recognized. Practically the whole of the town's population of 250 000 was vaccinated within 5 days (Douglas & Edgar, 1962).

This episode illustrates the unpreparedness of hospitals in the United Kingdom to cope with an outbreak of smallpox at that time, given the large proportion of unvaccinated professional and domestic staff, the difficulty of recognizing haemorrhagic-type smallpox and the risks thereby incurred, and the problems encountered in effectively containing the outbreak once it had been recognized. The response to the provision of vaccination clinics demonstrated the existence of considerable public fear and apprehension about smallpox.

Outbreak in Skodsborg, Denmark, and Tromsö, Norway

In August 1970 smallpox was imported into Denmark by a 22-year-old Danish medical student who had returned to Copenhagen after a curtailed holiday in Afghanistan. He had been successfully vaccinated in 1956 in Norway and revaccinated with liquid vaccine in May 1970, but the result had not been checked and he said later that the revaccination had been unsuccessful. He arrived in

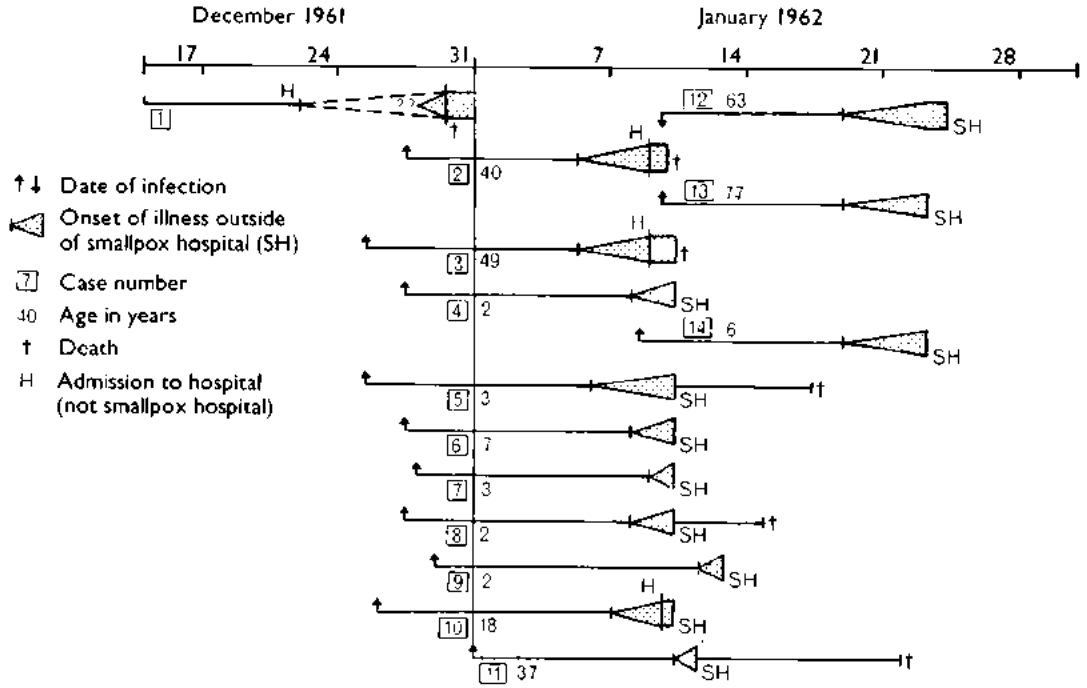

Fig. 23.2. Outbreak of smallpox in Bradford, England, in December 1961 – January 1962. All cases were hospital-associated. The index case was a Pakistani girl who was admitted to the Bradford Children's Hospital and died of unrecognized haemorrhagic smallpox. Cases No. 4-9 were patients at that hospital, case No. 2 a hospital visitor, and cases No. 3,10, and 11 a resident cook, a nurse and the pathologist, respectively. The three second-generation cases occurred at another hospital to which case No. 2 had been admitted, and case No. 14 at a third hospital to which case No. 4 had been admitted before it was realized that he had smallpox. (Based on England and Wales, Ministry of Health, 1963.)

Kabul early in August, and was admitted to hospital on the 14th, suffering from severe gastroenteritis. Because cholera was suspected, he was transferred to the infectious diseases ward, where he was exposed to cases of smallpox between 17 and 19 August. On 26 August he returned to Copenhagen, feeling reasonably well and with a normal temperature.

On 28 August, when he was living in the staff quarters of the Skodsborg Hospital, near Copenhagen, he became feverish and was treated with penicillin. The next day he developed a rash, which was attributed to the penicillin. On 31 August he was admitted to the infectious diseases ward of the Blegdam Hospital with a diagnosis of pneumonia and dysentery. On 2 September, smallpox was suspected and he was placed in isolation. The State Serum Institute in Copenhagen confirmed the diagnosis by laboratory examination a day later. On 4 September the rash became confluent and haemorrhagic, and secondary infection occurred, with severe pneumonia. He later developed renal symptoms and died.

Some 400 direct or indirect contacts of the patient were identified, traced, vaccinated and put into quarantine at the Blegdam Hospital. They were mainly persons who had lived with the medical student in the dormitory at the Skodsborg Hospital and personnel at the Blegdam Hospital who had cared for the patient or had had contact with his clothing and bed-linen.

The Danish health authorities at no time contemplated mass vaccination, but maintained an alert for potential secondary cases until mid-October, because there might have been a missed case which would be detected only if the infection were transmitted to others. However, the only subsequent case that did occur was recognized in Norway.

Smallpox infection was carried to Tromsö, in the far north of Norway, by a 25-year-old Norwegian medical student who had been living in the staff quarters of the Skodsborg Hospital in a room next to that of the Danish

student. On 28 August, after they had talked briefly, the Norwegian student had left for Norway, travelling by car with another young Norwegian.

At the beginning of September, when the case in Denmark was confirmed as smallpox, the Norwegian medical student was identified by the Danish national health service as being a close contact. The Norwegian health authorities were notified, and on 4 September he was traced, vaccinated and kept under surveillance. Five days after vaccination he developed an accelerated reaction on the vaccination site. On 5 September, 9 days after contact, he developed low back pain and a rash suggestive of smallpox. Paired sera were sent to Oslo for serological tests, the results of which indicated smallpox. The person who had driven with him from Skodsborg to Norway and 33 other possible contacts were traced, vaccinated and isolated, but no further case occurred. This pattern, with good surveillance and minimal or no secondary spread, occurred in about half of the recognized importations into Europe during the period 1959–1973.

IMPORTATIONS INTO NORTH AMERICA AFTER 1959

The transmission of smallpox had been interrupted in the USA and its territories in 1949. In that year the last known outbreak, resulting in 8 cases and 1 death, occurred in Texas and was probably due to an importation from Mexico, in which the last case of smallpox occurred in 1951. Reports of smallpox during the 1950s turned out on further investigation to have been cases of chickenpox. In Canada, endemic smallpox was eliminated in 1943, but there were 7 imported cases in 1945 and 1946.

As international air traffic increased in the 1960s and 1970s, and many more people travelled from Canada and the USA to Africa, South America and Asia, in which smallpox was still endemic, there was a constant and increasing risk of importing smallpox into North America. In contrast to Europe, there were no introductions of variola major from the Indian subcontinent into North America, despite the fact that Americans were the most numerous short-term travellers to the subcontinent. For example, Mack (1972) estimated that there were over 3 times as many travellers to India from the USA as from the Federal Republic of Germany (in 1969, 50 000 Americans compared with 14 000 Germans). However, after 1958, there were 5 importations from India into the Federal Republic of Germany but none into the USA. Only 1 importation of smallpox into North America was reported—a single case of variola minor imported from Brazil into Canada via the USA.

Sixteen years after Canada's last case of smallpox, the disease was brought back to Toronto from Brazil in 1962 by a 15-year-old Canadian boy, who had lived for several years in Paraná State, Brazil. At the end of July 1962 he had been in contact with 4 children who were said to be suffering from chickenpox. On 10 August he and his family left Brazil by air and arrived in New York City on 11 August. Just before his departure from Brazil, the boy had developed fever and malaise which were diagnosed as influenza. On arrival in New York he had presented a smallpox vaccination certificate dated 22 July 1962 (*Wkly epidem. rec.*, 1962), but in fact he had not been vaccinated for approximately 6 years (Best & Davis, 1965).

The family remained in New York for some 6 hours before boarding a train to Toronto. Soon after his arrival there on 12 August, the boy developed a rash, which 2 days later had spread widely over the body, showing a typical centrifugal distribution. He was admitted to hospital in Toronto on 18 August. The clinical diagnosis of smallpox was confirmed on 20 August by the isolation of variola virus. Passengers on the plane on which he had travelled from Brazil to New York were identified, vaccinated and placed under surveillance, as were the members of his family and other known close contacts in Toronto. Persons who had travelled on the train from New York or had had possible contact in the railway stations were requested through the mass media to report for vaccination, and those who did so were also placed under surveillance. No additional cases were reported.

IMPORTATIONS INTO JAPAN

Japan, the only large industrialized country in eastern Asia, had been free of smallpox since 1951. There were a few imported cases each year until 1955; then, after an absence of smallpox for 18 years, 2 importations oc-

Plate 23.4. The Japanese government official who was infected in Dhaka in 1973 worked in this conference room of the parliament building in Tokyo while suffering the prodromal symptoms of smallpox, which was diagnosed a few days later. Health officials disinfected the room.

curred, in 1973 and 1974, at a time when the number of travellers from Japan to the Indian subcontinent had increased substantially. The first case was in a 33-year-old Japanese traveller, who had stayed in Dhaka, Bangladesh, from February to mid-March 1973, when Dhaka and its surrounding areas were experiencing an extensive epidemic of smallpox (see Chapter 16). The patient, who was reported to have been vaccinated in mid-January, returned to Tokyo via Bangkok on 18 March, became ill on 23 March and was hospitalized on 26 March. On 31 March he was isolated in the Tokyo Metropolitan Infectious Diseases Hospital and a diagnosis of smallpox was virologically confirmed a day later. Close contacts were identified and placed under surveillance, but no secondary cases occurred (*Wkly epidem. rec.*, 1973a).

The second importation into Japan occurred in January 1974 (*Wkly epidem. rec.*, 1974). The index case was a Japanese Buddhist pilgrim, who was exposed to smallpox while travelling through northern India. He had no record of vaccination in childhood, and the result of his vaccination in Japan on 7 December 1973 was interpreted to be a "reaction of immunity". He developed symptoms on 22 January 1974, 5 days after his return to Japan. Control measures, initiated on 28 January, when smallpox was suspected, included the isolation of the patient and his family, and the vaccination and surveillance of some 270 persons considered to be close contacts, including 19 pilgrims who had accompanied the patient to India. No secondary cases occurred.

IMPORTATIONS INTO RECENTLY ENDEMIC COUNTRIES, 1959–1976

Besides the countries of Europe, North and Central America, Oceania and eastern Asia in which smallpox was not endemic in 1959 (see Chapter 9, Fig. 9.3), there were a number of countries in Africa, South America, south-eastern Asia and south-western Asia in which smallpox had been endemic in the 1950s but had been eliminated during the next decade, and which were thereafter exposed to the risk of importations from neighbouring endemic areas. Importations also occurred across the borders of countries that continued to

harbour foci of endemic smallpox (see, for example, Chapter 15, which discusses importations from India into Nepal).

Data on importations into non-endemic countries of South America are reasonably complete from 1959 onwards, but data from Africa and Asia were very scanty prior to the establishment of the Intensified Smallpox Eradication Programme in 1967. Even after 1967, not much information is available on importations into African countries. Comments on importations into these continents are therefore limited to tabulations of importations from one country into another within each continent, from 1959 for South America, and from 1967 for Africa and Asia. However, a connected series of outbreaks in Iran, Iraq and the Syrian Arab Republic in 1970–1972 will be described in greater detail.

Africa

By 1958, 13 of the 47 countries of Africa appeared to have become free of endemic smallpox. In the period 1959–1966, when WHO encouraged the remaining African States to institute national smallpox eradication programmes, 17 countries (5 of them reinfected) are believed to have succeeded in interrupting smallpox transmission (Table 23.6). When the WHO Intensified Smallpox Eradication Programme began in Africa in 1967, smallpox was endemic in 23 countries, and between 1968 and 1976 endemicity was re-established in 3 countries.

Between 1967 and 1976, over 70 importations of smallpox from neighbouring endemic countries into non-endemic countries were reported (Table 23.7). International boundaries in Africa, most of them drawn during the 19th century by the European colonial powers, bore little relationship to ethnic or tribal distribution, so that many of them were crossed and recrossed as frequently as were state or district boundaries in a country such as India. The transfer of smallpox across these boundaries occurred repeatedly, and the figures for importations in the late 1960s, when smallpox was becoming much less common and surveillance was improving, are not complete. It is known that in several instances (indicated by the symbol "+" in Table 23.7) there were more importations than those reported; it is also clear that importations from Ethiopia into neighbouring countries were at least as numerous before 1971 as after that year, when effective surveillance began.

In most cases the disease did not persist long after importation, as, for example, after the numerous transfers from Ethiopia to Djibouti and Somalia between 1971 and 1975. However, importations into the Sudan (1967), Botswana (1971) and Somalia (1976) led to the re-establishment of endemicity in the recipient countries and had a considerable impact on the global eradication programme. In each country, transmission persisted until a full-scale eradication programme had been set up and the local health staff had grasped the concept of surveillance and containment, which enabled them finally to interrupt transmission. Of more than 17 importations into non-endemic countries of western Africa that were recorded after 1966, at least 10 originated in Nigeria. Ethiopia was an even more important source country: all but 7 out of more than 47 importations reported anywhere in Africa between 1971 and 1976 originated there.

[a] Numbers in brackets indicate the number of reported cases associated with each importation.

South America

By 1959 smallpox transmission had been interrupted in Chile, Peru, Uruguay and Venezuela. In the 8-year period from 1959 to 1966 another 5 countries became smallpox-free: Argentina, Bolivia, Colombia, Ecuador and Paraguay. Except in Peru, importations during the period 1959–1970 did not result in large numbers of cases. However, in Peru in 1963, following its introduction from Brazil, variola minor became endemic and remained so until 1966. From 1964 onwards, Brazil was the only known source from which smallpox was exported to other countries in the subcontinent (Table 23.8).

Southern Asia

Apart from importations into countries of south-eastern Asia that had long been smallpox-free (see Chapter 8), information on importations into the non-endemic non-industrialized countries in Asia is fragmentary before 1967 and still incomplete after that date. What is known can be most effectively discussed in respect of 2 regions: countries adjacent to India, and south-western Asia.

Countries adjacent to India

Reported importations into non-endemic countries near India during the period 1967–1974 are shown in Table 23.9. The 12 outbreaks fall into 5 groups: importations into Sri Lanka, Afghanistan, Bangladesh, Bhutan and Burma.

Importations into Sri Lanka (outbreaks No. 2 and No. 6) and Afghanistan (3 outbreaks, grouped together as No. 7) were effectively contained. Sri Lanka had been free of endemic smallpox since 1951 and was vigilant in its efforts to maintain that status. The 2 reported cases were contained without local spread, vaccination being carried out on a large scale in Kandy (outbreak No. 2) and Colombo (outbreak No. 6) respectively. Three importations into Afghanistan occurred in 1973, the year after smallpox had been eliminated; they were discovered promptly and the containment methods used during the eradication programme limited spread.

The importation of smallpox into Bangladesh early in 1972, following the return from India of millions of refugees, led to the re-establishment of endemic smallpox and to many thousands of cases. Eradication was not achieved until October 1975.

Table 23.9 Importations of smallpox into non-endemic countries adjacent to India, 1967–1974

Serial number	Year	Importing country	Country of origin	Number of reported cases	Comment
1	1967	Bhutan	India	14	2 outbreaks, originated in markets in Assam.
2	1967	Sri Lanka	India	1	–
3	1968	Burma	East Pakistan	181	Affected 14 villages, over a period of 7 months.
4	1969	Burma	East Pakistan	68	Affected 3 villages, over a period of 2 months.
5	1972	Bangladesh	India	Numerous	Refugees returning from India re-established endemicity in Bangladesh.
6	1972	Sri Lanka	Afghanistan	1	German tourist infected.
7	1973	Afghanistan	Pakistan	25	3 outbreaks of 1, 11, and 13 cases respectively.
8	1973	Bhutan	India	6	Originated in West Bengal.
9	1974	Bhutan	India	3	Originated in Assam.

From an epidemiological standpoint, Bhutan is equivalent to an Indian state, so that it is not surprising that smallpox spread across the border from Assam (outbreaks No. 1, No. 8, and No. 9). Because of the small and sparse population the disease did not persist. In Burma, on the other hand, introductions from Chittagong, East Pakistan (Bangladesh), in 1968 and 1969, shortly after smallpox had been eliminated (outbreaks No. 3 and No. 4), spread without control for several months, because it was very difficult for the health services to operate in the area, in which there were many insurgents.

South-western Asia

This region (Fig. 23.3) consists of Iran (now the Islamic Republic of Iran) and Iraq to the north, Israel, Jordan, Lebanon and the Syrian Arab Republic to the west, and the Arabian peninsula, comprising Democratic Yemen, Saudi Arabia, Yemen, and the 5 Gulf states of Bahrain, Kuwait, Oman, Qatar and the United Arab Emirates. The Arabian Peninsula is mostly desert and the majority of the population is concentrated in a few cities. However, this area was the crossroads of smallpox transmission, since between 1 and 2 million pilgrims came to Mecca by sea, land and air every year, many from the endemic countries of Africa and Asia. Even more important were the numerous migrant workers in the Gulf states, mostly from Pakistan and India.

By 1963, all countries in south-western Asia, except Yemen, appeared to have interrupted smallpox transmission, but frequent importations, particularly from the Indian subcontinent, and deficiencies in the notification of cases to WHO (including the occasional suppression of reports) made it very difficult to know precisely when these countries became non-endemic and to judge the magnitude of outbreaks following importations (Table 23.10). Smallpox was poorly reported, not only because of inadequate health services, but also because of national pride and the fear that the presence of the disease might lead to restrictions on travel or the imposition of an economic embargo by neighbouring countries. In Saudi Arabia, it was believed that reports of the presence of smallpox would inhibit visits by pilgrims. The reliance of some countries in this area on their own capacity to control outbreaks of smallpox occasionally resulted in large numbers of cases and the spread of the disease for up to 2 years. In some of these countries, moreover, clinical and laboratory diagnoses were unreliable, so that the health services could not be certain whether the cases that they recorded were indeed smallpox. They hesitated to request WHO's assistance in improving laboratory diagnosis, because the rendering of such support might lead to international disclosure of the suppression of information about outbreaks.

Between 1967 and 1972, Iran, Iraq, Kuwait, Saudi Arabia, the Syrian Arab Republic, or the United Arab Emirates continued to report cases of imported smallpox every year except 1969. Brief comments on these outbreaks are provided in Table 23.10. The

Table 23.10 Importations of smallpox into non-endemic countries of south-western Asia, 1967–1972

Serial number	Year	Importing country	Country of origin	Number of reported cases	Comment
1	1967	Kuwait	Bangladesh	41	Hospital-associated outbreak (Arita et al., 1970); probably spread to Iran.
2	1967	United Arab Emirates	India	10	Probably 3 importations from different dhows (Swinhoe, 1970).
3	1968	United Arab Emirates	India	1	No local spread.
4	1968	United Arab Emirates	India	1	
5	1970	Iran	Afghanistan	29 (1971) 2 (1972)	Reports suppressed; origin of large epidemic that spread westwards (No. 9 and No. 10), eventually reaching Europe.
6	1970	Saudi Arabia	Bangladesh	12	Pilgrims on ship which was quarantined in harbour.
7	1970	Saudi Arabia	?	2	Diagnosed by WHO epidemiologist in Riyadh area; not reported by national authorities.
8	1970	United Arab Emirates	Pakistan	48	Outbreak lasted until June 1971; greatly underreported.
9	1971	Iraq	Iran	37 (1972)	Extension of No. 5; disease became endemic.
10	1972	Syrian Arab Republic	Iraq	54	Extension of No. 9; hundreds of cases, but outbreak controlled within 4 months.

Suppression of Information on Quarantinable Diseases

Suppression of the reporting of diseases of international importance has been—and remains—a common practice in many countries, both developing and developed. So far as the countries of south-western Asia are concerned, the failure to report smallpox can be ascribed in part to recent experience with cholera. This disease, which had been absent from the area for many years, was reintroduced in the mid-1960s. Governments were unfamiliar with it, and although the outbreaks were caused by the milder *eltor* biotype, there were many deaths. A variety of measures were introduced to control the spread of cholera, including the imposition of a cordon sanitaire, prohibition of the import of goods and widespread vaccination. These had a serious economic impact, which led some governments to suppress reports of the disease. Against this background, it is not surprising that when smallpox was reintroduced after an absence of many years, governments sometimes responded by not reporting. Suppression of information occurred not only at the central national level, but also often at lower peripheral levels within countries. Smallpox, however, was rather more difficult to conceal than cholera.

WHO actively sought to discourage the suppression of reports of smallpox. Several approaches were used. Endemic countries were encouraged to report fully, and when this led to an apparent increase in the recorded incidence the governments were congratulated on their improved surveillance. As the numbers of smallpox cases declined, WHO encouraged countries to offer a reward for reporting cases to both health personnel and the public, to make it clear that government officials appreciated receiving this information. Finally, when rumours of smallpox in what was thought to be a smallpox-free country were reported by such persons as visitors or foreign officials, governments were asked to institute inquiries.

1970–1972 outbreak, which originated in Afghanistan and spread through 4 countries—Iran, Iraq, the Syrian Arab Republic and Yugoslavia—was of particular interest and importance, because of its extent, the degree of underreporting, and its occurrence at a time when the Intensified Smallpox Eradication Programme was in full swing.

THE 1970–1972 OUTBREAK IN SOUTH-WESTERN ASIA AND EUROPE

Iran officially reported 29 cases in 1971 and 2 in 1972; Iraq reported 37 cases and the Syrian Arab Republic 54 cases in 1972 (Table 23.10). However, it was known that the actual numbers of cases were much greater, especially in Iran, and it was feared that the epidemic in these countries would cause a substantial set-back to the global eradication programme.

Epidemic spread began in Iran towards the end of 1970, but reports of cases were suppressed. Iran had eliminated smallpox in 1963 by a well-organized mass vaccination campaign; one additional outbreak is known to have occurred in Khorramshahr in 1967, but it was not reported. Apart from this experience and the excessive measures recently taken against countries which had reported cholera, the authorities in Iran had also to take into account the forthcoming major celebrations commemorating the 2500th anniversary of the Persian Empire, which they did not wish to jeopardize; the major function was to be held in Persepolis, in Fars Province, on 12 October 1971, and the heads of state and dignitaries from more than 100 countries were to attend it.

However, extensive outbreaks of smallpox could not long go undetected in a large, cosmopolitan country such as Iran. Acting on information received through the United States Center for Disease Control, WHO sent a cable to Iran on 13 January 1971: "Informed presence smallpox cases 46, deaths 8, Tabriz, E. Azerbaijan province ... appreciate any additional information." About a month later Iran cabled that 9 cases had, indeed, occurred, saying that 3 infected Afghans in Mashhad had led to 4 more cases there and 2 in Tabriz.

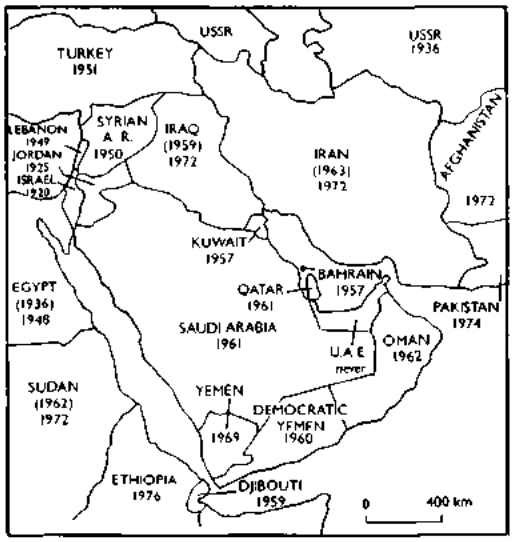

Fig. 23.3. South-western Asia: years in which smallpox ceased to be endemic in each country, before the 1970–1972 epidemic in Iran, Iraq and the Syrian Arab Republic.

No epidemiological details were given and no further cases were reported.

During the following months, reports of smallpox in Iran from various sources grew more and more numerous until finally, on 17 November 1971, the Surgeon General of the United States Public Health Service cabled the following message to the Director-General of WHO: "Reliable reports of smallpox in Shiraz and Abadan, Iran. Can you inquire as to the validity of the report? Until matter resolved U.S. will require valid [vaccination] certificates of arrivals from Iran." It should be noted that the USA had discontinued routine vaccination in 1971 and naturally a smallpox epidemic in a country with which the USA was in close contact was of great concern. Iran's cabled response to an inquiry from WHO, 11 days later, was that 20 cases had occurred between 28 August and 3 October 1971 but none since then, making a total of 29 acknowledged and reported cases in 1971.

Nothing further was heard until 6 March 1972, when Iran, without prompting, notified WHO that 2 cases had occurred on 16 January on its "eastern border". Following a request by WHO for more information, the Ministry of Health stated that the reported cases had occurred in the children of a Baluchi mother who normally lived in Quetta, Pakistan. No information was given as to their recent whereabouts in Pakistan, and at that time active surveillance had revealed no cases in the Quetta area.

At this point it became clear that an epidemic, which could no longer be concealed, was occurring—and not merely in Iran. On 5 March 1972, Iraq reported to WHO by cable that sporadic cases had occurred on its border with Iran and requested 500 000 doses of vaccine. On 17 March, Yugoslavia reported the presence of smallpox to WHO; on 25 March, the Syrian Arab Republic reported the discovery of 15 cases; and on 28 March, the Federal Republic of Germany notified a case in Hanover, in a man who had come from Yugoslavia. In the face of this evidence, the resistance of all the countries of south-western Asia to reporting the disease weakened, but it did not collapse.

Iran

Iran (population in 1972, 30.3 million) officially reported 31 cases of smallpox in 1971–1972. The suspicion that there had been many more cases was confirmed following a visit to Iran by Henderson from 2 to 13 August 1972. He reported that over 2000 cases had been hospitalized and that 6000–8000 cases had probably occurred. Subsequently, a confidential government report supplied to the Global Commission for the

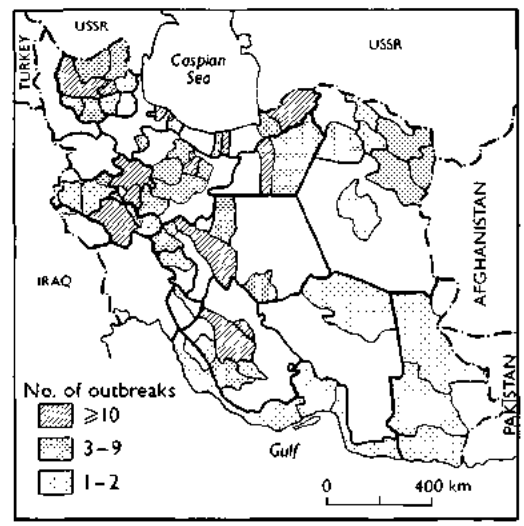

Fig. 23.4. Iran: distribution by district of 400 smallpox outbreaks with some 2000 locally reported cases over the period between November 1970 and September 1972.

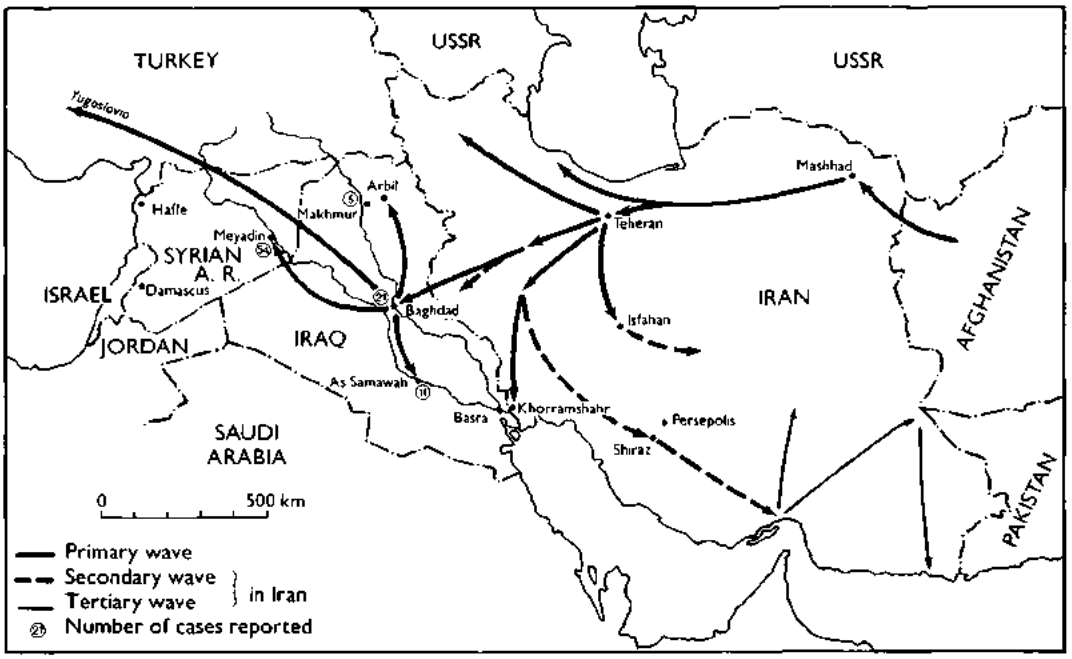

Fig. 23.5. Spread of smallpox in Iran, Iraq and the Syrian Arab Republic, 1970–1972. The disease was introduced from Afghanistan into Mashhad, Iran, in October 1970. There were three waves of dispersion through Iran, which lasted over a period of 22 months. By the end of 1971 smallpox had crossed into Iraq, where it spread north to Arbil and south to As Samawah. Transmission in Iraq was interrupted by June 1972. In February 1972, smallpox spread from Baghdad in Iraq to Meyadin in the Syrian Arab Republic, where a smaller outbreak occurred that was contained by June 1972.

Certification of Smallpox Eradication in December 1978 gave details of 1996 cases in 400 widespread outbreaks between November 1970 and September 1972 (Fig. 23.4). Of these cases, 1349 had been confirmed by laboratory tests.

The epidemic seems to have started when an Afghan family of 6 left their village near Kabul on 16 October 1970 and began a pilgrimage through the smallpox-endemic areas of Afghanistan to the holy city of Mashhad, in Khorasan Province in north-eastern Iran, where several thousand pilgrims congregate daily during the hadj. The family arrived in Mashhad on 20 October. One of the children developed a rash on 3 November and 2 others were similarly afflicted 6 weeks later. Although the first imported case was apparently promptly diagnosed by a local health worker, the disease had already been transmitted to many other pilgrims.

The primary wave of smallpox spread to another 6 provinces in the north (Fig. 23.5), which were to be the most severely affected and for the longest time. Once smallpox reached Teheran it was amplified by hospital-associated spread, and became a typical urban outbreak affecting slum areas and semi-urban districts around the city. Teheran and the original foci in the northern provinces became the principal sources of infection for another 12 provinces in the west-central part of the country during 1971, from which 2 more in the southern part were affected in 1972. Subsequent review suggested that the confidential report, which had noted that 73% of the cases occurred in cities, seriously underreported the numbers of cases occurring in the rural areas.

The strategy adopted by the health authorities was containment by mass vaccination, with only a rudimentary surveillance component. The little freeze-dried vaccine available was below standard; liquid vaccine was used for most vaccinations. Primary take rates were reported to be no more than 65%. Many persons who claimed to have been vaccinated subsequently developed the disease. Although it was reported that 12.5 million vaccinations had been performed in 1970 and 19.8 million in 1971, smallpox continued to spread throughout Iran. There were major outbreaks

in Shiraz, which was the largest city near Persepolis, where the celebrations were to be staged. The health authorities conducted repeated mass vaccination campaigns in Shiraz itself, but partly because liquid vaccine of low potency was being used, transmission was not interrupted. The authorities were in a quandary; they recognized that the vaccine was of low potency, but could not apply to WHO for potent vaccine because of instructions issued at a higher level of government. Eventually, in November 1971, freeze-dried vaccine was sent to Iran by WHO Headquarters: 2 million doses in 1971, followed by 11 million in 1972. A second round of mass vaccination was performed and during 1972 more than 20.6 million people were vaccinated. The last case of smallpox in Iran was reported from Fars Province, with onset of rash in September 1972.

The epidemic in Iran lasted for 22 months, and at least 400 outbreaks occurred in 70 out of the 162 districts in the country.

Iraq

Once the Iranian outbreak had begun in Mashhad in November 1970, smallpox moved relatively quickly along the main road to Teheran and Kermanshah, which is the principal route to Baghdad, the capital of Iraq (population in 1972, 10 million). It seems likely that smallpox arrived in Baghdad at the end of 1971 and then spread north and south along the principal roads running parallel to the Tigris and Euphrates rivers (see Fig. 23.5). An estimated 800 cases of smallpox probably occurred in the country, the last case being in Baghdad in June 1972.

The presence of smallpox in Iraq first came to the attention of WHO when a cable was received on 5 March 1972 reporting the presence of smallpox cases on its northern border with Iran and requesting 500 000 doses of vaccine. The Smallpox Eradication unit received further information on the outbreak on 8 March, during the debriefing of Dr N. Maltseva, who had been touring vaccine production facilities in Iraq, Iran and the Syrian Arab Republic in January and February. She reported that there had been cases of smallpox in Baghdad in January. On 18 March, Iraq informed WHO that 20 cases had occurred in widely separated areas: in Arbil in the north-east, in Baghdad, and in As Samawah in the south. A letter dated 19 March from the Ministry of Health mentioned 2 more cases and stated that the infection had spread from Arbil to Baghdad and from there to As Samawah. It was reported that all known cases had been isolated in fever hospitals and that contacts had been vaccinated and placed under strict surveillance. The population of areas in which cases had been notified were subjected to mass vaccination and surveillance measures were instituted. All provinces had been requested to intensify the mass vaccination campaign begun in December 1971. Subsequently, it was reported that over 2.3 million vaccinations were performed in 1971, followed by 8.2 million in 1972 and 1.2 million in 1973.

Three more cases were reported in Baghdad in June and 1 in July 1972. In August Dr Ehsan Shafa, of the Smallpox Eradication unit, visited Iraq. He was presented with records of only 37 cases, with 5 deaths, in 3 provinces, for none of which could the source of infection be determined. However, the pilgrim responsible for the outbreak in Yugoslavia (see below) had been infected between 3 and 6 February 1972, before the onset of any of the reported cases. In addition to Dr Maltseva's report, an oral statement by a WHO nurse indicated that cases had occurred in a province for which data had not been provided. Furthermore, cases from Iraq had given rise to outbreaks in both Yugoslavia and the Syrian Arab Republic, and long experience with smallpox had shown that such exports to other countries usually indicated the presence of an outbreak of considerable size in the exporting country.

When Dr Shafa reviewed the data with a special technical committee in Iraq, the meeting agreed that a number of cases had been "overlooked" or "misdiagnosed". A more realistic estimate put the total number of cases at a minimum of 800. Nevertheless, the measures taken by the health authorities were found to have interrupted transmission in June 1972. Slow transmission might still have been going on undetected only to flare up later, but continued surveillance in the latter part of 1972 and in 1973 indicated that transmission did not continue after June 1972.

Syrian Arab Republic

On 25 March 1972, the Syrian health authorities notified WHO that cases of smallpox had been discovered in the Syrian

Arab Republic (population in 1972, 6.7 million). The index case was reported to be a 9-year-old boy who had visited Baghdad with his mother for a religious festival between 28 February and 5 March. He developed fever on 9 March, 4 days after his return from Iraq, and rash on 15 March. He was a pupil at the primary school in a village near Meyadin District (see Fig. 23.5). His condition was diagnosed at a dispensary as chickenpox, but on 21 March another schoolchild from the same locality, with a severe skin rash, was diagnosed by a physician in Meyadin as having smallpox. Simultaneously, a physician in another town diagnosed smallpox in 2 other schoolchildren with skin rashes. The disease spread through school contacts to the other villages in the area. A total of 54 cases and 2 deaths were reported, the date of onset of illness in the last case being 27 April 1972.

To control the outbreak, an isolation camp was established in Meyadin and the affected villages were cordoned off. Vaccination of everyone in the Syrian Arab Republic was made compulsory, starting with the affected region. WHO provided more than a million doses of freeze-dried vaccine and a supply of bifurcated needles in March 1972. Health centres and dispensaries were reported to have performed 75 748 vaccinations in 1971, 897 828 in 1972, and 106 176 in 1973.

There were inconsistencies in the data reported. The onset of illness in the index case occurred only a few days before the onset in those reported as secondary cases, an event which suggests multiple introductions or an earlier start to the outbreak. Nevertheless, the government had acted promptly in reporting to WHO and appeared to have done reasonably well in containing further spread.

However, pockmark surveys conducted in 1978 during the preparation of a report for the Global Commission for the Certification of Smallpox Eradication confirmed that far more cases had occurred in the Meyadin area in 1972 than had been reported (see Chapter 26). In fact, one case with pockmarks dating back to 1971 was found in Haffe District, on the other side of the country. Evidence of facial scarring, indicating the occurrence of cases in 1966–1967, which had not been reported, was also found. It was not clear in this instance whether the reporting of cases had been suppressed or whether cases had gone unnotified or had been misdiagnosed as chickenpox. However, the International Commission that visited the country in 1978 found that no smallpox had occurred there after 1972.

Yugoslavia

The reappearance of smallpox in Yugoslavia in 1972 (population in that year, 20.8 million), after more than 45 years without a case, was totally unexpected and caused great concern throughout the world. The epidemic has been described by Stojkovic et al. (1974) and, more briefly, by Litvinjenko et al. (WHO/SE/73.57).

Origin of the epidemic

The outbreak began with an infected pilgrim returning from Iraq. A bus-load of 25 Muslims from the semi-autonomous province of Kosovo in the south of Yugoslavia left on a pilgrimage to Mecca and Medina on 1 January 1972. On their way home they spent 3 nights in Baghdad and visited religious sites between Basra and Baghdad from 3 to 6 February, before leaving for Yugoslavia. The index case, a 38-year old Muslim priest, returned to his village of Danjane (population, 750), 20 kilometres north-east of Djakovica (Fig. 23.6), on 15 February 1972. The next day he fell ill with symptoms of fatigue, shivering and fever, which he thought were due to the

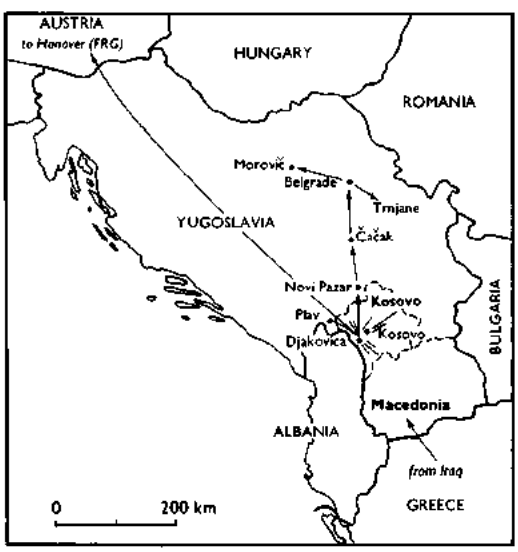

Fig. 23.6. Spread of smallpox in Yugoslavia in 1972. The index case arrived from Iraq on 15 February; the last 2 cases in Yugoslavia became ill in Kosovo and Belgrade on 11 April. The case in Hanover, Federal Republic of Germany, occurred on 22 March.

strenuous bus journey of several thousand kilometres. He denied ever having had a rash and a month later no evidence of skin lesions could be seen on his face or body. Although he had been vaccinated on 5 December 1971, no vaccination scar had developed. No one else on the bus contracted smallpox.

Spread of smallpox in Kosovo Province

A few days after his return, the index case was visited by many of his close relatives, friends and acquaintances, 11 of whom contracted smallpox. Nine cases occurred in Kosovo Province, 1 in Novi Pazar, 160 kilometres to the north (in Serbia), and 1 in a village north of Novi Pazar. These 11 cases were first generation cases, with onsets between 1 and 7 March (Fig. 23.7). None of them was suspected to be smallpox.

It was not until the evening of 14 March that smallpox was recognized by a doctor in the infectious diseases ward of the hospital in Prizren, in the district adjacent to Djakovica, who notified the federal health authorities of suspected smallpox in 4 patients coming from Danjane. The same day 4 other patients admitted to the hospital in Djakovica were recognized as having smallpox.

On 17 March the Yugoslav federal health authorities cabled to WHO that 8 cases of suspected smallpox had been detected. The clinical diagnosis was confirmed by laboratory tests on lesion material at the Institute of Immunology and Virology in Belgrade, confirmation being sent to WHO on 20 March. On 21 March, the WHO Regional Office for Europe informed Member States of the situation and a day later Dr R. Lindner, an Austrian epidemiologist who had previously worked in the Indonesian smallpox eradication programme, was sent to Yugoslavia as a WHO consultant to assist with the investigations.

Between 15 and 31 March, 100 additional cases of smallpox occurred among the immediate family members and relatives of known cases and among the patients of hospitals in Djakovica and Prizren, who had come into contact with cases before the correct diagnosis had been made (Fig. 23.7). This group formed the second generation of cases in Kosovo. Between 1 and 11 April, 14 more cases were recorded in Kosovo. With this third generation of cases the epidemic in Kosovo itself came to an end. It had affected 124 persons, of whom 26 died.

Spread of the disease outside Kosovo

A tragic and unusual chain of events led to considerable spread outside Kosovo. It started when a 30-year old teacher (Lj. M.), from a village near Novi Pazar, went to Djakovica on 21 February to enrol at the Higher Institute of Education. He came into contact with the index case, became feverish on 3 March after his return and developed a rash on 5 March, when he went to the local medical centre at Novi Pazar and was treated with penicillin. On 7 March he went by bus with his brother to the hospital in Čačak. After spending 8 March in the Dermatology and Venereal Diseases ward in Čačak, he was transferred by ambulance to the Belgrade Dermatology and Venereal Diseases Department on 9 March, because his condition was deteriorating. There he was shown to students and staff as a case demonstrating an unusual drug reaction to penicillin. With the development of severe haemorrhagic complications, the patient was taken, on 10 March, to the Surgical Clinic, where he died during the night. No one in any of the 4 medical establishments through which he had passed had had any suspicion that he might be suffering from smallpox. The brother of the deceased accompanied the body back to Novi Pazar, where it was buried on 12 March. The brother developed a rash on 20 March, and since the Yugoslav medical personnel were by then alerted to the disease, smallpox was diagnosed on 21 March. Only at this point was it realized that Lj. M. had died from haemorrhagic-type smallpox.

Retrospective epidemiological investigation showed that the patient had infected a total of 38 persons, 8 of whom died; 2 were infected in Novi Pazar, 9 in the Čačak hospital (8 patients and a nurse), and 27 in the Belgrade hospitals (20 patients and 7 hospital staff, including 2 physicians and a nurse). In view of the time that had elapsed before the diagnosis was made and of the difficulty of tracing the thousands of contacts of the patient, it was decided to undertake mass vaccination throughout Serbia. A few other cases occurred in additional foci outside Kosovo Province, and 1 case in a Yugoslav migrant worker, who became ill in Hanover, Federal Republic of Germany.

Control measures

On 15 March, a team of epidemiologists and infectious diseases specialists from Bel-

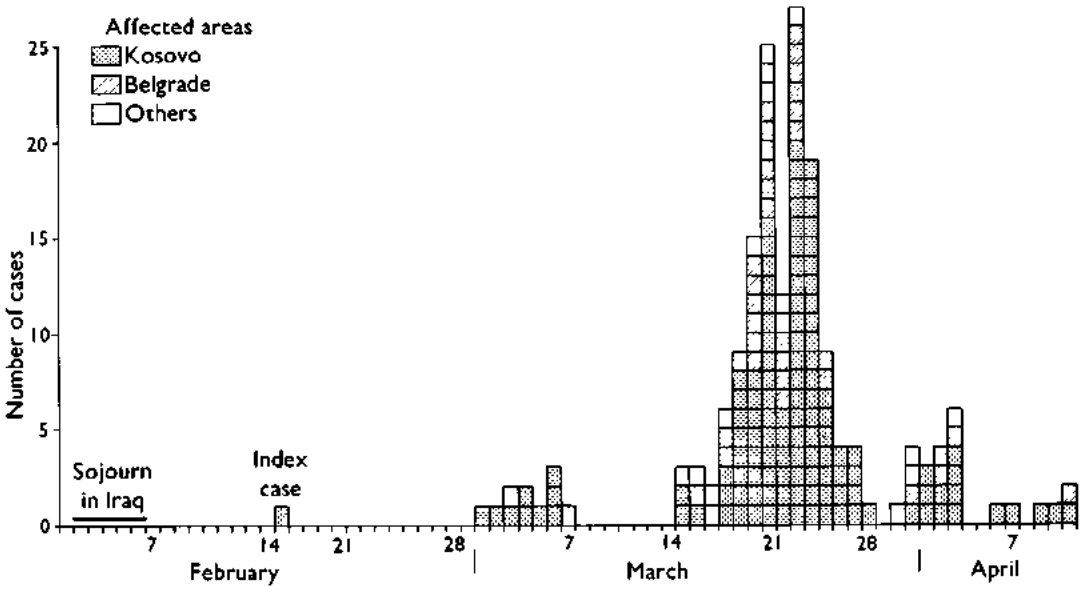

Fig. 23.7 Yugoslavia: number of cases of smallpox, by date of onset and locality, 1972. The first generation of cases occurred in Kosovo province and adjacent areas; the large second generation in Kosovo, Belgrade and some other places.

grade went to Kosovo and joined local health staff in clinical examinations and epidemiological investigations.

The Province of Kosovo, bordering on Albania, was then a rural, relatively undeveloped area, whose Albanian-speaking inhabitants regarded outsiders with suspicion. The population was composed of large extended families, whose members constantly visited one another, and the men frequently travelled long distances to look for work. Most of the epidemiologists carrying out the field investigations had to communicate through an interpreter with a rather uncooperative population, and this caused them some difficulties. The index case, for instance, never admitted to having had a rash and it was some time before circumstantial epidemiological and serological evidence confirmed the diagnosis of smallpox. The reticence of the man concerned was understandable. He belonged to the semi-secret Bektachi religious sect and was most reluctant to have his illness associated with the pilgrimage or to discredit his religion thereby. Indeed, had he been identified as the source of an infection which had killed several members of his village and of surrounding villages, his life might have been in danger.

Vaccination of the population in the initial foci in Kosovo began on 16 March and was extended in concentric rings, until by the end of the month almost all the population in the affected province had been vaccinated. There were problems, however, with coverage and unsuccessful vaccination owing to the use of liquid vaccine. It was not until the end of April that 95% successful coverage was achieved. By the third generation of the outbreak, most cases were occurring among persons who had been unsuccessfully vaccinated.

Containment measures in the 25 localities in villages and towns in which cases of smallpox had been detected included the strict isolation of patients, quarantine of their contacts in facilities specially established in hospitals, hotels, pensions etc., and vaccination of the population. In households in which more than one family member had been infected, their home was turned into a quarantine centre. Where necessary, whole villages were put under surveillance, the inhabitants' temperatures were taken and the skin of patients was inspected regularly. Population movement to affected areas was restricted and public meetings were prohibited.

In Kosovo, extensive vaccination of hospital staff and the general population was begun as soon as the diagnosis of smallpox had been confirmed, and the same procedure was

adopted for all 25 smallpox foci. The Federal Epidemiological Commission then decided to undertake a mass vaccination programme throughout the country. In 3 weeks, 18 million out of a total population of 20.8 million were vaccinated.

The epidemic, which caused 175 cases and 35 deaths, was brought under control 6 weeks after the first diagnosis of smallpox. Surveillance for the next 4 weeks having revealed no other case, Yugoslavia was declared free of smallpox on 9 May 1972.

Plate 23.5. Control measures taken during the 1972 outbreak in Yugoslavia. **A:** More than 300 health teams, some of them army medical units, took part in the vaccination campaign. **B:** Protective clothing worn by medical personnel in emergency smallpox hospitals. **C:** Check-points were established at hundreds of places along the main roads to check vaccination certificates.

It is interesting to note that there was an unusually high proportion of haemorrhagic-type cases: 10% as opposed to the usual 1%. Hospital transmission accounted for 48% of the infections. A high rate of transmission (an average of 12.8 new infections per case) during the second generation of cases was assumed to be associated with inadequate protection from vaccination, 37% of these cases having occurred among previously vaccinated persons. While the number of deaths among previously vaccinated persons was half that among the unvaccinated, the overall case-fatality rate was 20%. The age distribution of cases corresponded with that of the population affected, and the sex ratio was 57% males to 43% females.

The unusual magnitude of the outbreak was considered to be due to the sizeable proportion of susceptible individuals in the population, delayed diagnosis, hospital transmission, the initially large number of unsuccessful revaccinations, communication problems in the tracing of contacts, and an atypical haemorrhagic-type case, which gave rise to the extraordinarily high number of 38 secondary infections.

The spread of smallpox in south-western Asia in 1970–1972 and its importation into Yugoslavia and the Federal Republic of Germany embarrassed several of the countries involved and retarded the progress of the global eradication programme. However, they did help to mobilize support for the programme and to reinforce surveillance efforts in all the countries of south-western Asia.

LABORATORY-ASSOCIATED OUTBREAKS IN THE UNITED KINGDOM

Microbiological laboratory space inevitably becomes contaminated with the bacteria or viruses in use, the more easily if safety measures are not taken (see Chapter 30). Smallpox laboratories were no exception. However, the regular vaccination and revaccination of persons in any way associated with these laboratories provided good protection against their infection with variola virus.

In countries that still had endemic transmission of smallpox, it was only when cases occurred among laboratory workers that it was possible to ascribe them with any certainty to an infection acquired in a laboratory. Although laboratory-associated outbreaks of smallpox may have occurred in various countries of the Americas, Asia and Europe when the disease was endemic in them, only 3 known laboratory-associated outbreaks and 1 suspected outbreak have been recognized; they all occurred in the United Kingdom after smallpox had ceased to be endemic there (Table 23.11). Only 2 of these were fully documented: one in London (1973), the other in Birmingham (1978). A single-case outbreak in Liverpool, in 1949, involved a laboratory worker who was accidentally infected with variola virus while handling contaminated materials (A. W. Downie, personal communication, 1980). An outbreak of variola minor in the Midlands and Wales in 1966 was later associated with infection acquired from a laboratory. The 2 confirmed outbreaks will be described first.

Table 23.11 Laboratory-associated outbreaks of smallpox in the United Kingdom

1978	Birmingham	2	1	Birmingham Medical School laboratory

[a] Suspected.

The London Outbreak, 1973

This outbreak followed the last importation of smallpox into the United Kingdom, which occurred in February 1973, when an Anglo-Indian infected during a holiday in Calcutta became ill after his return to London at the end of February (No. 34, Table 23.2). There were no contact infections.

The laboratory-associated outbreak occurred in March and April 1973, during which another 4 cases of smallpox were reported in the United Kingdom (Cox, 1974). On 11 March 1973 a 23-year-old female laboratory assistant in the Mycological Reference Laboratory at the London School of Hygiene and Tropical Medicine became ill with influenza-like symptoms—headache, backache and high fever. She had been

vaccinated as a child and revaccinated in 1972, but did not recall noting any reaction at that time. On 13 March she visited her doctor, who assumed that she had influenza and treated her with oxytetracycline. On 15 March she developed a slight rash and a day later was admitted to St Mary's Hospital, London, with a provisional diagnosis of glandular fever, and placed in a general ward. A drug rash due to oxytetracycline was suspected and later, because she worked in a mycological laboratory, the possibility of fungal infection was considered.

On 22 March she was visited by a friend working in the mycology laboratory, who, at the request of the head of the laboratory, took scrapings from the patient's skin lesions, which were investigated the same afternoon. To the surprise of all, brick-shaped poxvirus particles characteristic of variola virus were seen with the electron microscope. An investigation of the patient's movements before the onset of fever revealed that on 28 February she had entered the poxvirus laboratory (located in the same building as the mycology laboratory) and had watched the chorioallantoic membranes of eggs inoculated with variola virus being harvested on the open bench.

The poxviruses being studied in the laboratory at that time included variola major virus (Harvey strain) and two strains of "whitepox" virus (see Chapter 30). Subsequent investigations showed that it was the Harvey strain of variola virus with which the technician had been infected (Dumbell, 1974).

The patient was taken to Long Reach Isolation Hospital in Dartford, Kent, and the diagnosis of smallpox was confirmed. As many identifiable contacts as possible were traced, vaccinated and placed under surveillance. Unfortunately this group did not include a woman who had occupied the bed next to the laboratory technician's until 20 March, at St Mary's Hospital, nor her son and daughter-in-law, who had often visited her in the general ward. On 30 March the 34-year-old son and his 29-year-old wife fell ill with a headache, back pain and nausea. On 2 April their condition deteriorated and they were admitted to an isolation ward of the West Hendon Hospital with a provisional diagnosis of viral gastroenteritis. A skin rash developed on 3 April and became vesicular a day later, when smallpox was suspected and confirmed by laboratory examination. On the same day both patients were transferred to the Long Reach Isolation Hospital and died, the wife from haemorrhagic-type smallpox and the husband from confluent ordinary-type smallpox.

On 24 April another case, diagnosed as variola sine eruptione, was notified in a nurse, successfully vaccinated on 4 April, who had tended the couple with smallpox in the West Hendon Hospital. A week later, she had fever accompanied by headache, backache and shivering, with a papular rash on her hands. She was transferred to Long Reach, where a diagnosis was made on the basis of the clinical history.

Thus, the "escape" of variola virus from the London poxvirus laboratory resulted in 4 cases, of which 2 were fatal. The British government set up a committee of inquiry, whose report (Cox, 1974) concluded that the technician had probably been infected by the respiratory route while watching the harvesting of chorioallantoic membranes from eggs on 28 February, and that the other 2 patients had been infected on 17 March, when visiting the hospital.

The important feature of the report, in the light of later actions about methods of handling variola virus in laboratories, is the description of the laboratory facilities used at that time. The report noted that the laboratory was of an old-fashioned design, grossly overcrowded and poorly equipped. Work with variola virus was done on an open bench and a deep-freeze for storing variola virus stood in the corridor. But, as Dr K. R. Dumbell of St Mary's Hospital Medical School testified, the conditions which prevailed there were comparable with those in other teaching hospitals and medical schools in London. Even as recently as 1973, then, scientists working with variola virus did not handle it as a highly dangerous agent but relied on good microbiological techniques and on the regular vaccination of all personnel involved in the laboratories rather than on physical safety facilities. This did not apply to laboratories specially built for handling dangerous microbial pathogens, such as the Microbiological Research Establishment at Porton Down, Wiltshire, in which elaborate physical facilities were provided for the safe handling of dangerous viruses and bacteria. The report concluded with a recommended Code of Practice for Safety in Laboratories Handling Variola Virus (see Chapter 30).

The Birmingham Outbreak, 1978

Ten months after the last case of endemic smallpox in the world had been detected in Somalia in 1977, the British health authorities reported to WHO that on 27 August 1978, a 40-year-old Englishwoman had been confirmed to be suffering from smallpox. The patient, Mrs Janet Parker, a medical photographer in the Anatomy Department of the Medical School of the University of Birmingham, became ill with fever, headache and muscular pains on 11 August and developed a rash on 15 August. This was at first thought to be a drug rash. She remained at her own home until 21 August, when she was transferred to her parents' house. On 24 August the appearance of vesicles led to a suspicion of smallpox, the patient was admitted to the East Birmingham Hospital and when a diagnosis of smallpox was confirmed by electron microscopy, she was placed in the Catherine-de-Barnes Isolation Hospital. Variola major virus was isolated from vesicle fluid on 27 August. Her condition, complicated by renal involvement, deteriorated rapidly and she died on 11 September.

Mrs Parker had last been vaccinated in 1966. She had not travelled abroad in the recent past and to the best of her knowledge had had no contact with any persons recently returned from abroad. Indeed, endemic variola major had not been present anywhere in the world since October 1975.

In order to investigate the matter, a Source of Infection Committee composed of 5 experts was established by the University of Birmingham on 28 August 1978. One of the members was Professor Henry S. Bedson, Head of the Department of Medical Microbiology of the Medical School of the University of Birmingham, in which the smallpox laboratory functioned as the regional diagnostic smallpox laboratory. Bedson was an active participant in WHO's coordinated laboratory investigations of variola and "whitepox" viruses (see Chapter 30). The committee suspected that the smallpox laboratory was the probable source of infection.

Meanwhile the health authorities had identified about 290 persons who might have had contact with the patient during her illness. These included the immediate members of her family and other relatives, patients of the East Birmingham Hospital, and colleagues at the Medical School. All were vaccinated and placed under surveillance at

Impact of the Birmingham Outbreak

In July 1978 there was a growing belief that the last case of smallpox in the world had occurred in Somalia in October 1977. It was not surprising, therefore, that the Birmingham incident led to a great deal of publicity in the media and caused considerable concern in the medical community throughout the world. Health administrators in the developing countries of Africa, in particular, renewed their calls for the cessation of laboratory studies of variola virus and the destruction of all stocks of the virus.

Because of the publicity, WHO received inquiries from the press and from health administrators in many countries concerning proposals for reducing the risk of another escape of variola virus from a laboratory. Information officers were recruited by the Smallpox Eradication unit to handle the inquiries, and Arita, as chief of the unit, developed plans to deal with the situation. Two meetings were convened: a meeting of experts in February 1979 to evaluate the justification for retaining variola virus stocks in laboratories, and a conference in April with the directors of 9 laboratories which were then retaining the virus, together with representatives of the governments concerned, to discuss control measures and future actions.

The plans were debated at a special open meeting held during the sixty-third session of the Executive Board in January 1979, which was attended by a large number of journalists, and the meetings took place as scheduled. Thus the Birmingham laboratory-associated outbreak, though an unfortunate incident, hastened a recognition of the risk of holding variola virus stocks and led to an immediate reduction in the number of laboratories retaining the virus, from 13 in 1978 to 7 in 1979 (see Chapter 30, Table 30.7).

home. Four of them were hospitalized with different illnesses, none of which was smallpox. Three were discharged from hospital, while the fourth person—the 77-year-old father of the deceased patient—developed fever on 1 September, 12 days after his daughter had been brought to his house in his car in the vesicular stage of her illness. He did not develop a rash but died suddenly on 5 September from a heart attack. The tragedy was not over. On 2 September the 49-year-old Professor Bedson was found severely ill after an apparent suicide attempt and died 5 days later. On 7 September Mrs Parker's mother, aged 70, became ill while in quarantine at home and on 8 September developed a sparse macular rash, which was confirmed by laboratory examination as being due to smallpox. She recovered and was discharged from isolation on 22 September.

In view of the mildness of the illness which the second patient developed, as well as the vigorous surveillance and control measures, a further community-wide spread of smallpox was judged to be very unlikely. Priority vaccination was restricted to contacts, persons who worked or lived in nearby foci and persons who needed vaccination to travel.

On 30 August 1978, the Secretary of State for Social Services requested Professor R. A. Shooter to conduct an official investigation, the results of which were published in July 1980 (Shooter, 1980). Dr Joel Breman, from the WHO Smallpox Eradication unit, participated as an observer in the first 3 meetings of this investigation. As in the episode in London in 1973, the index case was in a person not directly connected with work in the smallpox laboratory. Mrs Parker was a medical photographer who worked in another department of the medical school, though in rooms on the floor immediately above the smallpox laboratory (Plate 23.6).

The team of investigators inspected the premises thoroughly, carried out tests on air movement between the laboratory and the photographer's room and made exhaustive inquiries to determine whether there might have been personal contact between Mrs Parker and any worker in the virus laboratory during the last week of July.

It concluded that Mrs Parker had been infected with a strain of smallpox virus used in the smallpox laboratory, probably during the last week of July 1978, but how the virus was transferred to Mrs Parker was less certain.

"The evidence points to two possible routes by which smallpox virus was transmitted from the pox laboratory to Mrs. Parker: by the airborne route, either through the duct in the 'telephone room' or while visiting the Medical Microbiology corridor; or by the personal contact route, transfer being by the visitor from the Medical Microbiology Department who regularly entered the animal pox room. We are unable to say with certainty which of these two routes might have led to Mrs. Parker contracting smallpox. Both are possible though neither seems capable of delivering a large dose of virus unless an accident occurred involving the liberation of virus, which was not recognised or recalled. Nevertheless, from what we know small doses of virus could have been liberated from time to time which could have been responsible for Mrs. Parker's infection. We believe that the airborne route through the duct to the 'telephone room' is the most probable way by which Mrs. Parker was infected because this seems to be the one route that could have selectively affected her." (Shooter, 1980.)

This episode constituted the last known outbreak of smallpox in the world, and Mrs Parker's mother the last known case of smallpox in the world. It is ironic that when cases of variola major had occurred again, they had emanated not from a remote source in Africa or Asia, but from a well-equipped laboratory in one of England's largest cities. As a consequence of this episode, much attention was paid to the problem of variola virus stocks in laboratories, a matter which actively interested many Member States at the Thirty-second and Thirty-third World Health Assemblies in 1979 and 1980 respectively (see Chapter 30).

Outbreak of Variola Minor in the Midlands and Wales, 1966

minor in England and Wales in 1966 was brought to the attention of the team of investigators. The first case in this earlier outbreak to be identified and reported to WHO, on 2 May 1966, was in an unvaccinated 17-year-old girl who had developed an influenza-like illness on 16 April. Four days later a rash appeared, and she was admitted on 25 April to the Moxley Infectious Diseases Hospital, Walsall, Lancashire, as a case of chickenpox. Four days after that, smallpox was suspected and the girl was admitted to a smallpox hospital on 29 April. The diagnosis was confirmed by the isolation of variola minor virus.

Investigation of the girl's family and associates led to the discovery of an additional 71 cases of variola minor in the Midlands and Wales between February and August 1966. Detailed inquiries held in 1966 had failed to establish the source of infection. However, 12 years later, the team of investigators headed by Professor R. A. Shooter carried out a retrospective examination of all available reports and correspondence concerning the 1966 outbreak (Shooter, 1980). The earliest case identified was in an unvaccinated 23-year-old photographer employed at the Medical School of the University of Birmingham. He had become ill on 18 February with fever, headache and backache and had developed a generalized rash 4 days later. During the first week of illness he had remained at home and when the rash had appeared he had returned to work. He denied having had any contact with a person exhibiting a rash similar to his or with any recent immigrants or travellers from abroad. He himself had never been outside the United Kingdom. The relevant feature disclosed during the Shooter investigation was that the photographer had worked in the same studio and darkroom of the Medical School of the University of Birmingham as those used by Mrs Parker.

Eleven days before the index case of the 1966 outbreak became ill, work was being carried out with variola minor virus in the Birmingham smallpox laboratory, on the floor below (see Plate 23.6). Thus the photographer might have been infected, 12 years earlier, by the same route as Mrs Parker; hence the inclusion of this outbreak in Table 23.11 as "suspected" laboratory-associated.

The photographer became ill between 4 and 20 March 1966; his fiancée, his parents and a schoolteacher were infected at a folk-dance evening, and a 72-year-old man during a visit to a public house. These secondary cases gave rise to 2 main chains of transmission. The first spread from the photographer's fiancée to members of a youth club in her town and from them to their families and associates. The other chain stemmed from the 72-year old man, who infected 2 of his grandchildren, who in turn infected their friends and families. The spread continued, and at least 25 persons had been infected before 29 April, when the diagnosis of smallpox was made in the 17-year-old girl mentioned earlier. By June, 47 smallpox cases had been reported in the heavily populated West Midlands. Subsequently, new foci of infection appeared in Wales and Lancashire, although no connection could be established between these outbreaks and those in the Midlands, probably because of missed cases wrongly diagnosed as chickenpox.

The last known case occurred in Salford, Lancashire, with onset on 9 July 1966. The patient concerned was discharged from the isolation hospital on 1 August, but in compliance with the International Sanitary Regulations England and Wales were not declared free of smallpox until 18 August of that year. The reaction of the public and the health authorities to this outbreak differed greatly from the response, described earlier, to importations of variola major into European countries. Many cases in the 1966 outbreak had been misdiagnosed as chickenpox, and even when the health authorities became involved, they had not been particularly diligent in searching for cases and isolating and vaccinating contacts. The possible origin of the outbreak was not elucidated until the striking resemblance of the occupation and place of work of the first case to those of the index case in the laboratory-associated outbreak in Birmingham in 1978 became apparent.

CONCLUSIONS

Smallpox importations into European countries emphasized the risk of infection to which professional staff and patients in hospitals and other medical institutions were exposed. Over half of all cases associated with importations were found in this group, whose protection by regular vaccination with potent vaccine could have reduced the number of cases very substantially. Nevertheless, the

majority of the outbreaks were effectively controlled by surveillance and containment, and smallpox importations caused few disastrous events in Europe.

The review of importations into south-western Asia, especially the epidemic in 1970–1972 that spread from Afghanistan into Iran, Iraq and the Syrian Arab Republic and eventually into Europe, demonstrates that poor surveillance, and especially the deliberate suppression of reports of the disease, had extremely serious consequences both for the countries concerned and for their neighbours.

For most of the period after 1950, the Indian subcontinent was the major source from which smallpox was occasionally transferred to the countries of Europe, especially the United Kingdom and the Federal Republic of Germany, and to non-endemic countries in Asia. The majority of importations into Europe were due to Europeans returning home after travelling in the Indian subcontinent. In spite of the large volume of air traffic between the Indian subcontinent and the USA during this period, there were no importations into the latter country, possibly because of the better vaccination status and stricter enforcement of health regulations in the USA than in Europe.

As countries in Africa and South America became free of smallpox, they experienced importations mainly from one country in each of these continents with a large population and extensive endemic foci, which became the major exporter of smallpox to its neighbours—namely, Ethiopia in Africa and Brazil in South America.

The number of diagnosed laboratory-associated outbreaks was remarkably small, probably because of the high level of vaccination among laboratory staff. However, the last tragic incident in Birmingham emphasized the need for close supervision of variola virus stocks during the period following eradication.

INTRODUCTION

On 8 May 1980 delegates to the Thirty-third World Health Assembly, representing all 155 Member States of the World Health Organization, unanimously accepted the conclusions of the Global Commission for the Certification of Smallpox Eradication (World Health Organization, 1980), namely that:

(1) Smallpox eradication had been achieved throughout the world.

(2) There was no evidence that smallpox would return as an endemic disease.

The first conclusion was based on the findings of a series of independent international assessments, undertaken under WHO's auspices, of the efficacy of smallpox eradication programmes and surveillance in countries throughout the world, especially those in which smallpox had been endemic in 1967 and others at special risk. These activities constituted the programme for the "certification" of smallpox eradication. The second conclusion was founded on epidemiological investigations and research studies carried out during the course of the Intensified Smallpox Eradication Programme and summarized in Chapter 30.

Certification of the eradication of smallpox was possible because the virus had no animal reservoir, subclinical infections were rare and did not result in subsequent transmission, and latent infections did not occur. Just as the strategies and tactics used in the eradication of smallpox in different countries evolved over time (see Chapters 9 and 10), so also did the strategies adopted for certification increase in rigour and sophistication.

The present chapter describes these changing strategies and tactics, culminating with the declaration of global smallpox eradication at the World Health Assembly in 1980. The actual operations involved in the 79 countries in which special measures were taken are described in the following three chapters, which deal in turn with the activities of international commissions for the certification of smallpox eradication between 1973 and 1977 (Chapter 25), the varied activities outlined by the Consultation on the Worldwide Certification of Smallpox Eradication in 1977 and supervised by the Global Commission for the Certification of Smallpox Eradication (Chapter 26), and the final certification operations in the world's last stronghold of smallpox, the Horn of Africa, and in the world's most heavily populated country, China (Chapter 27).

HISTORICAL DEVELOPMENT OF THE CONCEPT OF CERTIFICATION

As outlined in Chapter 9, programmes to eradicate specified human diseases from particular localities, and eventually globally, date from the early years of the 20th century. Apart from Jenner's prophetic but hardly practical pronouncement in 1801 (see Chapter 6, Plate 6.8), the first explicit statement about the possible large-scale eradication of a human disease was a comment by Gorgas (1911a) on the eradication of yellow fever, a disease later (1915) nominated for global eradication by the International Health Commission of the Rockefeller Foundation (see Chapter 9). With the realization in the mid-1930s that there was an animal reservoir of the yellow fever virus (Soper, 1936), global eradication of that disease ceased to be a tenable objective. It was replaced by the idea of eradicating its urban vector, *Aedes aegypti*, from countries in the Americas, a concept that gained acceptance in 1942 partly because of the successful eradication of the imported African malaria vector, *Anopheles gambiae*, from Brazil in 1940 (Soper & Wilson, 1943). With these programmes of vector eradication came the need for some means of assessing whether the mosquito in question had indeed been eliminated from particular localities, regions and countries. The first "certification" procedures for *Aedes aegypti* eradication were developed by the Pan American Health Organization in 1954, revised in 1960, and issued in a definitive form in 1971 (Pan American Health Organization, 1971b). The criteria called for the absence of *Aedes aegypti* from a region for a period of at least 1 year, during which 3 surveys confirming the absence of the mosquito had been made. The final survey had to be carried out with the cooperation of the Pan American Health Organization, which provided the technical personnel needed for the task. If the survey confirmed the absence of *Aedes aegypti* mosquitos, the country was entered on the Pan American Health Organization's registry of countries considered free of this species.

When the malaria eradication programme was begun by WHO in 1955, it was realized that some mechanism was needed for convincing those outside the regions and coun-

tries concerned that they were free of the disease. In 1960, the Thirteenth World Health Assembly requested the Director-General of WHO "to establish an official register listing areas where malaria eradication had been achieved, after inspection and evaluation by a WHO evaluation team". The methodology and procedures for certification were laid down in 1961 (WHO Expert Committee on Malaria, 1961) and amplified in 1966 and 1974. The essential feature of the assessment procedure was that a regional WHO evaluation team would visit the area for which registration had been requested by a government, analyse the epidemiological and operational data collected during the consolidation phase (a period of 3 consecutive years, during which no evidence of transmission had been found and during the last two of which no general measures of anopheline control had been practised), and examine the organization, methodology and quality of the surveillance operations and the plans for their maintenance. Each WHO evaluation team included at least one member of the WHO Expert Committee on Malaria, together with staff from the relevant WHO regional office or short-term consultants appointed by it. National experts from the country being assessed were not included, but the team relied heavily on briefing by them. The team's report was first reviewed at the WHO regional office and later by the WHO Expert Committee on Malaria, and on the latter's recommendation the area was entered in the official register.

With the imminent eradication of smallpox from South America in 1971, it became necessary for WHO, through its Smallpox Eradication unit, to develop procedures for the assessment of the claim that smallpox had been eradicated from the Americas. The earlier eradication programmes had established the important principle that it was not possible for any independent authority, such as a team of WHO experts, acting entirely on its own, completely to confirm the status of a country or region in respect of *Aedes aegypti* or malaria for any definite period of time. Instead, it was necessary for it to depend on records compiled by the national authorities, the quality of which could then be determined by field appraisal undertaken by a team of experts from outside the country.

The global eradication of smallpox, if it could be achieved, would be uniquely different from that of *Aedes aegypti* or malaria since two valuable but expensive public health measures could then be abolished: routine vaccination of populations in all countries and the requirement that international travellers had to be vaccinated. For this to be possible, however, the world community of public health officials and medical scientists would have to be convinced that global eradication had really been achieved. Assessment of the situation in each country therefore needed to be carried out by teams of highly respected scientists and health officials, independent both of the national authorities of the country being assessed and of WHO, which might be regarded as having a vested interest in the results. Having established the goal of global eradication—never a realistic objective in the case either of *Aedes aegypti* or of malaria—the Smallpox Eradication unit saw that the independence of the assessment teams needed to be placed beyond all possible doubt.

With these requirements in mind, a strategy for the certification of smallpox eradication was developed by the unit. This consisted first of the preparation of detailed "country reports" by the national health authorities of the countries concerned, assisted by WHO staff and consultants. The reports outlined the procedures by which it was believed that smallpox had been eliminated and described the capability of the surveillance system to detect cases of suspected smallpox. When the Smallpox Eradication unit judged that these preparations had reached an appropriate stage, arrangements were made for a group of independent international experts, who constituted what came to be called an "international commission for the certification of smallpox eradication", to visit the country or countries concerned. Their task was to study the country report, make visits wherever they thought necessary, assess carefully the capability of the surveillance system to detect cases of smallpox should they have occurred, and make recommendations about public health activities relevant to smallpox. This was a new strategy designed to solve the novel problem of convincing the international community that smallpox, formerly a universal disease, had been eradicated from particular countries, regions, continents and finally the world. On the basis of experience of the best tactics for particular situations, the certification process was modified and improved, but the essential features—adequate preparations and detailed documentation of the evidence of freedom

from smallpox for at least 2 years, and the independence and authority of the certification team—remained unchanged throughout.

ERADICATION: DEFINITION AND CRITERIA

To understand the way in which certification of smallpox eradication evolved, it is necessary to examine the definition of, and criteria for, eradication developed in 1967 by the WHO Scientific Group on Smallpox Eradication (1968) and ratified and slightly elaborated in 1971 by the WHO Expert Committee on Smallpox Eradication (1972).

From the time of WHO's foundation in 1948, the control of smallpox had been a matter of concern both to the World Health Assembly and to the WHO Secretariat. The concept of the global eradication of smallpox, as distinct from control within Member States, was first enunciated by WHO in 1958 and accepted as WHO policy by the Twelfth World Health Assembly in 1959 (see Chapter 9). The Intensified Smallpox Eradication Programme was launched in 1967 (see Chapter 10). Between these two dates, 1959 and 1967, the concept of the way in which eradication could be achieved underwent a very important change.

Definition in Terms of Vaccination Programmes (1962)

In 1962, in his report on smallpox eradication to the Fifteenth World Health Assembly (document A15/P&B/18; unpublished), the Director-General of WHO defined eradication by stating that: "From a practical viewpoint, countries in which smallpox has recently been persistently present may consider the disease to be eradicated when no cases of smallpox occur during the three years following the end of a satisfactory vaccination programme." In suggesting a period of 3 years, the Director-General was probably influenced by the use of this period in certification procedures for malaria eradication.

Definition in Terms of the Interruption of Transmission (1968–1980)

The first meeting of the WHO Expert Committee on Smallpox was held in Geneva in 1964. The WHO smallpox eradication programme was discussed (WHO Expert Committee on Smallpox, 1964), but no attempt was made to define specific criteria for eradication. However, in 1967 a meeting of the WHO Scientific Group on Smallpox Eradication (1968) specified the basic definition of, and the criteria for, eradication. Meeting in 1971, with 4 years' experience of the Intensified Smallpox Eradication Programme, the WHO Expert Committee on Smallpox Eradication (1972) confirmed both the definition and the criteria, although it stated them in slightly different terms.

The definition produced by the Expert Committee was subsequently endorsed without change by the Consultation on the Worldwide Certification of Smallpox Eradication in 1977 and by successive meetings of the Global Commission for the Certification of Smallpox Eradication in 1978 and 1979. Because they were formulated later, we shall use the 1971 definition of the criteria for eradication (WHO Expert Committee on Smallpox Eradication, 1972) as the basis for discussion:

> "Eradication of smallpox is defined as the elimination of clinical illness caused by variola virus. Since smallpox is transferred direct from man to man in a continuing chain of transmission, and since there is no human carrier state of epidemiological importance and no recognized animal reservoir of the disease, the absence of clinically apparent cases in man may be assumed to signify the absence of naturally occurring smallpox.
>
> "In order to be able to confirm the interruption of smallpox transmission an effective surveillance is needed so that clinical infections can be detected. Recent experience indicates that, in all countries with a reasonably effective surveillance programme, residual foci can be detected within 12 months of apparent interruption. Thus, in countries with active surveillance programmes, at least 2 years should have elapsed after the last known case—excluding well-defined and contained importations—before it is considered probable that smallpox transmission has been interrupted.
>
> "Because of the ease with which smallpox can be transmitted from one country to another, the concept of 'eradication' can apply only to a continent. Thus, although smallpox may be considered to have been eradicated from certain continents, it cannot yet be said to have been eradicated from Africa, Asia, or South America.
>
> "On the basis of epidemiological and technical considerations and the considerable experience

acquired so far, the Committee believes that the global eradication of smallpox, as defined above, is possible."

Since the foregoing formulation of "eradication" became the basis of the whole certification process, several aspects of it warrant comment and explanation.

Disease or virus

In the first paragraph the phrase "Eradication of smallpox is defined as the elimination of clinical illness..." provides the most important criterion; this could be used because, as already pointed out, there was no animal reservoir, subclinical infections were rare and epidemiologically unimportant, and latent infections did not occur. It was therefore logical to base a certification programme on the results of campaigns of active surveillance, which could detect only manifest disease. It would be impossible to use such a criterion for diseases such as plague or tuberculosis.

Furthermore, this criterion took into account the difference between interrupting person-to-person transmission of smallpox and supplementing this by the destruction of all variola virus stocks, as some experts had urged. Achievement of the interruption of human transmission throughout the world was a practical and verifiable goal; ensuring the destruction of all variola virus stocks, in the deep-freeze cabinets of every laboratory in every country of the world, was impracticable and unenforceable.

Period of freedom from smallpox

In the second paragraph, the stipulation that "... in countries with active surveillance programmes, at least 2 years should have elapsed" before certification could be undertaken, proved to be a conservative but manageable criterion for determining the timing of certification activities, although the choice of a period of 2 years was an arbitrary one. It had been adopted by the 1967 meeting without much discussion, and by 1971 further experience of eradication programmes suggested that it was realistic. In all countries in which WHO-assisted programmes were implemented, the surveillance systems improved greatly during such programmes and, in the great majority of countries, no outbreaks of smallpox had occurred after transmission was thought to have been interrupted. There were, however, a few exceptions. In Brazil, Indonesia and Nigeria, outbreaks were discovered 10–34 weeks after transmission was thought to have been interrupted, but in no case was the stipulated period of 104 weeks even remotely approached. After these incidents, countries in which national eradication programmes were still in progress further strengthened their surveillance systems. The effectiveness of such systems was always evaluated by WHO before a date was fixed for the visit of an international commission.

In a practical sense, the reliability of certification was related to two factors – namely, the lapse of time since the last known case and the intensity of surveillance. If the intensive surveillance in operation during the eradication campaign had been maintained for 2 years thereafter, this period was more than long enough to judge whether or not eradication of the disease had been achieved. Where longer periods had elapsed, a less sensitive surveillance system was sufficient to detect the serial transmission of smallpox since many hundreds of cases would need to occur to maintain the chains of transmission. Because the supply of susceptible subjects would soon be exhausted, smallpox could not persist for prolonged periods in sparsely populated inaccessible regions; and in towns and cities, in which the population density was high enough to support continued transmission, large numbers of cases could not go unobserved. After eradication had been achieved in the Indian subcontinent, the Smallpox Eradication unit believed that, in countries in which active surveillance had been maintained after an energetic eradication campaign had been successfully completed, the interval could well be reduced from 2 years to 1. However, to make assurance doubly sure, it was decided to adhere to the earlier decision.

Importations and laboratory-associated outbreaks

The second paragraph of the definition of eradication excludes "well-defined and contained importations". Apart from importations by travellers from endemic countries into countries in which transmission had been interrupted, as occurred in Europe, the Americas, Africa and Asia (see Chapter 23), this exclusion was used by the Global Commission as a basis for its decision regarding the status of the last cases of smallpox in the world. This outbreak, which occurred in

Birmingham, England, in August September 1978, was associated with variola virus being used for experimental work in the virology laboratory of the University of Birmingham (see Chapter 23). The United Kingdom had been free of endemic smallpox since 1934, although there had been a number of importations from the Indian subcontinent after that date. This event, like the well-contained laboratory-associated outbreak in London in 1973, was regarded in the same manner as an importation into a country that had long been free of endemic smallpox. It was a tragic and potent reminder of the risks of working with variola virus with anything except the strictest containment facilities (see Chapter 30), but it was in no way a threat to the eradication programme.

The outbreaks in China in the mid-1960s, which resulted from the activities of variolators but were not reported to WHO until 1984 (see Chapter 27), could be regarded in the same light as a laboratory-associated outbreak.

Eradication as a "continental" concept

In the third paragraph, the statement that "the concept of 'eradication' can apply only to a continent" meant that the eradication of smallpox should not be certified when the endemic disease was absent in a single country or even a group of adjacent countries, but only on a continental or global basis. The practice developed of using the terms "interruption of transmission of smallpox" or "elimination of smallpox" to signify the achievement of smallpox-free status by individual countries.

In fact, the certification of eradication in an entire continent was possible only in the Americas. In Asia and Africa it proved impracticable to delay national certification until smallpox was eradicated throughout these continents. Thus in Asia, since there had not been a recorded importation of smallpox into Indonesia since 1949, certification was arranged in 1974, 2 years after the last reported case but before other Asian countries were smallpox-free. Certification of eradication in Africa posed special problems because of the persistence of smallpox in Ethiopia long after freedom from the disease had been achieved in western Africa. Certification activities were therefore not started in western Africa until 1976 and certification in other areas was undertaken in stages, both because of the shortage of personnel and time and because of the differing eradication programmes of African countries.

DEVELOPMENT OF STRATEGIES FOR CERTIFICATION

The occurrence of what was believed to be the last case of smallpox in Brazil (and thus in the Americas) in April 1971 forced the Smallpox Eradication unit to plan immediately the steps to be taken before eradication of smallpox from the Americas (in practice from South America) could be certified for acceptance by the international community, in 1973, 2 years after the last case. Two operations new to the unit needed to be planned and implemented: (1) the collection in South America of basic data for the assessment of the smallpox status of each country; and (2) the selection and mode of operation of the international assessment team, which in 1973 would examine the evidence collected during the preceding 2 years. The way in which these operations developed can best be appreciated by a consideration of certification procedures in 3 areas of the world—South America, Indonesia and western Africa.

South America

National preparations

In 1971 a general plan of work was outlined by agreement between WHO Headquarters and the Regional Office for the Americas. It called for specific reports on the smallpox status of all countries in South America except Chile, which, because of its geographical isolation, was judged to be at only slight risk of importations from Brazil or elsewhere, following its last case in 1954. WHO staff and consultants were assigned to visit the various countries, for most of which little information had previously been available, and were instructed to prepare detailed reports in line with requirements specified prior to their visits. While these assessments were being made, it became apparent that the surveillance systems in some of the countries were improving, and the data gathered became increasingly valuable as time progressed. Special programmes were undertaken for the

areas of greatest concern—e.g., the Amazon basin.

Because of the paucity of established health units in the Amazon basin and the inaccessibility of many of the areas of interest, special investigations were undertaken in parts of the basin within Bolivia, Colombia, Ecuador, Peru and Venezuela. The Brazilian parts of the basin were systematically and thoroughly searched by smallpox teams working with the malaria service; these teams progressed systematically through the entire area, vaccinating people wherever they were found and inquiring about smallpox. Other measures, outlined in Chapter 25, were also taken. Because only variola minor had been present in South America in recent decades, pockmark surveys would have been of little assistance, and none was attempted.

A mechanism of international assessment

Drawing primarily on the precedent of assessment of the malaria status of countries in which that disease was thought to be eradicated, the Smallpox Eradication unit proposed that the results of the reports provided by national authorities and WHO consultants should be evaluated by what came to be called an "International Commission for the Certification of Smallpox Eradication". The first such commission to be established, that for South America, suffered from defects in both its composition and its performance, which were largely remedied when the next one (for Indonesia) was set up and did not recur. In the first place, the Commission for South America included several persons who had been involved in the eradication programme in South America including as chairman, at the insistence of the Brazilian government, Dr Alfredo Bica, Secretary of Public Health of Brazil and formerly Director of the Communicable Diseases Division of the Pan American Sanitary Bureau/WHO Regional Office for the Americas. The Smallpox Eradication unit, for its part, failed to provide a detailed plan of action for the Commission. As a consequence, procedures and records and the history of smallpox eradication programmes in various countries were examined in a rather cursory and superficial manner. Finally, when the Commission framed its recommendations, it showed little appreciation of the significance of the eradication of smallpox from the Americas, calling for continued routine vaccination throughout the continent, as before. Fortunately for the reputation of the Commission, the Smallpox Eradication unit and WHO as a whole, subsequent history showed that smallpox had indeed been eradicated from South America.

Indonesia

The last case of smallpox in Indonesia occurred on 23 January 1972. Since there was no record of a case of smallpox having been introduced from the nearby endemic countries in Asia since 1949, it was judged appropriate to proceed with arrangements to certify eradication in Indonesia (as an isolated country) in 1974. In the light of the experience in South America, the methods of preparation for certification and for field activities by the members of the International Commission were strengthened.

National preparations

Like many other governments, that of Indonesia was not enthusiastic about continuing active surveillance after it was believed that smallpox had been eliminated and had to be persuaded of its importance. Then, sufficient data would need to be collected to satisfy the Commission that smallpox had been eradicated. Dr Paul Wehrle, an experienced smallpox consultant, therefore visited Indonesia in order both to identify weaknesses in the surveillance system, and to work with the government and WHO advisers to develop a plan which in his opinion would provide such data. Subsequently, health staff carried out intensive precertification activities, including an active search in high-risk areas and the collection of separate written declarations by the chiefs of tens of thousands of villages, stating that they had searched for smallpox throughout the area under their authority and had failed to find any cases.

Two factors which facilitated the preparations in Indonesia, compared with those in South America, were that pockmark surveys were useful because the prevailing variety of smallpox had been variola major, and that a reward was offered to anyone reporting a case of smallpox.

Selection of members of the International Commission

Profiting from the experience in South America, the Smallpox Eradication unit

modified the procedure for the selection of members of the International Commission, adopting an approach that was applied in the formation of all subsequent commissions. The major problem with the constitution of the South American Commission was that a national of the major country under examination, Brazil, was appointed chairman. This mistake was never repeated, but after a good deal of debate Dr Julie Sulianti Saroso, Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health, was made a member of the Indonesian Commission. Subsequently nationals of the country concerned were appointed to an international commission only in special circumstances—as in India, where this was necessary to enable the Commission to have access to Bhutan. Governments of neighbouring countries (Australia and Malaysia) were asked to nominate representatives, on the grounds that these countries were most at risk of importations should smallpox still be present in Indonesia so their nationals might be expected to be especially critical of the material presented. In general, the Smallpox Eradication unit took the view that the certification process would be best served by the appointment to each commission of individuals (whether from governments or universities) respected by their own governments so that their opinions on smallpox eradication would also be respected. Great care was exercised in the appointment of the chairman, and the precedent set in Indonesia, whereby Dr Wehrle visited the country during the preparatory period and subsequently acted as chairman of the International Commission, was followed in other countries in which certification was of great importance—e.g., Ethiopia and India. After eradication had been certified in Indonesia, the Smallpox Eradication unit tried to include in each new international commission one or two members who had already had experience with an earlier commission.

This Commission and all subsequent commissions were asked to reach one of two conclusions: either that they were satisfied that eradication had been achieved, or that they would be satisfied that eradication had been achieved if certain specific measures were undertaken. At the initial briefing session in Jakarta, the Australian and Malaysian members of the Commission were extremely doubtful whether eradication had been achieved in Indonesia. One observed that he had recently heard rumours of cases in northern Sumatra and the other believed that cases were almost certainly occurring in the slum areas of Jakarta itself. Such scepticism was welcomed by the Smallpox Eradication unit since, if these members were persuaded by the evidence presented in the course of the activities undertaken by the Commission itself, their conclusions would be more convincing to the international community.

A feature of the work of the Indonesian Commission was that Dr Sulianti Saroso, speaking as Director-General for the Control and Prevention of Communicable Diseases in the Indonesian Ministry of Health, concluded her opening remarks at the first session by saying that Indonesia was convinced that it was free of smallpox. Consequently, she invited members of the Commission to feel free to "go anywhere, with anyone, and make any inquiries" they chose to. This statement was honoured and provided an important precedent for other international commissions.

Western Africa

The last case of smallpox in western Africa occurred in Nigeria in May 1970 and United States bilateral assistance was terminated in 1972. At that time, however, smallpox was still endemic in many other parts of Africa and certification was therefore postponed. Smallpox was progressively eliminated from one African country after another, but the stipulation that eradication was a continental concept made the Smallpox Eradication unit reluctant to undertake certification in Africa. However, by 1975 endemic smallpox appeared to be limited to the Horn of Africa, and it was decided to initiate the certification process in the African continent in phased groups of countries so as to reduce logistic and administrative problems. The epidemiological situation in different parts of the African continent was nevertheless borne in mind. A group of 15 countries in western Africa was certified first because transmission had first been interrupted there and because they were furthest away from the areas in which smallpox was still endemic. Surveillance had been intensive in these countries for 2 years after the presumed elimination of smallpox, but had then very largely declined. Documentation on activities carried out since 1972 was comparatively sparse in most countries in the region. On the other hand, the long period of

time that had elapsed since smallpox had been seen in any country of western Africa provided good grounds for believing that the disease had been eliminated and had not been reintroduced. While notification systems were not as well developed as might have been desired, they had been capable of detecting cases of monkeypox in human beings in 1970 and succeeding years, as well as outbreaks of unusual and extremely serious diseases, such as Lassa fever or Ebola virus disease, which had come to the notice of local health staff within 6 months and of central health personnel within 12 months of their occurrence. If smallpox, especially variola major, had occurred in western Africa after 1970, it seemed reasonable to expect that the health staff of the country concerned would have known about it within a year. The 6-year interval since the last case thus provided a very large safety margin.

Because the Commission's visit took place so long after the last known case, many national smallpox eradication staff, as well as United States epidemiologists who had worked in the programme, had long since left and taken up other employment. Moreover, the Commission had to deal with 15 countries covering a vast area—almost two-thirds of the size of the USA—in which the health services infrastructure was much less well developed than in South America or Indonesia. To cope with this situation, WHO regional staff and consultants made frequent visits to these countries and two important changes were made in the procedure. First, preparations for certification were simplified, compared with the elaborate precertification searches and detailed documentation that were used in Indonesia and subsequently in the Indian subcontinent. Preparation of the country reports was based on a standardized questionnaire developed by the Smallpox Eradication unit; when completed, this provided essential information about the national eradication campaign. Secondly, a new method of active search was developed for use in all areas in which variola major had occurred—namely, large-scale facial pockmark surveys in children (see later in this chapter). It was reasoned that, if these surveys included all children up to 15 years of age, there would be some who had had smallpox when it was still endemic and would have pockmarks which the teams should detect. This served as an internal control in the survey, in that failure to detect any individuals with pockmarks would call into question the work of the team concerned. When children with pockmarks were detected, efforts were made to find out in which year they had contracted the disease that had caused the scarring. Such information was surprisingly easily obtained from most villagers. The age of the youngest pockmarked child also provided objective evidence as to when smallpox had last occurred.

Western Africa was certified to be free of smallpox on 15 April 1976, and in May 1976 the Twenty-ninth World Health Assembly, commenting for the first time on the certification process, endorsed "the procedures developed by the Director-General in the use of groups of international experts in the certification of eradication and [asked] for the full cooperation of all countries concerned in carrying out these procedures, so that countries throughout the world may have confidence that eradication has been achieved" (resolution WHA29.54). The successful carrying out of certification in western Africa provided the experience necessary for the staff of WHO and various national health authorities to proceed with certification in other areas of Africa as well as in south-western Asia.

Coordination of Certification Activities

In consultation with staff from the appropriate regional office and the national smallpox eradication programme, the Smallpox Eradication unit was responsible for deciding whether a particular country was ready to receive an international commission and, if so, when. This obviously required frequent visits by WHO smallpox eradication staff and, on occasion, by WHO consultants, to countries preparing for certification. Thus, even though smallpox had been eliminated from all countries except Somalia by the end of 1976, a number of WHO smallpox eradication staff were retained or recruited to assist in the certification process. From 1977 onwards, the Smallpox Eradication unit in Geneva consisted of Arita, who replaced Henderson after his departure in February 1977, Dr Joel G. Breman, an epidemiologist from the Center for Disease Control, Atlanta, USA, with extensive experience in smallpox and tropical diseases, Dr Alexander Gromyko, Dr James Tulloch and Mr John Wickett. Dr Celal Algan, Dr Ziaul Islam, Ježek, Dr Daniel Tarantola and Dr Lev Khodakevich assisted

the programme as WHO staff members in the regional offices.

Certification of smallpox eradication was not solely a technical matter but also involved many managerial and political questions. Ladnyi, who had acted as WHO intercountry smallpox adviser in eastern Africa from 1965 to 1971, returned to WHO Headquarters in 1976 as an Assistant Director-General and remained in this post until 1983. In this capacity he was able to help to solve some of the political problems that inevitably arose during the organization of certification activities.

The support provided by WHO staff and consultants was of two types. First, in a country in which an eradication campaign had been developed and executed with the active participation of WHO staff epidemiologists or consultants, some international personnel continued to work with national staff after eradication in organizing and assessing the active searches for unreported cases of smallpox, as well as in pockmark surveys or in the surveillance of chickenpox cases. The last-named activity was carried out in a number of countries, being of special importance where variola minor had been endemic, since this disease rarely left pockmarks and was readily confused with chickenpox. Secondly, in countries of western, central and southern Africa, in which the eradication campaign had been organized many years before certification and in which WHO or outside epidemiologists were not involved in continued surveillance, special arrangements were made to assign experienced WHO consultants or staff epidemiologists from either inside or outside the country to assist the health services in precertification activities.

In countries from which smallpox had recently been eradicated great interest was shown in certification, whereas in those in which the disease had been eliminated many years before, certification was not considered by the national health administrators to be of high priority. In some countries, national health officials who had taken part in the national smallpox eradication campaign had risen in the local health service hierarchy and were important in persuading senior government administrators of the importance of certification. The assignment of special WHO consultants and epidemiologists also helped to promote certification activities.

To persuade governments to mobilize adequate numbers of staff to prepare properly for certification, several approaches were used: (1) WHO regional office and Headquarters staff communicated with countries by letter or memorandum, emphasizing the importance of certification if the final achievement of smallpox eradication was to be accepted by the world community; (2) further encouragement was provided through coordination meetings with representatives of the countries concerned and through visits by staff of the Smallpox Eradication unit; and (3) WHO funds were frequently provided to cover fuel and vehicle repair costs and the living expenses of national surveillance teams.

J. KUMAZAWA, 1980

Plate 24.3. Joel G. Breman (b. 1936) was a medical officer with the WHO Smallpox Eradication unit, 1977–1980, during the most active part of the certification programme, and participated in monkeypox surveys in western and central Africa. He also worked as an epidemiologist in the eradication campaign in western Africa, 1967–1969.

NATIONAL PREPARATIONS FOR CERTIFICATION

The methodologies employed in national preparations for certification (precertification activities) differed according to the variety of smallpox present in the countries concerned and whether eradication was followed immediately by post-eradication surveillance and preparation for certification, or precertification activities were carried out many years after the occurrence of the last known case of smallpox. In most cases the final product was a "country report" that was

assessed by the appropriate international commission or the Global Commission.

The WHO Scientific Group on Smallpox Eradication (1968) had pointed out the need for an effective surveillance system capable of detecting and investigating suspected smallpox cases in order to demonstrate that smallpox transmission had been interrupted. Although all countries in which smallpox had been endemic continued some form of smallpox surveillance after the date of onset of what they considered to be the last case, its intensity differed substantially from country to country. In the last countries to be affected by smallpox, such as Bangladesh, Ethiopia, India and Somalia, the national programmes continued active post-eradication surveillance that was even more intensive than during the eradication campaign itself. The documentation in such countries was more complete than that available elsewhere and these countries could be visited by international commissions just 2 years after they had reported their last case. On the other hand, in most countries of Africa, special surveillance programmes had ceased long before certification was undertaken. In all cases, country reports covered the following items, which are described more fully later:

(1) a description of the routine reporting system;

(2) an account of special active searches, both in high-risk areas and throughout the country, including the methods of assessing the quality of the searches;

(3) the results of pockmark surveys, if appropriate;

(4) a description of chickenpox surveillance, wherever it was undertaken;

(5) the status of rumour registers, in which all suspected cases of smallpox were recorded, and sometimes also cases with fever and rash;

(6) a list of specimens sent for laboratory investigation and the test results;

(7) an account of the publicity given to the need for reporting smallpox cases, the rewards offered for finding a case (where appropriate), and public awareness of such rewards;

(8) documentation on other precertification activities.

Effectiveness of the Routine Reporting System

Each country provided data on the number and distribution of health units, including the number and types of hospitals, health centres or stations and peripheral health units, with maps showing their distribution throughout the country, and on the regularity and completeness with which they reported. The number of monthly or other periodic reports called for was compared with the number actually received. Data were also supplied on the reporting of cases of chickenpox, especially those with a fatal outcome. Finally, records of the action taken when a suspected smallpox case was reported were examined. During visits by WHO consultants in preparation for certification, action was taken to increase awareness among health personnel of the need to report immediately any cases where smallpox was suspected.

Active Searches for Unreported Cases

In most countries, specially organized mobile teams conducted field surveys in order to obtain up-to-date information regarding activities in connection with smallpox. The teams were organized and directed by the national smallpox eradication programme (when still operative), by those who had been involved in the eradication programme during its active phase, or by those responsible for the communicable diseases programme.

Special investigations were carried out in localities in which the risk of unreported smallpox was thought to be greatest. These included areas in which the last known outbreaks had been notified, those in which suspected smallpox cases or chickenpox deaths had been reported after the last known outbreak of smallpox, and those in which health coverage and communications were poor. Areas bordering on countries in which smallpox had recently been endemic, or in which there had been recent extensive population movements, were also included. Special attention was given to the villages in which the last known cases had occurred. Such investigations provided information as to the effectiveness of control measures and case detection during the concluding phase of the programme in the country. If it was found that all cases in an outbreak had been detected and containment was satisfactory, this increased confidence in the efficacy of the surveillance–containment activities.

A general survey was usually planned for cities, towns, and larger villages, since experience had shown that, if smallpox had per-

The Absence of Evidence is not Evidence of Absence

From the beginning of the global eradication programme, steps were taken to encourage the submission of all reports of smallpox in any country thought to be free of the disease and to investigate all such reports. There had always been serious doubts with smallpox, as with cholera, whether the absence of reported cases really meant that the disease was absent from the country concerned. Reports of suspected cases of smallpox in non-endemic countries had been queried by the Smallpox Eradication unit since the Intensified Smallpox Eradication Programme began, in order to determine definitely whether or not they were imported cases or whether they represented continuing endemic transmission. As the campaign progressed, such reports took on a greater significance and eventually in 1978 an international rumour register was established in Geneva (see Chapter 28). Rumours were very important. Thus, although no cases were officially reported from Iran after 1963, information that smallpox might be occurring there in 1971 was drawn to the attention of WHO by a WHO consultant as well as by a number of international staff working with other health agencies. Reports of imported cases in Somalia before 1976 were also received from embassies long before being notified officially by the government. Similarly, the serious outbreaks which occurred in the Salt Lake refugee camp in West Bengal in 1971 were unknown to the government and to WHO until reported by an American epidemiologist who had observed cases of smallpox in a television news film taken at the camp (see Chapter 15).

sisted in smaller villages or nomadic groups, it would ultimately reach the larger population centres. The localities to be visited were selected so as to include communities with health units and primary schools, since these attracted people from a large area who might report suspected cases. The usual objective was to reach a sufficient number of communities to ensure that at least 20–25% of the entire population of the country was covered by the survey.

In the countries which were the last to become free of smallpox—Bangladesh, Ethiopia, India, Nepal, Pakistan and Somalia—country-wide house-to-house searches to discover possible cases were conducted on several occasions. A large number of health staff, volunteers and temporarily recruited searchers were deployed so that the search could be completed within a period of 3–4 weeks.

Search teams were organized in order to obtain information about cases of smallpox and chickenpox, actual or rumoured, in primary schools, health units, markets and other places at which people congregated, from nomadic and other migratory groups, and on some occasions from all households in selected villages or urban areas. Their training covered the following aspects:

(1) The status of smallpox eradication in the country, including details of the last outbreaks, suspected cases, and deaths from chickenpox, and an indication of particular localities requiring special investigations and field surveys.

(2) The characteristic features whereby facial pockmarks caused by smallpox could be distinguished from scars caused by other conditions. In this connection, it was emphasized that only persons with facial pockmarks caused by smallpox or suspected smallpox were to be investigated and the findings documented.

(3) Techniques for the epidemiological investigation of suspected cases, including the collection of specimens for laboratory investigation.

(4) Methods to be used in selecting the itinerary for field visits and the recording and reporting of data.

The organization of active searches in various countries is described in detail in subsequent chapters. One universal and important feature on which WHO consultants and staff preparing for certification insisted, however, was that the effectiveness of the searchers themselves should be properly assessed by follow-up staff whose task was to

Plate 24.4. Facial pockmarks. **A**: Moderately severe in a Nigerian girl 7 years after an attack of smallpox. **B**: Severe, in an Afghan who had suffered from smallpox many years before.

evaluate the work done by visiting houses and villages selected at random from among those previously visited by the search teams. Special assessment teams directed by national programme staff were organized for this purpose and each month visited up to 10% of the places previously visited in the course of the searches.

Pockmark Surveys

Permanent facial pockmarks were found in about 70% of those who survived Asian variola major, the rates being slightly lower after infection with the somewhat less virulent forms of variola major virus found in some parts of Africa. Heavy diffuse facial scarring, readily observed at a distance of 5 metres, was seen on the faces of many victims, but others had lesser degrees of scarring that could be detected only by close inspection. Residual pockmarks, which tended to flatten out over time, were found less frequently among those infected during the first few years of life. The presence of 5 or more depressed facial scars 2 mm or more in diameter at the base was accepted as indicating a probable previous attack of smallpox (see Plate 24.4) and such persons were carefully interrogated to determine the time of occurrence of the illness and its cause. Contrary to what might be expected, it was found that, as mentioned before, most villagers generally remembered precisely when an individual had acquired the disease which caused the scars. Chickenpox also sometimes leaves residual scars, but it was unusual to find 5 or more scars on the face. Facial scarring or pitting resulting from other causes, such as burns and acne and other skin diseases, could usually be distinguished by experienced observers, but these cases too were investigated by interrogation and, where possible, by review of the medical records.

Variola minor, which was prevalent in Brazil and in several parts of Africa during the period of the Intensified Smallpox Eradication Programme, caused far less scarring. A careful follow-up study in Somalia (Ježek & Hardjotanojo, 1980) showed that 5 or more facial pockmarks could be detected in only 7% of patients seen 1 year after recovery. Pockmark surveys were of little use and were not carried out in countries such as Brazil, Ethiopia and Somalia, in which only variola minor had occurred in recent years. A number of African countries had experienced both

variola major and variola minor and in many the pockmark surveys were supplemented by surveillance of cases of chickenpox (see below).

When a pockmarked person was found, the dating of his illness became a matter of importance; if it was more recent than the last known case of smallpox, the adequacy of the surveillance system was open to question. The surveys concentrated on the examination of children, as their illnesses were usually more recent than those of adults. Failure to find pockmarks in any children born since the occurrence of the last known case in the country provided important evidence that transmission of variola major had been interrupted.

A widely varying incidence of pockmarks was observed in pockmark surveys carried out by national teams in 34 African and 5 Asian countries. A relatively high incidence was found in schoolchildren in some countries, particularly where large outbreaks of variola major had occurred a few years before transmission had been interrupted. However, when the date of illness of each case was carefully investigated, no children were found whose illness was more recent than the last reported case.

In many countries the members of the international commission also carried out pockmark surveys during their field visits. The prevalence of facial pockmarks which they observed was often higher than that recorded during the national surveys, since they tended to focus on high-risk areas, such as those in which the last known cases of smallpox had occurred.

Chickenpox Surveillance

Where variola minor was prevalent and residual pockmarks were uncommon, emphasis was placed on the surveillance of chickenpox cases, which were sometimes clinically confused with smallpox. It was thought that a surveillance system sensitive enough to detect a large proportion of chickenpox cases would, in all likelihood, detect smallpox, if it were present. Efforts were made to verify the diagnosis of a number of such cases, especially those which were severe or fatal, by the examination of scabs or vesicular fluid in the laboratories of WHO collaborating centres.

Both the fixed and the mobile health units sought to discover and report chickenpox cases. In addition, some countries introduced the notification of chickenpox during the post-eradication period where previously this had not been required. The taking of specimens from at least one case in each outbreak, especially if a death had occurred, was requested and specimens were also obtained from patients who had not been vaccinated against smallpox and those with an extensive rash involving the palms and soles. In a few countries, a small reward was offered for the discovery of the first case of chickenpox in a previously unrecognized outbreak.

Rumour Register

In 1974, a new device was introduced in India—a register in which all cases of smallpox were recorded, and later all cases of fever with rash. It was particularly effective in countries in which smallpox was then endemic—namely, certain Asian countries and in the Horn of Africa. Rumour registers (Plate 24.5) were maintained at both national and lower levels. At the regional level, health officials kept a record of all patients, including the full name, age, sex, village or locality, presence or absence of a vaccination scar, date, and data relevant to the illness. All cases entered in the register were investigated by qualified personnel. If there was any doubt regarding the diagnosis, a consultation was sought through the national surveillance organization and specimens were collected. All the information supplied by the regions was recorded in national registers.

Specimens for Laboratory Diagnosis

Relatively few specimens were collected when smallpox was widespread because the diagnosis was usually obvious; if there was any doubt, cases were treated as smallpox. As the incidence fell to low levels, increasing numbers of specimens were taken and, as transmission came closer to being interrupted, specimens were collected from each suspected case.

In countries in which variola minor had been endemic, preparing for certification required the collection of large numbers of specimens from patients with chickenpox and with other types of fever with rash, and from other patients in whom smallpox was suspected. They were sought over a wide geographical area and especially in population

[a] Recorded by date of receipt in Geneva. Includes only specimens for which testing results were reported. Includes multiple specimens from the same individual if taken. Excludes serum, animal, variolation and other specimens associated with special studies.

[b] Of which positives for monkeypox by year numbered: 1970 (Zaire 1, Liberia 4, Sierra Leone 1), 1971 (Côte d'Ivoire 1, Nigeria 2), 1972(5), 1973(3), 1974(1), 1975(3), 1976(3), 1977(7), 1978 (Zaire 8, Benin 1), 1979 (Zaire 4, Cameroon 2).

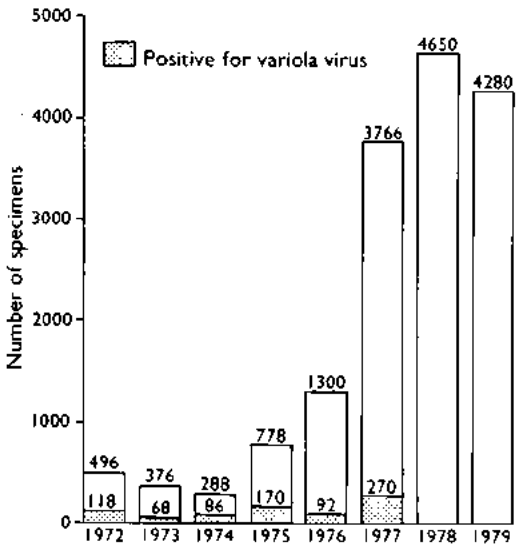

Fig. 24.1. Number of specimens collected from cases of smallpox, suspected smallpox, chickenpox, or suspected monkeypox and tested by WHO collaborating centres, 1972–1979.

groups and regions considered most likely to harbour smallpox. Specimens were forwarded to Geneva and from there sent either to the WHO collaborating centre in Atlanta or to that in Moscow. The specimens were shipped and tested with the least possible delay and those given priority were dealt with immediately, the results being cabled to the field.

Table 24.1 shows the national origin of specimens tested between 1969 and the end of 1979. The number tested rose from 288 in 1974 to over 4200 in 1978 and 1979 (Fig. 24.1). The percentage of specimens in which variola virus was found was relatively large during the earlier years, but none was positive after October 1977. About three-quarters of the specimens collected in 1978 and 1979 came from Ethiopia, Kenya and Somalia, which had reported their last cases (of variola minor) in 1976 and 1977 and were preparing for certification in 1979. Most specimens came from cases of chickenpox, the virus of which does not grow on the chorioallantoic membrane of the chick embryo. However, electron microscopy showed that many of them contained herpesvirus particles (varicella virus).

Publicity Campaigns and Rewards

Publicity campaigns aimed at encouraging people to report suspected cases and informing them that they would receive a reward if any of the cases turned out to be positive had been a feature of the eradication campaigns in the Indian subcontinent and the Horn of Africa and they continued until formal certification had occurred. In large urban centres, use was made of radio, newspapers, and television. In smaller villages and remote areas, leaflets and posters showing pictures of smallpox patients were more frequently used. Health unit personnel were encouraged to inquire about smallpox and other illnesses with fever and rash, and mobile teams repeatedly visited schools, markets and other places, where they informed the public about the disease, either in conversation or by loud hailer. In several countries so many posters and signs were fixed to walls that the smallpox teams were asked to desist because they were defacing the buildings.

The rewards were initially small but were gradually increased until they ultimately reached the sum of US$1000, offered by WHO in 1978 (Plates 24.6 and 24.7). In their contacts with schoolchildren or other segments of the population, active search teams showed the smallpox recognition card, asked people what the disease was, when cases had last been seen, and whether there were any reports or rumours of smallpox or chickenpox in the area. The teams also inquired whether people knew where to report if they did know of such a case and also whether they knew about the reward and its value. Since the value of the reward was changed at intervals, the replies provided an indication of how recently information had been received about the campaign.

The reward system was not readily accepted in all countries, since some national health authorities feared that it would establish a precedent with regard to the reporting of other diseases, although in fact no evidence of this was subsequently found. In western Africa, for example, the offering of rewards was discussed at the coordination meeting in 1975, during preparations for certification, but was finally rejected. However, rewards became an important method of surveillance, especially in Asian countries.

For smallpox transmission to have continued without detection when a large proportion of the population knew about the disease and the reward appeared highly unlikely. Thus, many countries conducted surveys to assess what proportion of the population knew about smallpox and where to report a

Rewards for Reporting Smallpox

The idea of offering a reward for information on cases that were proved to be smallpox originated in Indonesia, following the discovery that information on known smallpox cases had been suppressed by local officials because they feared punishment for failure to control the disease. It was taken up in most Asian countries in which smallpox was still endemic, and in some African countries. The reward was important in several areas of India, in which the reporting of cases by a health officer was taken as *prima facie* evidence that the vaccination campaign for which he was responsible had not been sufficiently thorough and he was punished for this by transfer or other means. By announcing that a reward would be given for reporting a case, the government made it quite clear that it wanted cases to be reported. Moreover, if health officers continued to suppress reports, lower-level staff anxious to receive the money bypassed them and reported the cases.

The size of the reward increased as the likelihood of finding a case of smallpox declined. The existence of a reward proved to be most effective in two ways: it increased the reporting of suspected cases of smallpox and, during active searches, questions aimed at discovering whether people knew of the reward proved an excellent method of assessing the effectiveness of search teams.

In April 1978, a coordination meeting was held in Nairobi, Kenya, to discuss preparations for the certification of the Horn of Africa. At that time 5 months had elapsed without a reported case of smallpox despite continuing surveillance in the Horn of Africa, as well as elsewhere in the world. One of the proposals discussed during the meeting was that a global WHO reward should be established to promote the reporting of smallpox. Reporters covering the meeting enthusiastically supported this idea. As a result of a recommendation from this meeting, the Thirty-first World Health Assembly in May 1978, in its resolution on smallpox (WHA31.54), requested the Director-General

"... to establish a reward of US$1000 for the first person who, in the period preceding final certification of global eradication, reports an active case of smallpox resulting from person-to-person transmission and confirmed by laboratory tests, in the belief that such a reward will strengthen worldwide vigilance for smallpox as well as national surveillance in priority countries".

Thereafter, the reward was widely publicized through radio, newspapers, television, etc., and a specially designed poster (Plate 24.7) was distributed to all countries. Immediately after the announcement of the award, many suspected cases were reported to WHO Headquarters, not only from developing but also from developed countries, including France and the USA. All proved to be false alarms. The reward was never collected.

case, or had heard about the reward. The surveys were often combined with active searches for cases of unreported smallpox. In the more populous and more recently endemic countries these campaigns reached a very high proportion of the people.

Documentation

Each country expecting to be visited by a commission was asked by WHO to prepare a comprehensive report ("country report") containing demographic data, information on its notification and surveillance system, a description of its smallpox eradication programme, information about the most recent outbreaks and data on precertification surveillance activities. These reports were submitted to the international commission at the beginning of its visit and provided the basic information needed for the planning of its field trips.

OPERATION OF INTERNATIONAL COMMISSIONS

The membership of all the international commissions is set out in Annex 24.1 and their operation is described in Chapters 25–27. General features of the method of selecting commission members, as developed after the certification of Indonesia, and their usual mode of operation, are outlined below.

28 JULY 1978 — 53rd YEAR — 53e ANNÉE — 28 JUILLET 1978

SMALLPOX SURVEILLANCE — SURVEILLANCE DE LA VARIOLE

REWARD US$ 1 000 — RÉCOMPENSE

A reward has been established by the Director-General of WHO for the first person who, in the period preceding final certification of global eradication, reports an active case of smallpox resulting from person-to-person transmission and confirmed by laboratory tests.

(Resolution WHA31.54, World Health Assembly, 1978)

Le Directeur général de l'OMS a institué une récompense à attribuer à la première personne qui, au cours de la période précédant la certification définitive de l'éradication mondiale, signalerait un cas actif de variole résultant de la transmission d'un être humain à l'autre et confirmé par des essais de laboratoire.

(Résolution WHA31.54, Assemblée mondiale de la Santé, 1978)

SMALLPOX-FREE WEEKS WORLDWIDE **39** SEMAINES SANS CAS DE VARIOLE DANS LE MONDE

LABORATORIES RETAINING VARIOLA VIRUS

With the interruption of transmission of smallpox in the world population, the only remaining possible source of infection will be laboratories still retaining stocks of the causative virus.

Accordingly, the Thirty-first World Health Assembly (1978) has requested that all laboratories retaining variola virus, except WHO Collaborating Centres, destroy their stocks or transfer them to a WHO Collaborating Centre. Of at least 76 laboratories identified by WHO to have variola virus since all countries and areas were polled from 1975 to 1977, 57 had voluntarily transferred or destroyed their strains by the end of 1977. In 1978 five additional laboratories have disposed of their strains.

Instituto Adolfo Lutz, São Paulo (Brazil)
Laboratoire national de la Sante publique, Paris (France)
Microbiological Research Establishment, Porton Down, Salisbury (United Kingdom)
Virus Instituto Salud Pública, Lima (Peru)
Walter Reed Army Institute of Research, Washington (USA)

Currently there are at least 14 laboratories with variola virus *(Table 1)*. China reports that more than one laboratory has this virus.

Security measures for such laboratories were recommended by a "Workshop Meeting on Safety Measures in Laboratories Retaining Variola Virus", convened by WHO in August 1977. With continued cooperation the number of laboratories retaining variola virus will be further reduced to not more than four WHO Collaborating Centres by 1980.

LABORATOIRES DÉTENANT ENCORE DU VIRUS VARIOLIQUE

Avec l'arrêt de la transmission de la variole dans la population mondiale, la seule source possible d'infection sera constituée par les laboratoires détenant encore des stocks de virus pathogène.

Aussi la Trente et Unième Assemblée mondiale de la Santé (1978) a-t-elle demandé à tous les laboratoires, autres que les centres collaborateurs de l'OMS, détenant du virus variolique de détruire leurs stocks ou de les transférer à un centre collaborateur. Sur au moins 76 laboratoires identifiés par l'OMS comme détenant du virus variolique depuis l'enquête conduite de 1975 à 1977 sur tous les pays et circonscriptions, 57 avaient volontairement transféré ou détruit leurs souches à la fin de 1977. En 1978, cinq autres laboratoires se sont défaits de leurs souches, soit:

Instituto Adolfo Lutz, São Paulo (Brésil)
Laboratoire national de la Sante publique, Paris (France)
Microbiological Research Establishment, Porton Down, Salisbury (Royaume-Uni)
Virus Instituto Salud Publica, Lima (Pérou)
Walter Reed Army Institute of Research, Washington (EUA)

Actuellement, il existe au moins 14 laboratoires qui possèdent du virus variolique *(Tableau 1)*. La Chine signale que plus d'un laboratoire de ce pays détient le virus en question.

Un atelier sur les mesures de sécurité à appliquer dans les laboratoires conservant des stocks de virus variolique réuni par l'OMS en août 1977 a recommandé les mesures de sécurité à appliquer dans les laboratoires en cause. Grâce à un esprit de collaboration de toutes les parties, il n'y aura plus en 1980 que quatre laboratoires qui conserveront des stocks de virus variolique, il s'agira dans les quatre cas de centres collaborateurs de l'OMS.

Epidemiological notes contained in this number:

Adenovirus Infections, Legionnaire's Disease, *Neisseria gonorrhoeae*, Poliomyelitis Surveillance, Smallpox Surveillance, Surveillance of Animal Rabies, Surveillance of Nosocomial Infections, Viral Diseases Surveillance.

List of Newly Infected Areas, p. 228.

Informations épidémiologiques contenues dans ce numéro:

Infections à adénovirus, Maladie de l'*American Legion*, *Neisseria gonorrhoeae*, surveillance de la poliomyélite, surveillance de la rage animale, surveillance de la variole, surveillance des infections nosocomiales, surveillance des maladies à virus.

Liste des zones nouvellement infectées, p. 228.

Plate 24.6. The *Weekly epidemiological record* was used extensively to promote the certification activities by publishing pertinent information. The front page of the issue for 28 July 1978 announced the offer of a reward of US$1000 for reporting an active case of smallpox and recorded that 39 weeks had passed since the last case in the world. The front-page article reported on laboratories that had disposed of their stocks of variola virus; such stocks were by then considered the only possible remaining source of infection.

REWARD · RECOMPENSE
$1000
Smallpox Variole ОСПА Viruela Smittkoppor
The World Health Organization offers US $ 1000 to the first person reporting an active smallpox case resulting from human-to-human transmission and confirmed by laboratory tests. Valid until global eradication is certified.

Membership

The timing of the visits to the countries by international commissions and their membership were decided by WHO in the course of discussions with national health authorities. Individuals were selected who would be critical in their assessments and whose views as experts would be respected both nationally and internationally. Some of those selected were experts in communicable disease control, others in virology or health management. On each commission, one or two members were appointed from the countries most at risk of importation of smallpox from the country or countries to be certified. As time passed a deliberate effort was also made to include in the international commissions experts from as many different countries as possible, so that the nature and extent of the efforts made to document the interruption of transmission would be widely known. Special care was taken in the selection of the chairman. Apart from the first international commission, in South America, the chairman was not a national of any country under review and, after the certification of Indonesia, officials from the country concerned were, with few exceptions, excluded from the international commissions. Exceptions were made for the single group of experts who, as members of separate international commissions, certified Bangladesh and Burma respectively, by including a Burmese member in the commission assessing the adjacent country of Bangladesh and a Bangladeshi as a member of the commission assessing Burma. In addition, a senior Indian military medical officer was included in the Indian commission, so that visits could be made to areas to which foreigners did not have access at that time.

After the appointment of the Global Commission for the Certification of Smallpox Eradication early in 1978, its members served as chairmen or members of almost all of the international commissions. In this way members of the Global Commission became familiar with the certification process at the country and regional levels. In all, 76 experts from 48 countries served on international commissions (see Annex 24.1).

Mode of Operation

The principal aim of a commission's visit to a country was to evaluate the reliability of that country's report by interviewing health personnel and examining records at both central and peripheral levels, so as to ascertain whether smallpox transmission had been interrupted as claimed. It was recognized that no commission could expect to examine even a small proportion of the population of a country in order to confirm that none had smallpox. Moreover, if experts of the right calibre were to participate, it was appreciated that they would be unable to spend more than 3–4 weeks away from their normal place of work. The objective of an international commission was to assess the quality of the local surveillance programme and to determine whether cases of smallpox would have been detected if transmission had occurred during the preceding 2 years. In doing so, commission members themselves usually carried out their own, rather limited surveys.

In most instances preliminary visits by one or two of the commission's members (often

Plate 24.8. Holger B. Lundbeck (b. 1924), Director of the National Bacteriological Laboratory, Stockholm, participated in several international commissions for the certification of smallpox eradication and was an influential member of the Global Commission. He is shown here signing the scroll certifying eradication which is reproduced as the frontispiece of this book.

the chairman) were arranged by WHO so that they could examine the state of the documentation and recommend any additional measures which they thought were indicated.

After arrival in the country to be certified, the commission usually spent 2–3 days in the capital reviewing the country report. If several countries were involved, the commission selected a conveniently situated capital city for its initial meeting, during which it scrutinized all the country reports; it then divided up into several groups to visit individual countries, and finally reassembled to assess the findings and prepare a report. In each country, in order to visit as many areas as possible, the commissions usually divided themselves up into teams consisting of one or two members, the areas selected being those identified as having the least satisfactory documentation or as being at unusual risk. Members of the commission had both the right and the responsibility to decide exactly which areas, villages and health units they would visit each day. The teams travelled extensively in the field for 1–3 weeks before reconvening.

PROCEDURES FOR GLOBAL CERTIFICATION

By June 1977, international commissions had already visited or were preparing to visit all the previously endemic countries and countries at special risk. However, there were other countries in which there was a need to determine what measures should be taken in order to certify that the transmission of smallpox had been interrupted for at least 2 years. Furthermore, there were several countries—China, Democratic Kampuchea, Iran, Iraq, Madagascar, Namibia, South Africa, Southern Rhodesia (Zimbabwe), the Syrian Arab Republic, Thailand and Viet Nam—for which the staff of the Smallpox Eradication unit needed outside advice on how best to deal with the situation. Clearly, countries such as Madagascar and Thailand would not be expected to undertake the same kind of precertification activities as had been carried out in the countries of western Africa, yet they could not be ignored. Others, such as Democratic Kampuchea, Namibia, South Africa and Southern Rhodesia (Zimbabwe), were not readily accessible to WHO staff.

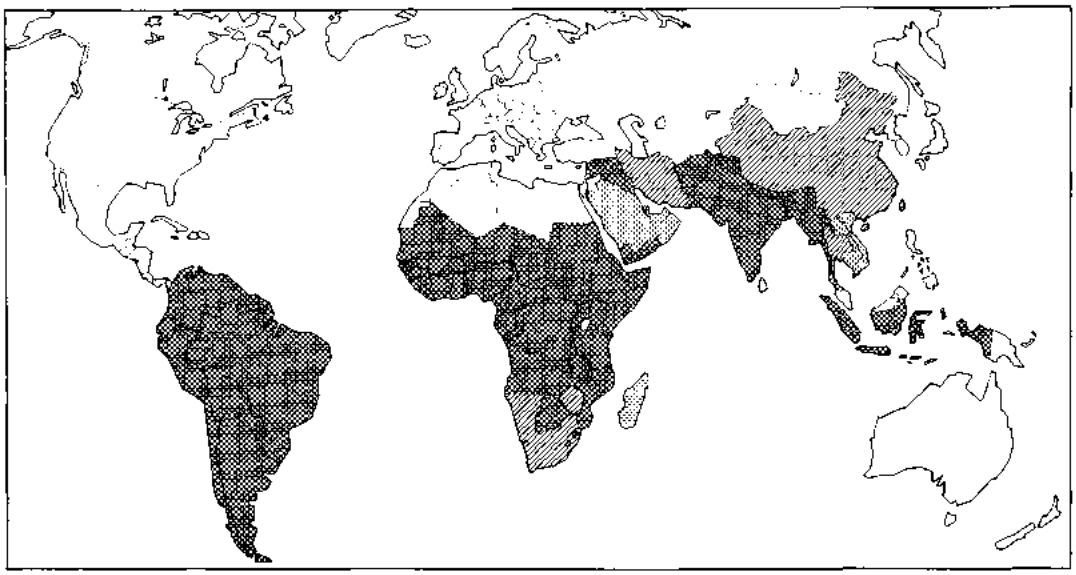
Another important matter was the international credibility of a claim that smallpox had been eradicated throughout the world. The problem was that, if the staff of the Smallpox Eradication unit themselves were to decide as to the data to be provided in confirmation of eradication, such a decision was open to criticism by government officials and health professionals around the world, since those responsible for a programme obviously have a stake in its success. However objective their judgements might be, other scientists would be justified in questioning that objectivity.

As has already been pointed out, the practical implications of the global eradication of smallpox were substantial. If the World Health Assembly were to accept that smallpox had been eradicated, this would mean that all preventive measures against the disease, including routine vaccination and international certificates of smallpox vaccination, could be abandoned. However, it was clear that these changes in well-established public health practices and the consequent financial savings would materialize only if the international community confidently accepted the assertion that smallpox had indeed been eradicated, first from countries, regions and continents and, finally, from the world. To gain such acceptance would not be a simple matter, for disbelief in the feasibility of smallpox eradication was common throughout the duration of the Intensified Smallpox Eradication Programme.

Consultation on the Worldwide Certification of Smallpox Eradication

The practical solution to the problems described above was to set up a global commission of respected scientists which, as one of its functions, could advise WHO as to what data should be collected, for clearly this was a matter of judgement. Eventually, when such outside experts were fully satisfied that global eradication had been achieved, this conclusion would have been reached, not by WHO itself or by putting together the reports of a series of international commissions each dealing with one or a few countries, but by an international group of senior scientists and administrators capable of taking a global view of the problem.

To obtain advice on how best to achieve the certification of global eradication, the Director-General of WHO convened a consultation which was held in Geneva on 11–13



Category 1 – **Formal certification by international commissions** of experts visiting the countries concerned and assessing their smallpox-free status by examining records and making field visits to determine whether surveillance activities would have been adequate to detect a case of smallpox if one had occurred during the previous 2 years.

Category 2 – **Certification by the visit of selected experts** to verify and document the smallpox incidence since 1960, the last known outbreak and control measures employed, and procedures for handling suspected cases.

Category 3 – **Certification through submission of detailed country reports.**

Category 4 – **Official statements by countries** declaring their smallpox-free status during the previous 2 years and signed by government health authorities.

Fig. 24.2. Methodologies used for the certification of smallpox eradication in various categories of countries.

October 1977. The participants (Annex 24.2) included 17 experts on epidemiology, virology and public health administration from 15 countries: 3 from Africa, 3 from the Americas, 4 from Asia, 6 from Europe and 1 from Oceania. During the succeeding 2 years, most of the participants in the consultation served on the Global Commission for the Certification of Smallpox Eradication. Documentation for the meeting had been prepared by the staff of the Smallpox Eradication unit, and the consultation made important recommendations (WHO/SE/77.98) as to how certification should proceed so that the stage could be reached, as quickly as possible, at which it could be certified that smallpox had been eradicated globally. For this purpose, the countries of the world were divided into three categories; a fourth was subsequently added by the Global Commission (Fig. 24.2). The various categories are discussed below.

Category 1—Formal certification by international commissions

The most stringent assessment was required in countries in which smallpox was endemic at the inception of the Intensified Smallpox Eradication Programme in 1967, or had become endemic since then. For such countries, the consultation recommended that the established procedure of formal certification by designated international commissions should be carried out. In October 1977, when the consultation met, this formal certification had already been performed in South America (1973), Indonesia (1974), 15 countries in western Africa (1976),

Afghanistan and Pakistan (1976), 5 countries in south-eastern Asia (1977) and 9 countries in central Africa (1977) (see Plate 24.11). The additional countries scheduled for formal certification from November 1977 onwards were:

South-eastern Asia: Bangladesh and Burma (scheduled for November–December 1977).

South-eastern Africa: Malawi, Mozambique, the United Republic of Tanzania and Zambia (scheduled for March 1978).

Eastern-central Africa: Sudan and Uganda.

Southern Africa, group I: Angola, Botswana, Lesotho and Swaziland.

Southern Africa, group II: Namibia, South Africa and Southern Rhodesia (Zimbabwe). Because of political complexities (see Chapter 26) it was apparent by 1978 that it would be both difficult and time-consuming to organize the certification of these countries by international commissions. Instead they were investigated as set out for Category 2 countries (see below) and certified by the Global Commission.

The Horn of Africa and neighbouring countries: Democratic Yemen, Djibouti, Ethiopia, Kenya, Somalia and Yemen.

Category 2 — Certification by the visit of selected experts

The consultation considered that some countries in which smallpox was not endemic in 1967 required special consideration, short of a visit by an international commission, because of the inadequacy of surveillance and/or their proximity to areas in which smallpox had recently been endemic. For such countries, it was suggested that visits by international experts (subsequently Global Commission members or WHO consultants) and/or WHO epidemiologists should be arranged during 1978 in order to verify and document their smallpox eradication status. The countries in this category are discussed below.

China. Although it was widely believed that smallpox transmission had been interrupted in China in about 1960, the country did not become a member of WHO until 1972. Even as late as 1977, little information was available to WHO as to what had been achieved, or how, or when, except that smallpox had been eradicated in China in 1960 or thereabouts. Since it was the most populous country on earth, and one in which smallpox had been widespread for over 1800 years, the consultation believed that special investigations were needed to assure the international community that smallpox was no longer endemic there.

Iran, Iraq and the Syrian Arab Republic. Although endemic smallpox had been eliminated from these countries in 1963, 1959 and 1957 respectively, variola major had become established again in all of them between 1970 and 1972. Smallpox was first reintroduced into Iran from Afghanistan and subsequently spread into Iraq and the Syrian Arab Republic (see Chapter 23). Because of the extent and duration of the outbreak, the consultation suggested that each of these countries should be asked to submit a detailed report of its surveillance programme and smallpox eradication activities during at least the past 5 years, after which members of the consultation or its successor, the Global Commission, would visit each country to review the situation.

Thailand. Although smallpox had ceased to be endemic in Thailand in 1962, the good communications with Bangladesh and India indicated the need for special evaluation, particularly in the border area of Thailand, Burma and the Lao People's Democratic Republic, which was notoriously inaccessible.

Category 3—Certification through submission of detailed country reports

WHO was requested by the consultation to ask certain countries to provide detailed reports, including but not limited to data on the incidence of smallpox since 1960, an account of the last known outbreak and the control measures employed, and the method of approach to be adopted should a suspected case of smallpox be found. Several countries about which detailed information was not available to the Global Commission fell into this category and are discussed below.

Gulf States: Bahrain, Kuwait, Oman, Qatar, Saudi Arabia and the United Arab Emirates. These countries had been free of endemic smallpox since 1963 but had experienced sporadic importations up to 1971. The Secretariat-General for the Ministers of Health of the Arab States of the Gulf was asked to coordinate the preparation of special country reports from these States.

South-east Asian countries. Because fighting had been going on for so long, detailed information was lacking from Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. A special report was

also requested from China (Province of Taiwan).

Madagascar. Although the last reported case of smallpox in Madagascar occurred in 1934, rumours had reached the consultation of outbreaks of a disease that might have been smallpox. A special report was therefore requested.

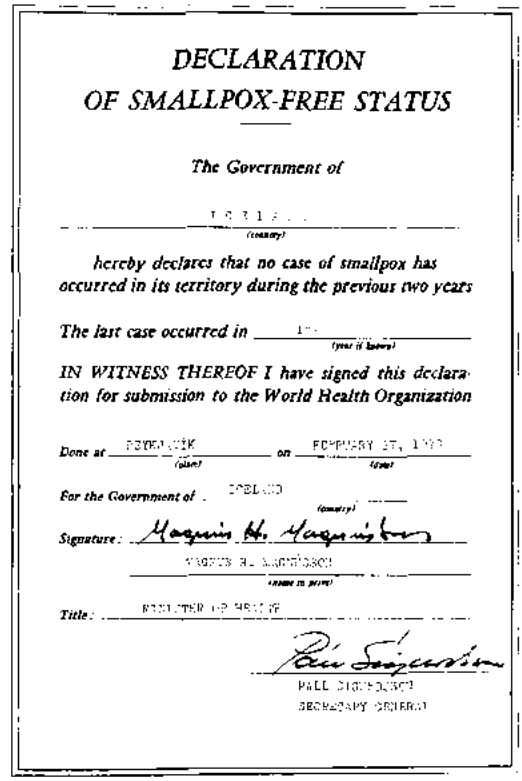
Category 4—Official statements by countries

In addition to these more stringent requirements, it was decided that every country and area should provide WHO with a signed statement that smallpox had not been present in that country or area during at least the preceding 2 years. Certification of freedom from smallpox by an international commission was considered to constitute such a statement.

Establishment and Responsibilities of the Global Commission

Finally, the consultation recommended that, since smallpox eradication was an unprecedented achievement, it should be promptly certified and appropriately recognized. For that reason, "... To assist in this effort and to provide authoritative endorsement, a formally constituted International Commission for the Global Certification of Smallpox Eradication (Global Commission) should be established by WHO to provide consultative assistance and verification of this event" (WHO/SE/77.98). Early in 1978 most of the participants in the consultation were designated by the Director-General of WHO as constituting the Global Commission for the Certification of Smallpox Eradication and at the same time a few new members were introduced (Annex 24.2; Plate 24.10).

Fenner, who had been Chairman of the consultation, was elected Chairman of the Global Commission, and acted in this capacity at the meetings in 1978 and 1979 (see below). Dr W. Koinange of Kenya was the Vice-Chairman at the 1977 consultation and Dr Jan Kostrzewski of Poland was Vice-Chairman at both meetings of the Global Commission. Arita, as Chief of the Smallpox Eradication unit, served as secretary both of the consultation and of the Global Commission. As has already been mentioned, Global Commission members were included in almost all of the 11 international commissions which met in 1978



DECLARATION
OF SMALLPOX-FREE STATUS

The Government of

ICELAND
(country)

hereby declares that no case of smallpox has occurred in its territory during the previous two years

The last case occurred in 1...
(year if known)

IN WITNESS THEREOF I have signed this declaration for submission to the World Health Organization

Done at REYKJAVIK (place) *on* FEBRUARY 27, 1...
(date)

For the Government of ICELAND (country)

Title: REGISTER OF BIRTHS

Páll Sigurðsson

PÁLL SIGURÐSSON
SECRETARY GENERAL

Plate 24.9. Official statements, like this one from Iceland, were received from 121 countries and territories declaring they had not had a case of smallpox for at least 2 years. They were accepted by the Global Commission for all countries other than the 79 where special measures were deemed necessary.

and 1979 to deal with specific geographical areas, an experience which further strengthened the assessment by the Global Commission of the progress of eradication as a whole.

The Global Commission met in Geneva in December 1978 and again in December 1979 to review certification activities in various countries in the four categories defined by the consultation and to consider other issues relevant to global certification. At the 1979 meeting, the Global Commission debated and approved its final report (World Health Organization, 1980), which was submitted to the Thirty-third World Health Assembly.

CHRONOLOGY OF CERTIFICATION

As has previously been noted, special measures had to be taken in 79 countries before the declaration of global smallpox eradication could be made. Between 1973 and 1979,

L. BIANCO

Plate 24.10. Participants at the meeting of the Global Commission for the Certification of Smallpox Eradication, 6–9 December 1979. *Left to right, front row:* Yemane Tekeste (Ethiopia), Z. Ježek (WHO), I. D. Ladnyi (WHO), I. Arita (WHO), Z. Islam (WHO), S. E. Woolnough (WHO), C. I. Sands (WHO); *second row:* **S. S. Marennikova (USSR), J. Azurin (Philippines), P. N. Burgasov (USSR), F. Fenner (Australia), J. Kostrzewski (Poland), D. A. Henderson (USA), W. Koinange (Kenya)**, Jiang Yutu (China); *third row:* A. I. Gromyko (WHO), **R. N. Basu (India), J. M. Aashi (Saudi Arabia), B. A. Rodrigues (Brazil), R. Netter (France), J. S. Moeti (Botswana), Kalisa Ruti (Zaire), P. N. Shrestha (Nepal)**, B. C. Dazo (WHO), M. C. de Souza (WHO), **Zhang Yihao (China)**, J. Magee (WHO); *back row:* G. Meiklejohn (USA), **P. F. Wehrle (USA)**, J. G. Breman (USA), **H. B. Lundbeck (Sweden), K. R. Dumbell (United Kingdom), I. Tagaya (Japan), A. Deria (Somalia)**, J. L. Tulloch (WHO), R. N. Evans (WHO), J. F. Wickett (WHO). The names of the Commission members are in bold type.

therefore, the status of smallpox in these countries was assessed by WHO and by independent groups convened by the WHO Secretariat (Fig. 24.3). The eradication of smallpox in 63 of these countries was certified by international commissions; the situation in the other 16 (No. 53–64, 66–67 and 78–79) was evaluated by other means.

Of the 79 countries concerned, 31 had been certified by international commissions between 1973 and 1976 (see Plate 24.11), but from 1977 onwards certification activities were much accelerated in view of the fact that global eradication was imminent. The 1977 Consultation on the Worldwide Certification of Smallpox Eradication and the establishment of a Global Commission substantially promoted the prompt completion of these activities, since these bodies were a source of advice and recommendations.

In May 1978, when 49 of the 79 countries had already been certified, a document entitled *Methodology for Preparation of Appropriate Data for the [30] Countries Remaining to be Certified Free of Smallpox* (SME/78.6) was prepared by the staff of the Smallpox Eradication unit. On the basis of experience gained with previous certifications, the document set out the minimum requirements for the country reports, guidelines and standard forms for field activities such as pockmark surveys and chickenpox surveillance, and procedures for the collection and dispatch of laboratory specimens. It was distributed to all countries still to be certified and proved to be extremely useful for both health planners and field workers in their preparations for certification.

Despite the existence of many politically insecure areas in the late 1970s and the large

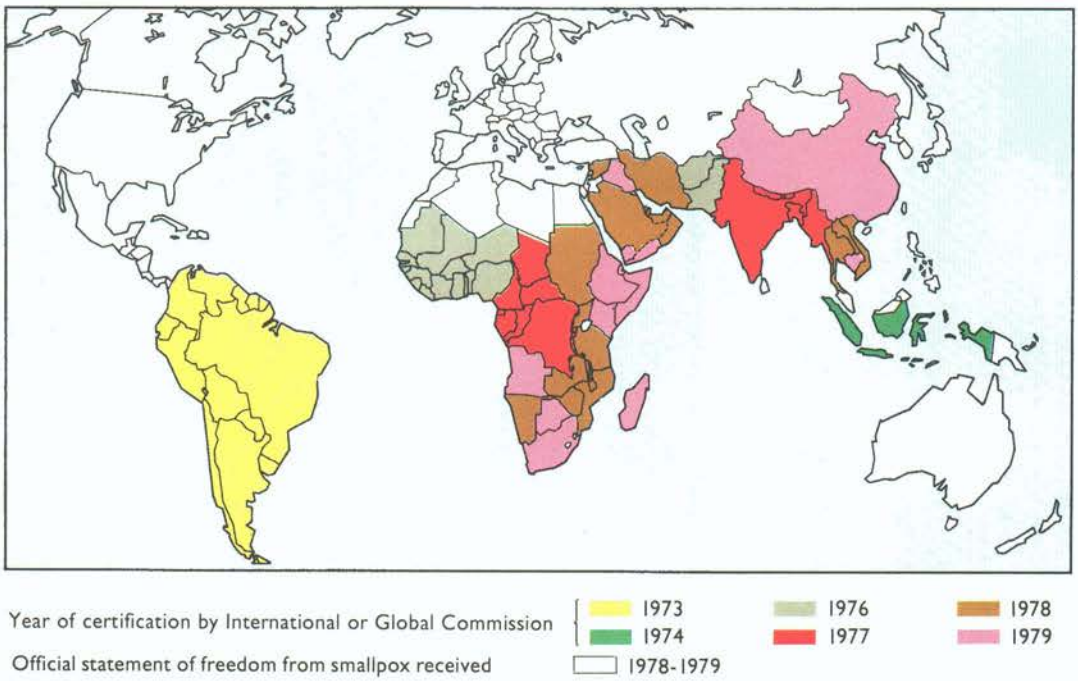

Plate 24.11. Chronological progress of certification in the 79 countries where special measures were necessary. All other countries provided an official statement that smallpox had not occurred in their country during the preceding 2 years.

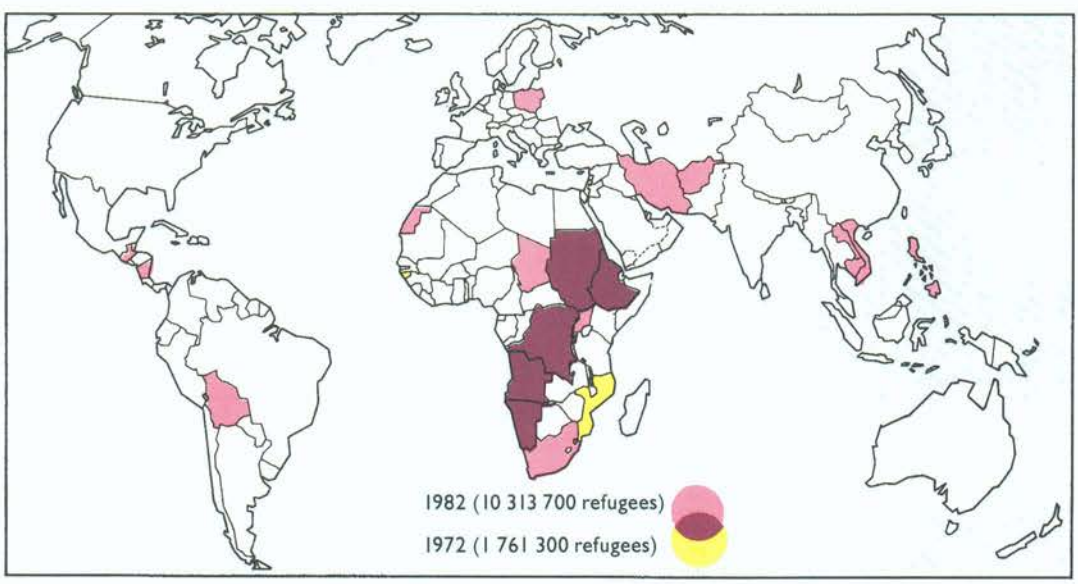

Plate 24.12. Smallpox eradication, and its certification between 1973 and 1979, were conducted when the numbers of refugees in the world were growing constantly. This map shows the country of origin of refugees assisted by the Office of the United Nations High Commissioner for Refugees in 1972 and in 1982 (the purple shading indicates countries common to both years). Although it clearly depicts the magnitude of this distressing problem, it does not show some areas in which, before or between those years, the conditions that caused people to become refugees also made eradication work particularly difficult — e.g., Nigeria (1967–1968), Bangladesh (1970–1971), and the Horn of Africa (1974–1978).

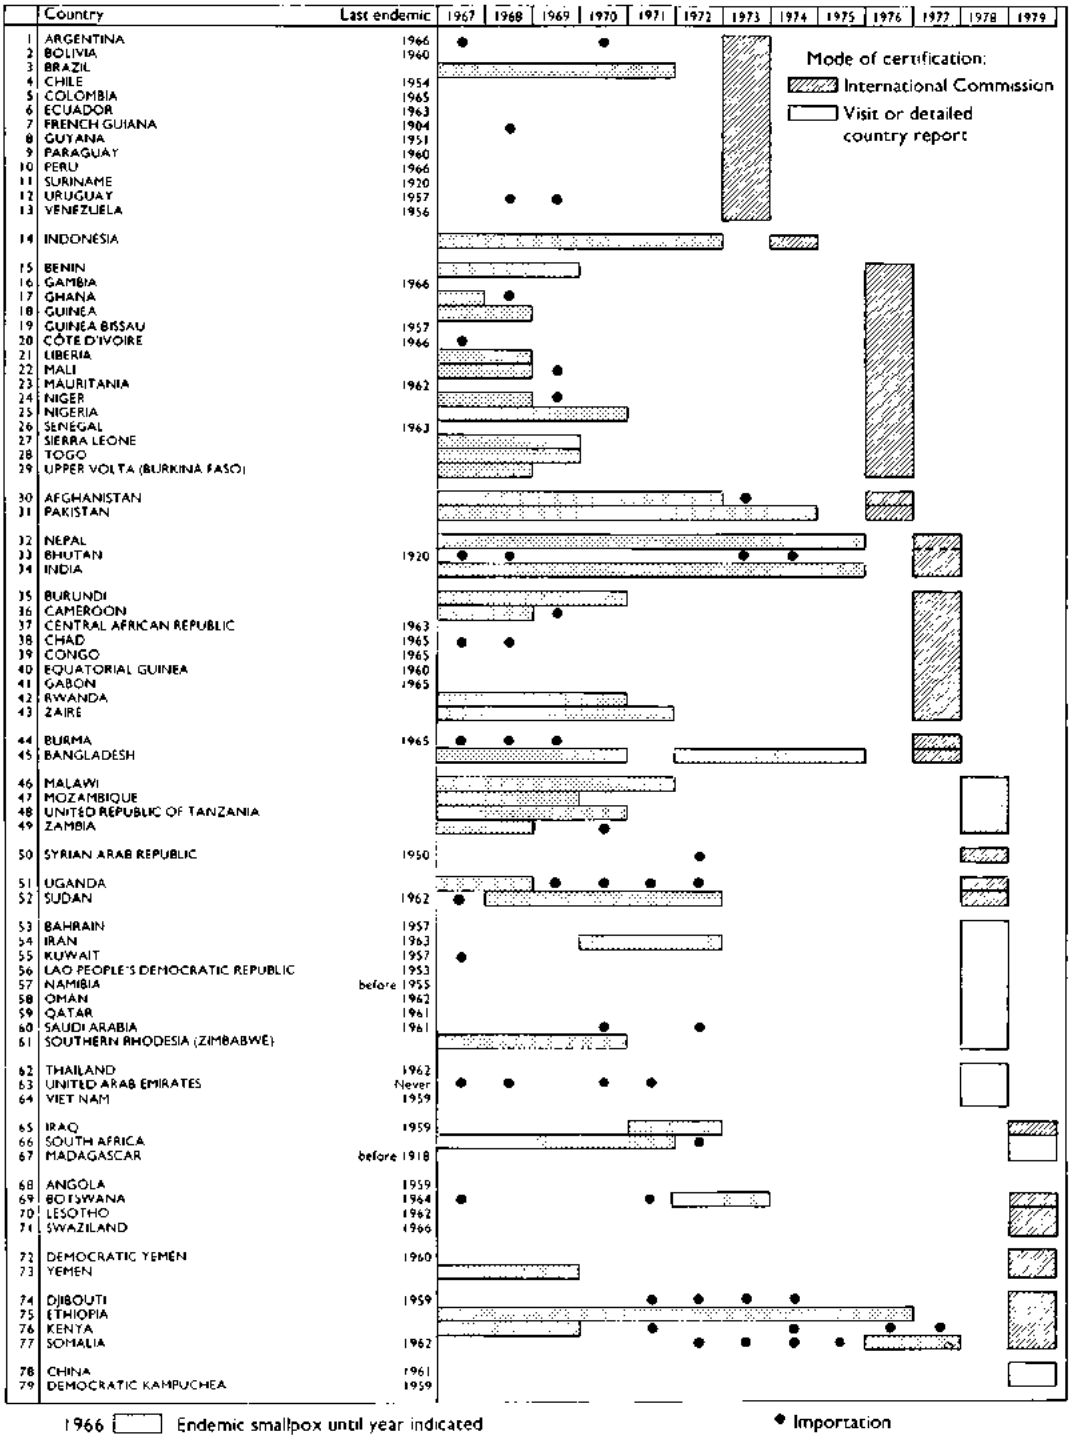

Fig. 24.3. Countries requiring special procedures for the certification of smallpox eradication. The year when the country ceased to be endemic, the year of the last known case, and the year and method of certification are also shown.

number of refugees, of whom there were ten times more in 1982 than in 1972 (see Plate 24.12), certification activities, including field visits by outside experts where necessary, proceeded surprisingly well, perhaps owing to the interest of the international community in this unprecedented event in the history of medicine.

Certification activities were strongly supported by a vigorous information campaign. From March 1978 to August 1980 a special information officer, Mr James Magee, was recruited to ensure good communications with major media agencies as well as medical periodicals. The goal of the information campaign was to reach beyond the scientific community with the news that:

(1) the world's last naturally occurring case of endemic smallpox had been found in Somalia on 26 October 1977;
(2) this was being confirmed globally by certification procedures involving an intensive search for cases; and
(3) it was expected that, if all went well, the target date for the declaration of global eradication, 26 October 1979—i.e., 2 years after the case in Somalia—would be met.

The benefits of eradication to the international community were stressed, including the end of the misery caused by this disease throughout human history and the enormous financial savings to the public health sector with the universal discontinuation of smallpox vaccination and associated control measures. Those with doubts were encouraged to speak out well in advance of the final global certification and countries were urged to change their legislation on smallpox vaccination at an early date.

The last certification activities by international commissions took place in October 1979 in the Horn of Africa—Djibouti, Ethiopia, Kenya, and Somalia, where, as has just been mentioned, the world's last case of endemic smallpox was discovered in October 1977. The 4 commissions that visited the countries of the Horn of Africa in October 1979 subsequently met in combined session in Nairobi, where they considered the region as a whole. On 26 October 1979, exactly 2 years after the onset of rash in the last case of endemic smallpox in the world, smallpox eradication was certified for Africa at a ceremony in which the Director-General of WHO and the directors of the Regional Offices for Africa and the Eastern Mediterranean participated.

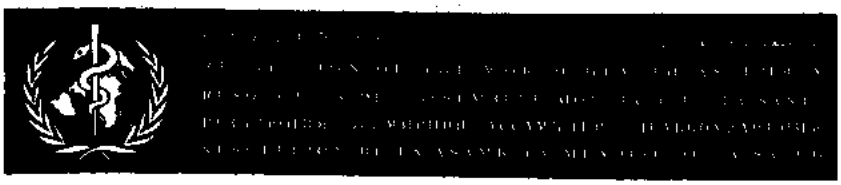
Plate 24.13. Gordon Meiklejohn (b. 1911), Professor of Medicine at the University of Colorado, Denver, USA. Worked with Dr A. R. Rao in Madras in the early 1960s and served as a WHO consultant on smallpox almost every year from the mid-1960s, and for a full year in 1968–1969. He was a member of several international commissions for the certification of smallpox eradication and was responsible for the preparation of the first draft of the Final Report of the Global Commission.

Certification of the Horn of Africa left only 2 countries uncertified, China and Democratic Kampuchea. However, in November 1979, a report prepared after the visit of a WHO team to China became available and the smallpox situation in Democratic Kampuchea was clarified. On 9 December 1979, at its last meeting in Geneva, the Global Commission agreed to certify smallpox eradication in these 2 countries.

By the end of 1979 all other countries—i.e., excluding those visited by the international commissions or certified by the Global Commission on the basis of other evidence—had submitted to WHO their signed declarations that no cases of smallpox had occurred during at least 2 years. The requirements for global certification recommended by the 1977 Consultation on the Worldwide Certification of Smallpox Eradication had thus been met.

DECLARATION OF THE GLOBAL ERADICATION OF SMALLPOX

The ultimate responsibility of the Global Commission, once it was satisfied that world-



The Thirty-third World Health Assembly, on this the 8th day of May 1980;

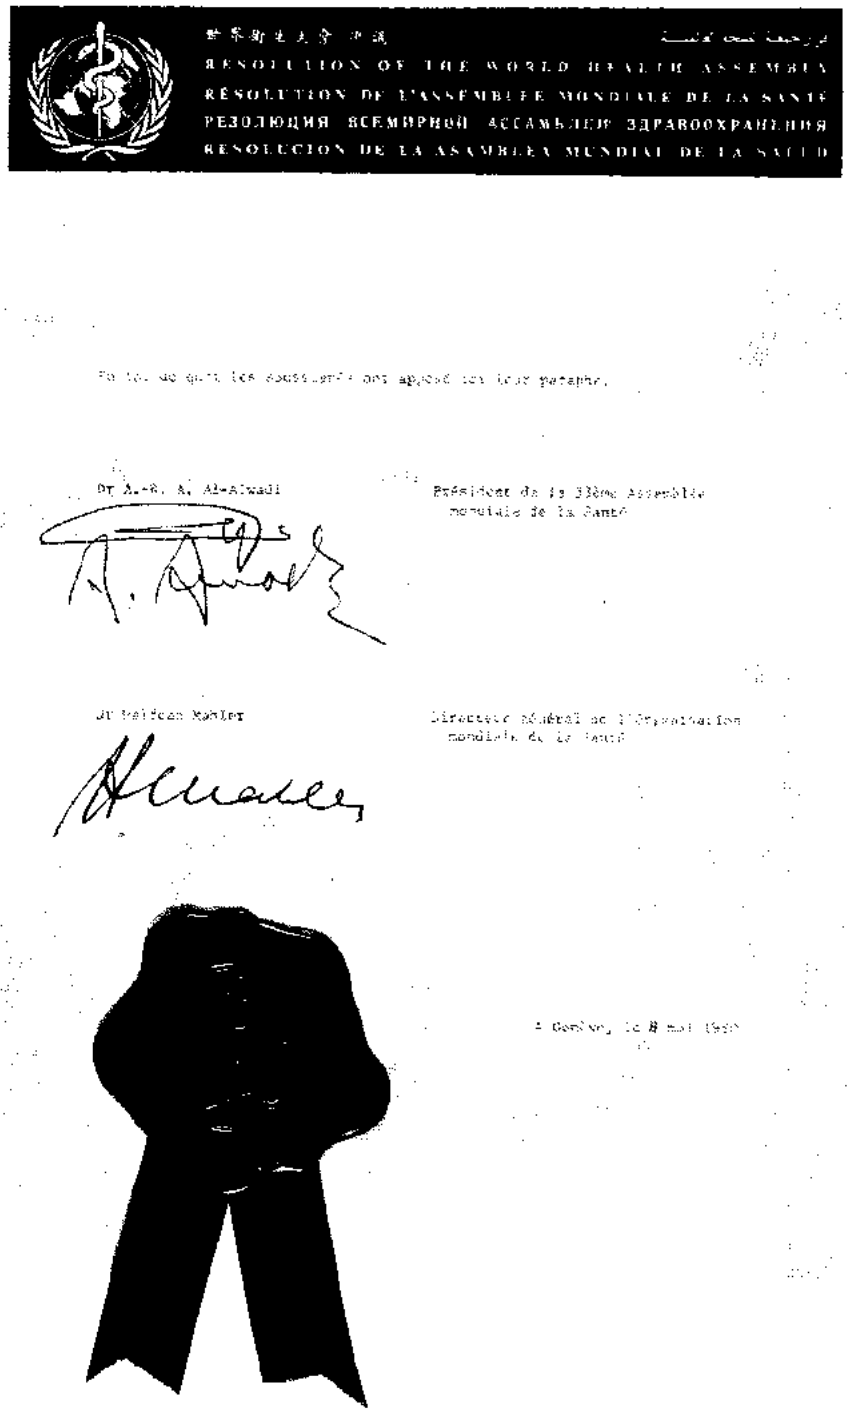
Having considered the developments and results of the global programme on smallpox eradication initiated by WHO in 1958 and intensified since 1967;

1. DECLARES SOLEMNLY THAT THE WORLD AND ALL ITS PEOPLES HAVE WON FREEDOM FROM SMALLPOX, WHICH WAS A MOST DEVASTATING DISEASE SWEEPING IN EPIDEMIC FORM THROUGH MANY COUNTRIES SINCE EARLIEST TIME, LEAVING DEATH, BLINDNESS AND DISFIGUREMENT IN ITS WAKE AND WHICH ONLY A DECADE AGO WAS RAMPANT IN AFRICA, ASIA AND SOUTH AMERICA;

2. EXPRESSES ITS DEEP GRATITUDE TO ALL NATIONS AND INDIVIDUALS WHO CONTRIBUTED TO THE SUCCESS OF THIS NOBLE AND HISTORIC ENDEAVOUR;

3. CALLS THIS UNPRECEDENTED ACHIEVEMENT IN THE HISTORY OF PUBLIC HEALTH TO THE ATTENTION OF ALL NATIONS, WHICH BY THEIR COLLECTIVE ACTION HAVE FREED MANKIND OF THIS ANCIENT SCOURGE AND, IN SO DOING, HAVE DEMONSTRATED HOW NATIONS WORKING TOGETHER IN A COMMON CAUSE MAY FURTHER HUMAN PROGRESS.

Plate 24.14. Resolution WHA33.3, the formal declaration of the eradication of smallpox, based on the report of the Global Commission to the Director-General of WHO, was adopted unanimously by the Thirty-third World Health Assembly on 8 May 1980.



RESOLUTION OF THE WORLD HEALTH ASSEMBLY
RÉSOLUTION DE L'ASSEMBLÉE MONDIALE DE LA SANTÉ
РЕЗОЛЮЦИЯ ВСЕМИРНОЙ АССАМБЛЕИ ЗДРАВООХРАНЕНИЯ
RESOLUCION DE LA ASAMBLEA MUNDIAL DE LA SALUD
Dr A.-R. A. Al-Awadi
Président de la 33ème Assemblée mondiale de la Santé
Dr Halfdan Mahler
Directeur général de l'Organisation mondiale de la Santé

Plate 24.15. As the President of the Thirty-third World Health Assembly, Dr A-R. A. Al-Awadi, and the Director-General of WHO, Dr Halfdan Mahler, signed resolution WHA33.3, the President remarked: "While doctors sign the death certificates of people, today we are signing the death certificate of a disease".

Plate 24.16. The ceremony of the declaration of global eradication of smallpox, on 8 May 1980, during the eighth plenary meeting of the Thirty-third World Health Assembly. **A:** Dr Frank Fenner (inset), Chairman of the Global Commission, addressed the Assembly and handed to the President the scroll that had been signed by the members of the Commission (see frontispiece). **B:** The President of the Assembly, Dr A-R. A. Al-Awadi, signing resolution WHA33.3, with the Director-General of WHO, Dr Halfdan Mahler, looking on.

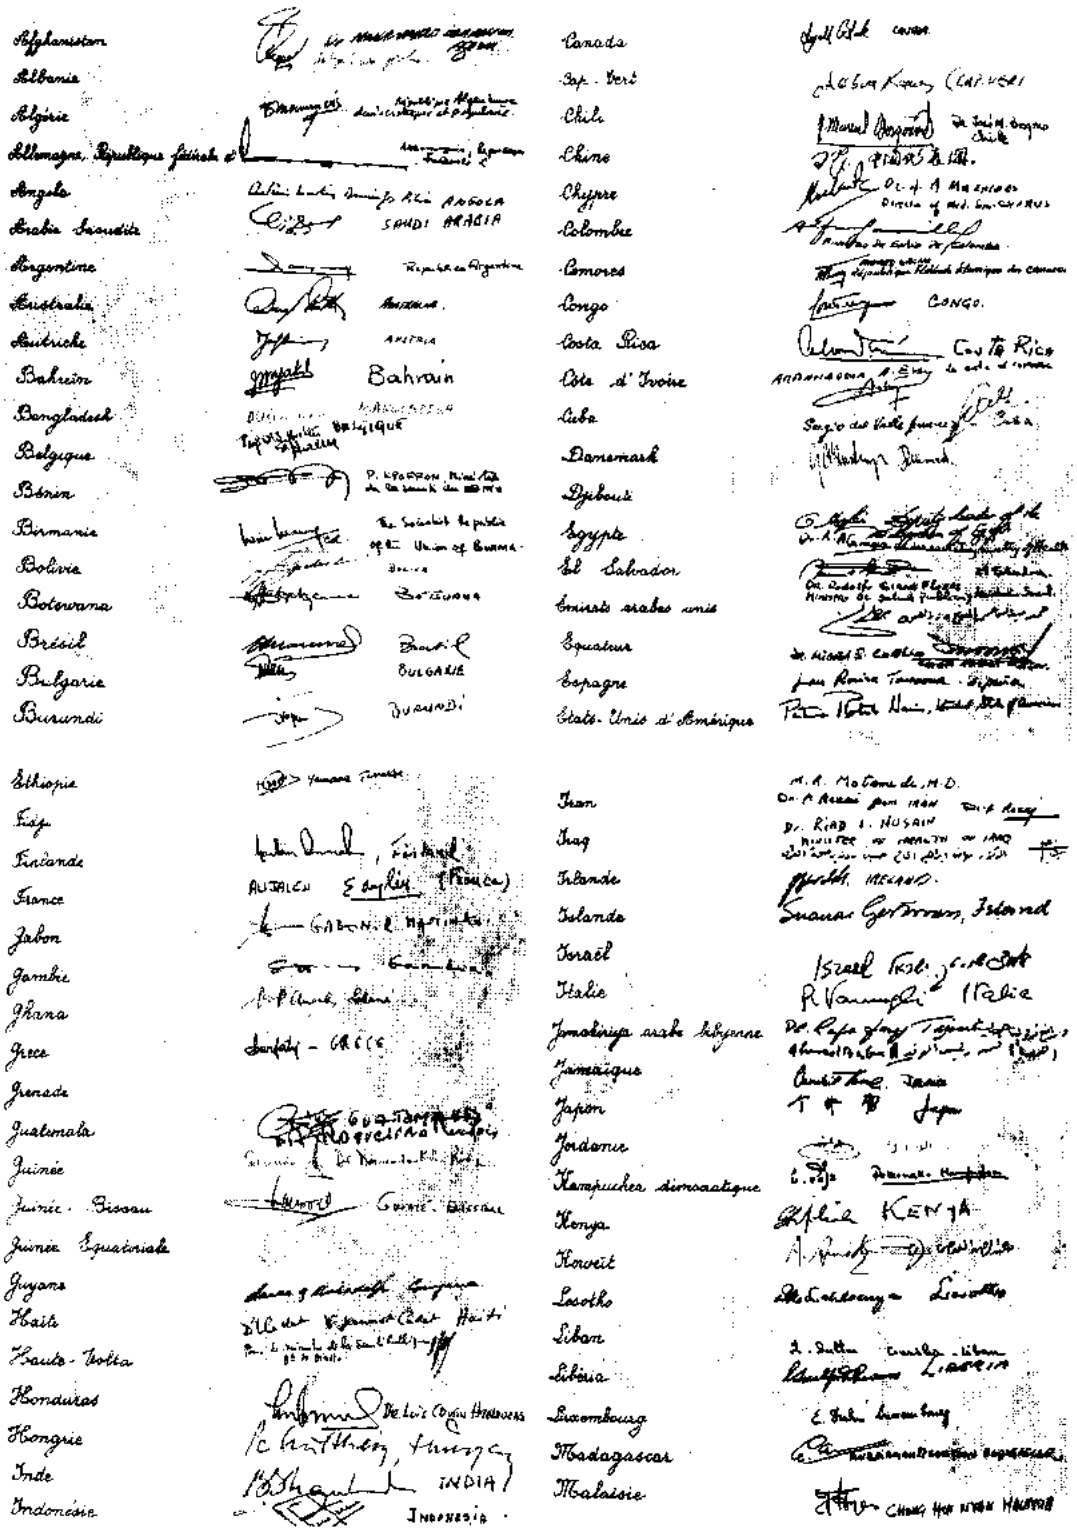


Plate 24.17. Signatures of the delegates of Member States, from Afghanistan to Malaysia, appended to resolution WHA33.3.

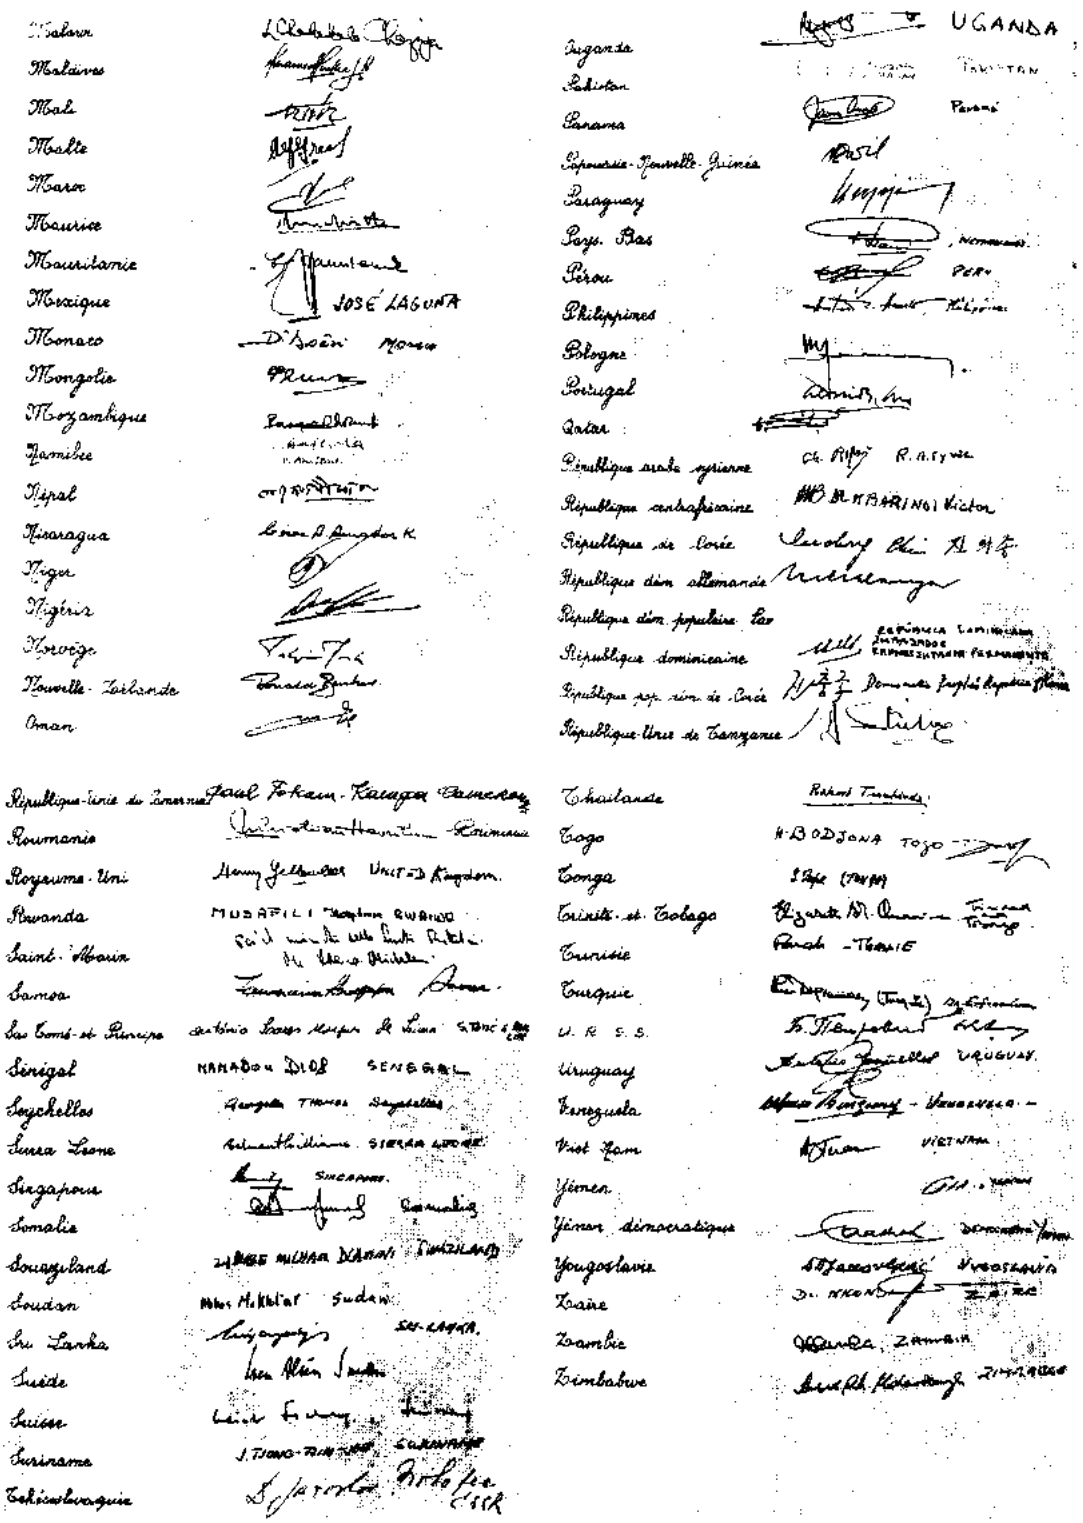

Plate 24.18. Signatures of the delegates of Member States, from Malawi to Zimbabwe, appended to resolution WHA33.3.

wide eradication of smallpox had been achieved, was to document the reasons for its decision in a way that would allow the World Health Assembly to declare that smallpox had been eradicated. In addition, it was important that a post-eradication strategy should be planned and machinery developed to implement it.

During 1979, with the help of Dr Gordon Meiklejohn, a WHO consultant, the Smallpox Eradication unit drafted a report for consideration by the Global Commission. This was reviewed in detail by the 12 members of the Global Commission present in Nairobi in October 1979 (see Chapter 27), and the revised report was the main subject of discussion at the 4-day final meeting of the Global Commission in December 1979. The final report (World Health Organization, 1980) outlines the criteria on the basis of which all members of the Global Commission signed a document proclaiming the global eradication of smallpox (see frontispiece). It also contained 19 recommendations covering all aspects of a post-eradication strategy (see Chapter 28) designed to ensure that all the countries of the world could remain confident that smallpox had indeed been eradicated.

On 8 May 1980 the Thirty-third World Health Assembly reviewed the Global Commission's report and declared that smallpox had been eradicated throughout the world. There were two resolutions: resolution WHA33.3 (see Plates 24.14–24.16) declared that the global eradication of smallpox had been achieved and resolution WHA33.4 endorsed the Global Commission's recommendations on policy for the post-eradication era (see Chapter 28).

ANNEX 24.1. MEMBERSHIP OF INTERNATIONAL COMMISSIONS FOR THE CERTIFICATION OF SMALLPOX ERADICATION

The positions held by members at the time of the international commissions give some indication of their standing and expertise. Members of the Global Commission who were also members of international commissions both before and after the establishment of the Global Commission are indicated by the letters GC in parentheses after their names.

1. SOUTH AMERICA: 12–25 August 1973 (PAHO document CD22/19)

Dr A. N. Bica	Secretary of Public Health, Ministry of Health, Rio de Janeiro, Brazil (*Chairman*)
Dr F. J. C. Cambournac	Director, Institute of Hygiene and Tropical Medicine, Lisbon, Portugal
Dr E. Echezuría	Chief, Department of Demography and Epidemiology, Ministry of Health, Caracas, Venezuela (*Rapporteur*)
Dr J. D. Millar	Director, State and Community Services Division, Center for Disease Control, Atlanta, GA, USA
Dr R. J. Wilson	Chairman, Connaught Medical Research Laboratories Ltd, University of Toronto, Canada

2. INDONESIA: 15–25 April 1974 (WHO/SE/74.68)

Dr N. McK. Bennett	Specialist Physician and Deputy Superintendent, Fairfield Hospital, Melbourne, Australia
Dr J. J. Dizon	Chief of Disease Intelligence, Disease Intelligence Centre, Department of Health, Manila, Philippines
Dr J. S. Gill	Assistant Director, Health and Epidemiology, Ministry of Health, Kuala Lumpur, Malaysia (*Rapporteur*)
Dr S. Kumarapathy	Senior Registrar, Quarantine and Epidemiology, Environmental Public Health Division, Ministry of Environment, Singapore

Dr J. Sulianti Saroso	Director-General for the Control and Prevention of Communicable Diseases, Ministry of Health, Jakarta, Indonesia
Dr I. Tagaya (GC)	Director, Department of Enteroviruses, National Institute of Health, Tokyo, Japan
Dr P. F. Wehrle (GC)	Hastings Professor of Pediatrics, Los Angeles County—University of Southern California Medical Center, Los Angeles, CA, USA (*Chairman*)

3. WESTERN AFRICA: 23 March–15 April 1976 (AFR/Smallpox/80)
Countries included: Benin, Côte d'Ivoire, Gambia, Ghana, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, Senegal, Sierra Leone, Togo and Upper Volta (Burkina Faso).

Dr S. Bédaya-Ngaro	Inspector General of Health Services, Bangui, Central African Republic
Dr W. Koinange (GC)	Director, Division of Communicable Disease Control, Ministry of Health, Nairobi, Kenya (*Chairman*, Abidjan)
Dr I. D. Ladnyi	Chief, Central Board of Quarantinable Diseases, Ministry of Health, Moscow, USSR
Dr Lekie Botee	Director-General, Department of Public Health, Kinshasa, Zaire (*Chairman*, Brazzaville)
Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France
Dr M. I. D. Sharma	Director (retired), National Institute of Communicable Diseases, New Delhi, India
Dr P. F. Wehrle (GC)	Hastings Professor of Pediatrics, Los Angeles County—University of Southern California Medical Center, Los Angeles, CA, USA (*Rapporteur*)

4. AFGHANISTAN: 22–29 November 1976 (WHO/SE/77.89)
and
5. PAKISTAN: 6–18 December 1976 (WHO/SE/77.90)

Dr H. S. Bedson	Professor of Medical Microbiology, University of Birmingham, Medical School, Birmingham, England
Dr N. McK. Bennett	Specialist Physician and Deputy Superintendent, Fairfield Hospital, Melbourne, Australia
Dr A. I. Idris	Director-General, Epidemiology, Ministry of Health, Khartoum, Sudan (*Chairman*, Pakistan)
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA (*Rapporteur*, Afghanistan and Pakistan)
Dr N. Kumara Rai	Director, Planning Department, Directorate General for Communicable Disease Control, Ministry of Health, Jakarta, Indonesia
Dr P. N. Shrestha (GC)	Chief, Smallpox Eradication Project, Department of Health Services, Kathmandu, Nepal (*Chairman*, Afghanistan)

6. CENTRAL AFRICA: 6–30 June 1977 (AFR/Smallpox/86)
Countries included: Burundi, Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, Gabon, Rwanda and Zaire.

Dr P. Agbodjan	Chief, Major Endemic Diseases Service, General Directorate for Health, Lomé, Togo
Dr J. G. Breman	Epidemic Intelligence Officer (Michigan Department of Public Health), Bureau of Epidemiology, Center for Disease Control, Atlanta, GA, USA

Dr E. Coffi	Director, Institute of Hygiene, Ministry of Public Health, Abidjan, Côte d'Ivoire
Dr F. Dekking	Health Science Laboratory, University of Amsterdam, Netherlands
Dr A. K. M'Baye	Chief Medical Officer, Major Endemic Diseases Service, and Deputy Director of Public Health, Dakar, Senegal (*Chairman*)
Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France (*Rapporteur*)
Dr M. Yekpe	Chief, Communicable Diseases Service, Ministry of Public Health, Cotonou, Benin

7. INDIA: 4–23 April 1977 (SEA/Smallpox/78)
NEPAL: 4–13 April 1977 (SEA/Smallpox/80)
BHUTAN: 28 March–1 April 1977; 22 April 1977 (SEA/Smallpox/80)

India and Bhutan

Dr J. Červenka	Chief (Epidemiology), Institute of Epidemiology and Microbiology, Bratislava, Czechoslovakia
Dr W. A. B. de Silva	Deputy Director (Planning), Ministry of Health, Colombo, Sri Lanka
Dr F. Fenner (GC)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia (*Rapporteur*)
Dr H. Flamm	Institute of Hygiene, University of Vienna, Austria
Lt.-Gen. R. S. Hoon	Director-General, Armed Forces Medical Services, New Delhi, India
Dr T. Kitamura	Chief, Division of Poxviruses, National Institute of Health, Tokyo, Japan
Dr W. Koinange (GC)	Director, Division of Communicable Disease Control, Ministry of Health, Nairobi, Kenya
Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland (*Chairman*)
Dr H. B. Lundbeck (GC)	Director, National Bacteriological Laboratory, Stockholm, Sweden
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr D. M. Mackay	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England
Dr M. F. Polak	Scientific Officer, Faculty of Medicine, Catholic University, Nijmegen, Netherlands
Dr R. Roashan	President, Foreign Relations Department, Ministry of Public Health, Kabul, Afghanistan
Dr D. J. Sencer	Director, Center for Disease Control, Atlanta, GA, USA
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma
Dr V. M. Zhdanov	Director, Institute of Virology, Academy of Medical Sciences, Moscow, USSR

Nepal

Dr T. Kitamura	Chief, Division of Poxviruses, National Institute of Health, Tokyo, Japan
Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland (*Chairman*)
Dr D. M. Mackay	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England (*Rapporteur*)

8. BURMA: 21–30 November 1977 (SEA/Smallpox/83)

Dr S. Jatanasen	Director, Division of Epidemiology, Ministry of Public Health, Bangkok, Thailand
Dr A. D. Langmuir	Professor, Harvard University Medical School, Department of Preventive and Social Medicine, Boston, MA, USA (*Secretary*)
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway
Dr H. von Magnus	Head, Department of Epidemiology, State Serum Institute, Copenhagen, Denmark (*Rapporteur*)
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr I. F. Setiady	Director, Epidemiology and Quarantine, Ministry of Health, Jakarta, Indonesia (*Chairman*)
Dr M. I. D. Sharma	Emeritus Medical Scientist, New Delhi, India
Dr P. N. Shrestha (GC)	Chief, Smallpox Eradication Project, Department of Health Services, Kathmandu, Nepal
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma

9. BANGLADESH: 1–14 December 1977 (SEA/Smallpox/84)

Dr S. Jatanasen	Director, Division of Epidemiology, Ministry of Public Health, Bangkok, Thailand
Dr A. D. Langmuir	Professor, Harvard University Medical School, Department of Preventive and Social Medicine, Boston, MA, USA (*Chairman*)
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway
Dr H. von Magnus	Head, Department of Epidemiology, State Serum Institute, Copenhagen, Denmark (*Rapporteur*)
Dr A. M. Mustaqul Huq	Director of Health Services (Preventive), Ministry of Health, Dhaka, Bangladesh
Dr I. F. Setiady	Director, Epidemiology and Quarantine, Ministry of Health, Jakarta, Indonesia
Dr M. I. D. Sharma	Emeritus Medical Scientist, New Delhi, India
Dr P. N. Shrestha (GC)	Chief, Smallpox Eradication Project, Department of Health Services, Kathmandu, Nepal
Dr U Thein Nyunt	Director, Disease Control, Ministry of Health, Rangoon, Burma

10. MALAWI, MOZAMBIQUE, UNITED REPUBLIC OF TANZANIA and ZAMBIA: 6–29 March 1978 (AFR/Smallpox/87)

Dr M. Davies	Chief Medical Officer, Ministry of Health, Freetown, Sierra Leone
Dr Z. M. Dlamini	Senior Medical Officer of Health, Ministry of Health, Mbabane, Swaziland
Dr J. A. Espmark	Department of Virology, State Laboratory of Biology, Stockholm, Sweden
Dr F. Fenner (GC)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia (*Rapporteur*)
Dr J. S. Moeti (GC)	Director of Medical Services, Ministry of Health, Gaborone, Botswana (*Chairman*)

11. IRAQ: 5–15 October 1978 (WHO/SE/78.127)
and
12. SYRIAN ARAB REPUBLIC: 15–22 October 1978 (WHO/SE/78.126)

Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France (*Chairman*)
Dr M. Chamsa	Assistant Director, Organization of Medical Services, Red Lion and Sun Society of Iran, Teheran, Iran

13. UGANDA: 11–27 October 1978 (AFR/Smallpox/88)

Dr A. Deria (GC)	Director, Department of Public Health, Ministry of Health, Mogadishu, Somalia (*Chairman*)
Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire (*Rapporteur*)
Dr Y. P. Rikushin	Chief, Department of Epidemiology, Pasteur Institute, Leningrad, USSR

14. SUDAN: 15–29 November 1978 (WHO/SE/79.134)

Dr A. M. Fergany	Adviser, Ministry of Health, Oman (*Chairman*)
Dr W. Koinange (GC)	Chief Deputy Director of Medical Services, Ministry of Health, Nairobi, Kenya
Dr C. Lerche	Director, National Institute of Public Health, Oslo, Norway (*Vice-Chairman*)
Dr S. S. Marennikova (GC)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA (*Rapporteur*)
Dr D. A. Robinson	Community Physician, Communicable Disease Surveillance Centre, London, England
Ato Yemane Tekeste	Project Manager, Smallpox Eradication Programme, Addis Abeba, Ethiopia

15. ANGOLA: 5–16 February 1979 (AFR/Smallpox/89)

Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire (*Co-Rapporteur*)
Dr Bichat A. Rodrigues (GC)	Regional Coordinator for the South-East Region, Ministry of Health, Brasilia, Brazil (*Chairman*)
Dr Cabral A. J. Rodrigues	National Director of Preventive Medicine, Secretariat for International Cooperation, Maputo, Mozambique (*Co-Rapporteur*)

16. BOTSWANA, LESOTHO AND SWAZILAND: 5–23 March 1979 (AFR/Smallpox/90)

Dr D. Chilemba	Chief Medical Officer, Ministry of Health, Lilongwe, Malawi
Dr A. Deria (GC)	Director, Department of Public Health, Ministry of Health, Mogadishu, Somalia
Dr P. E. M. Fine	Ross Institute of Tropical Hygiene, London School of Hygiene and Tropical Medicine, London, England
Dr W. Koinange (GC)	Chief Deputy Director of Medical Services, Ministry of Health, Nairobi, Kenya (*Chairman*)
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA (*Rapporteur*)

Dr E. A. Smith	Director of Medical Services, Federal Ministry of Health, Lagos, Nigeria
Dr I. Tagaya (GC)	Director, Department of Enteroviruses, National Institute of Health, Tokyo, Japan

17. DEMOCRATIC YEMEN: 3–11 June 1979 (WHO/SE/79.140)

Dr F. Jurji	Director of Epidemiology and Quarantine, Directorate General of Preventive Medicine, Ministry of Health, Baghdad, Iraq
Dr T. Kitamura	Chief, Division of Poxviruses, National Institute of Health, Tokyo, Japan (*Chairman*)
Dr V. Šerý	Chief, Department of Tropical Diseases, Postgraduate School of Medicine, Prague, Czechoslovakia

18. YEMEN: 2–10 June 1979 (WHO/SE/79.139)

Dr J. M. Aashi (GC)	Assistant Director-General of Preventive Medicine, Ministry of Health, Riyadh, Saudi Arabia (*Co-Chairman*)
Dr T. J. Geffen	Director, Communicable Diseases Division, Department of Health and Social Security, London, England (*Rapporteur*)
Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France (*Co-Chairman*)

19. DJIBOUTI: 9–18 October 1979 (WHO/SE/79.147)

Dr N. C. Grasset	Epidemiologist, Douvaine, France; formerly Regional Adviser for Smallpox Eradication in the WHO Regional Office for South-East Asia, New Delhi, India (*Rapporteur*)
Dr T. Nacef	Director, Department of Preventive and Social Medicine, Ministry of Public Health, Tunis, Tunisia
Dr R. Netter (GC)	Director-General, National Health Laboratory, Paris, France (*Chairman*)

20. ETHIOPIA: Preliminary visit: 3–18 April 1979; final visit: 1–19 October 1979 (WHO/SE/79.148)

Dr R. N. Basu (GC)	Assistant Director-General of Health Services, Directorate General of Health Services, New Delhi, India
Dr Z. M. Dlamini	Director of Medical Services, Ministry of Health, Mbabane, Swaziland
Dr K. R. Dumbell (GC)	Head, Department of Virology, The Wright–Fleming Institute of Microbiology, St Mary's Hospital Medical School, London, England
Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland
Dr H. B. Lundbeck (GC)	Director, National Bacteriological Laboratory, Stockholm, Sweden
Dr T. Olakowski	Deputy Director, National Tuberculosis Institute, Warsaw, Poland
Dr N. A. Ward	Save the Children Fund, London, England

Final visit: 1–19 October 1979

Dr K. R. Dumbell (GC)	Head, Department of Virology, The Wright–Fleming Institute of Microbiology, St Mary's Hospital Medical School, London, England (*Rapporteur*)
Dr D. A. Henderson (GC)	Dean, School of Hygiene and Public Health, The Johns Hopkins University, Baltimore, MD, USA (*Rapporteur*)

Dr J. Kostrzewski (GC)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland
Dr I. Noormahommed	Deputy National Director of Preventive Medicine, Ministry of Health, Maputo, Mozambique
Dr D. A. Robinson	Epidemiologist, Communicable Disease Surveillance Centre, London, England
Dr A. A. Stroganov	Assistant Professor, Central Institute for Advanced Medical Training, Communicable Disease Department, Moscow, USSR

21. KENYA: 1–19 October 1979 (WHO/SE/79.149)

Dr R. N. Basu (GC)	Assistant Director-General of Health Services, Directorate General of Health Services, New Delhi, India (*Chairman*)
Dr Kalisa Ruti (GC)	Medical Director, Expanded Programme on Immunization, Department of Public Health, Kinshasa, Zaire
Dr S. S. Marennikova (GC)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr G. Meiklejohn	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA (*Rapporteur*)
Dr J. S. Moeti (GC)	Senior Medical Officer of Health, Ministry of Health, Gaborone, Botswana

22. SOMALIA: 1 21 October 1979 (WHO/SE/79.146)

Dr J. M. Aashi (GC)	Assistant Director-General of Preventive Medicine, Ministry of Health, Riyadh, Saudi Arabia
Dr Z. M. Dlamini	Director of Medical Services, Ministry of Health, Mbabane, Swaziland
Dr T. J. Geffen	Director, Communicable Diseases Division, Department of Health and Social Security, London, England (*Rapporteur*)
Dr H. B. Lundbeck (GC)	Director, National Bacteriological Laboratory, Stockholm, Sweden (*Chairman*)
Dr J. D. Millar	Assistant Director for Public Health Practice, Center for Disease Control, Atlanta, GA, USA
Dr P. N. Shrestha (GC)	Chief, Planning Division, Tribhuvan University Institute of Medicine, Kathmandu, Nepal

ANNEX 24.2. PARTICIPANTS IN THE CONSULTATION ON THE WORLDWIDE CERTIFICATION OF SMALLPOX ERADICATION AND MEMBERS OF THE GLOBAL COMMISSION

The numbers in parentheses have the following significance:
(1) participated in the 1977 Consultation;
(2) attended the 1978 meeting of the Global Commission;
(3) attended the 1979 meeting of the Global Commission.

Participants in the Consultation and Members of the Global Commission

Dr J. M. Aashi (1, 2, 3)	Assistant Director-General of Preventive Medicine, Ministry of Health, Riyadh, Saudi Arabia
Dr J. Azurin (1, 2, 3)	Under-Secretary of Health, Department of Health, Manila, Philippines
Dr R. N. Basu (1, 2, 3)	Assistant Director-General of Health Services, Directorate General of Health Services, New Delhi, India

Dr P. N. Burgasov (2, 3)	Deputy Minister of Health, Moscow, USSR
Dr H. Corral (1)	Director-General, Ministry of Health, Quito, Ecuador
Dr A. Deria (1, 2, 3)	Director, Department of Public Health, Ministry of Public Health, Mogadishu, Somalia
Dr K. R. Dumbell (1, 2, 3)	Head, Department of Virology, The Wright–Fleming Institute of Microbiology, St Mary's Hospital Medical School, London, England
Dr F. Fenner (1, 2, 3; Chairman: 1, 2, 3)	Director, Centre for Resource and Environmental Studies, The Australian National University, Canberra, Australia
Dr D. A. Henderson (1, 2, 3)	Dean, School of Hygiene and Public Health, The Johns Hopkins University, Baltimore, MD, USA
Dr Kalisa Ruti (3)	Medical Director, Expanded Programme on Immunization, Kinshasa, Zaire
Dr J. Kilgour (1)	Head, International Health Division, Department of Health and Social Security, London, England
Dr W. Koinange (1, 2, 3; Vice-Chairman: 1)	Director, Division of Communicable Disease Control, Ministry of Health, Nairobi, Kenya
Dr J. Kostrzewski (1, 2, 3; Vice-Chairman: 2, 3)	Secretary, Medical Section, Polish Academy of Sciences, Warsaw, Poland
Dr H. B. Lundbeck (1, 2, 3)	Director, National Bacteriological Laboratory, Stockholm, Sweden
Dr S. S. Marennikova (1, 2, 3)	Chief, Laboratory of Smallpox Prophylaxis, Moscow Research Institute for Viral Preparations, Moscow, USSR
Dr J. S. Moeti (1, 2, 3)	Senior Medical Officer of Health, Ministry of Health, Gaborone, Botswana
Dr C. Mofidi (1, 2)	Minister of Higher Education and Science, Teheran, Iran
Dr R. Netter (1, 2, 3)	Director-General, National Health Laboratory, Paris, France
Dr Bichat A. Rodrigues (3)	Executive Secretary, National Council of Health, Brasilia, Brazil
Dr P. N. Shrestha (2, 3)	Chief, Planning Division, Tribhuvan University Institute of Medicine, Kathmandu, Nepal
Dr I. Tagaya (2, 3)	Director, Department of Enteroviruses, National Institute of Health, Tokyo, Japan
Dr P. F. Wehrle (1, 2, 3; Rapporteur: 1, 2, 3)	Hastings Professor of Pediatrics, Los Angeles County—University of Southern California Medical Center, Los Angeles, CA, USA
Dr Zhang Yihao (3)	Deputy Director, National Serum and Vaccine Institute, Beijing, China

WHO Advisers

Dr H. Corral (1)	Director-General, Ministry of Health, Quito, Ecuador
Dr W. H. Foege (2)	Director, Center for Disease Control, Atlanta, GA, USA
Dr T. J. Geffen (2)	Director, Communicable Diseases Division, Department of Health and Social Security, London, England
Dr N. C. Grasset (2)	Epidemiologist, Douvaine, France
Dr Jiang Yu-tu (3)	Military Academy of Medical Sciences, Beijing, China
Dr G. Meiklejohn (2, 3)	Professor of Medicine, University of Colorado Medical Center, Denver, CO, USA
Dr W. Nicol (2)	Area Medical Officer, Birmingham, England
Dr A. G. Rangaraj (2)	Epidemiologist, Nilgiris District, Madras, India
Dr Parviz Rezai (2)	Deputy Director-General, Communicable Diseases Control and Malaria Eradication, Ministry of Health and Welfare, Teheran, Iran
Ato Yemane Tekeste (2, 3)	Programme Manager, Smallpox Eradication Programme, Addis Abeba, Ethiopia

WHO Regional Office Staff

Africa:
Dr A. H. Abou-Gareeb (3), Director, Disease Prevention and Control, Brazzaville, Congo
Dr C. Algan (1, 2), Medical Officer, Health Services, Brazzaville, Congo
Dr Z. Islam (2, 3), Medical Officer, Epidemiological Surveillance of Communicable Diseases Project, Nairobi, Kenya
Dr L. N. Khodakevich (2, 3), Interregional Medical Officer, Smallpox Eradication Project, Addis Abeba, Ethiopia

Americas:
Dr J. Bond (3), Medical Officer, Communicable Diseases, Washington, DC, USA
Dr C. H. Tigre (2), Scientist, Communicable Diseases, Washington, DC, USA
Dr K. A. Western (1, 2), Chief, Communicable Diseases, Washington, DC, USA

South-East Asia:
Dr L. N. Khodakevich (1), Medical Officer, Smallpox Eradication, New Delhi, India

Europe:
Dr M. R. Radovanovic (1, 2), Medical Officer, Epidemiological Surveillance of Communicable Diseases, Copenhagen, Denmark

Eastern Mediterranean:
Dr P. Chasles (1), Medical Officer, Communicable Diseases Prevention and Control, Alexandria, Egypt
Dr F. Partow (2), Medical Officer, Communicable Diseases Prevention and Control, Alexandria, Egypt

Western Pacific:
Dr B. C. Dazo (3), Scientist, Communicable Diseases, Manila, Philippines
Dr R. R. Lindner (1), Medical Officer, Communicable Diseases, Manila, Philippines
Dr Chin Wentao (2), Consultant Medical Officer, Communicable Diseases, Manila, Philippines

WHO Headquarters Staff

Dr I. D. Ladnyi (1, 2, 3), Assistant Director-General
Dr A. Zahra (2, 3), Director, Division of Communicable Diseases
Dr I. D. Carter (2, 3), Epidemiologial Surveillance of Communicable Diseases
Dr H. J. Schlenzka (2), Legal Division
Dr E. Shafa (1, 2), Expanded Programme on Immunization

Smallpox Eradication unit:

Dr I. Arita (1, 2, 3), Chief Medical Officer
Dr J. G. Breman (1, 2, 3), Medical Officer
Mr R. N. Evans (2, 3), Technical Officer
Dr A. I. Gromyko (1, 2, 3), Medical Officer
Mr R. O. Hauge (1), Consultant Technical Officer
Dr Z. Ježek (2, 3), Medical Officer
Mr J. Magee (2, 3), Information Officer
Dr J. L. Tulloch (2, 3), Consultant Medical Officer
Mr. J. F. Wickett (1, 2, 3), Administrative Officer

INTRODUCTION

In the previous chapter we examined in broad terms the process by which the certification of smallpox eradication was undertaken, culminating in the adoption by the World Health Assembly on 8 May 1980 of a resolution declaring that smallpox had been eradicated throughout the world. In the present chapter and the two which follow, this process is examined in more detail. It is evident that the problems that occurred paralleled those encountered during the elimination of smallpox from different countries. In this chapter an account is given of the activities of 9 international commissions which operated before the Consultation on the Worldwide Certification of Smallpox Eradication took place at WHO Headquarters in Geneva in October 1977. These include the 3 commissions which laid the foundation for all the others (see Chapter 24)—namely, those for South America, the first exploratory effort; Indonesia, a much more sophisticated procedure, but still in process of development; and western and central Africa, which set the pattern for the certification of many other countries in Africa and Asia from which smallpox had been eliminated several years earlier. The chapter closes with a brief de-

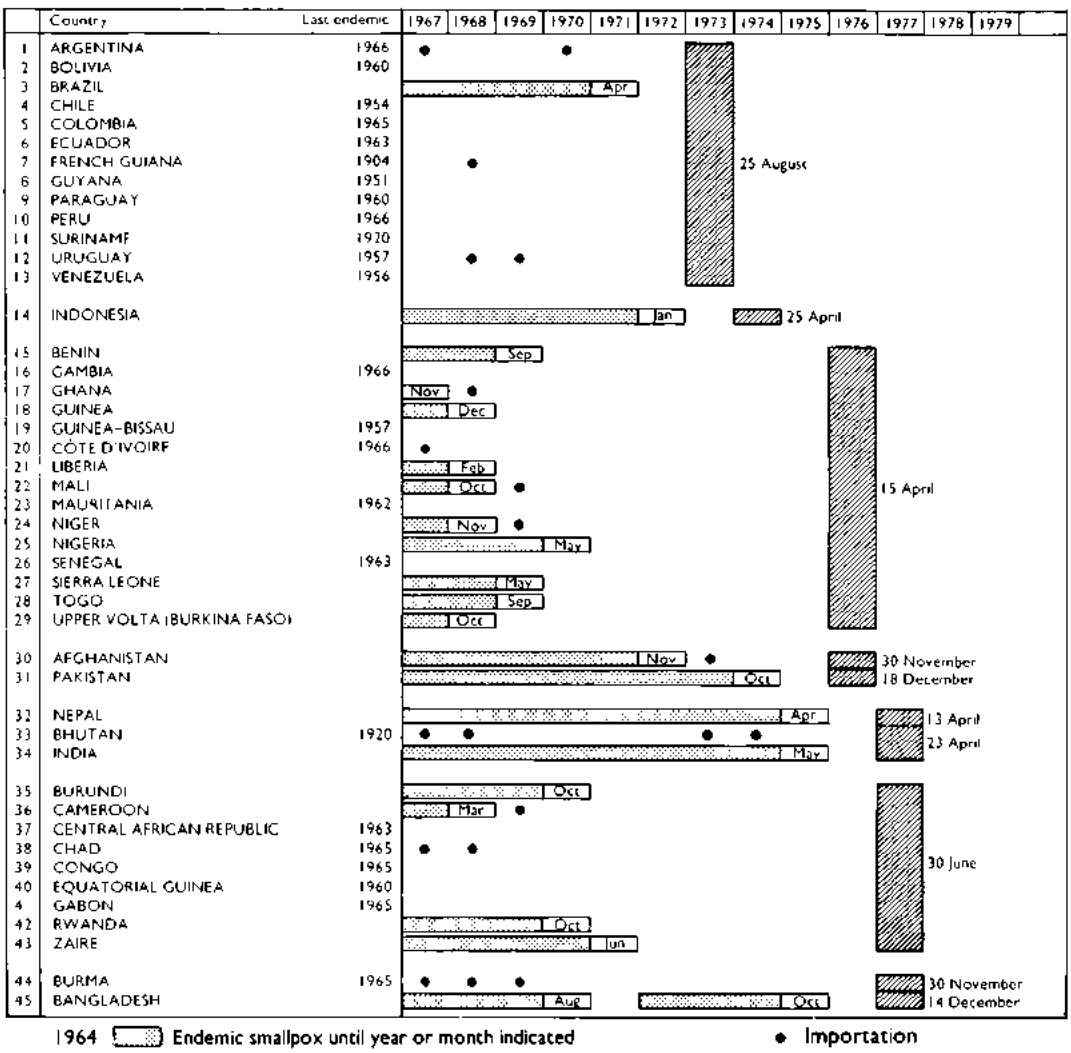

Fig. 25.1. Countries certified to be smallpox-free by international commissions operating between 1973 and 1977. The vertical boxes indicate the year in which the country was visited by an international commission; the dates on the right of these are those of the certification of the country or group of countries.

scription of the certification of the eradication of variola major from the world. This was carried out by the large international commissions which dealt first with Afghanistan and Pakistan in the west, and then with the principal and ancient home of variola major - India, Bangladesh and some of their small neighbours.

Fig. 25.1 shows the countries covered by these 9 international commissions, the month and year of the last cases in each country, and the dates of certification.

The special procedures adopted, the studies carried out and the factors which affected the decision by each of the international commissions to certify that eradication had been achieved are described in the sections which follow. Common to all countries, and of long standing, was the routine notification of a number of infectious diseases by hospitals and health centres, special attention being given to smallpox and the other diseases subject to the International Health Regulations (cholera, plague and yellow fever); all cases of these diseases had to be notified to WHO. Although the reporting of smallpox had been very incomplete when the Intensified Smallpox Eradication Programme began, the system then in place had served to detect and report cases in the endemic countries. During the course of the Intensified Programme, routine notification systems improved in all countries and, although they were not sufficiently sensitive to detect all the cases of smallpox that might have occurred, it was unlikely that any of them would fail to detect at least some of the numerous cases which would have had to occur if transmission was sustained over many years. The continuing absence of reports of cases of smallpox, often for a period of some years during which other diseases were being reported to WHO, increased confidence in the certification process, especially in countries in which certification was undertaken several years after the occurrence of the last known case of endemic smallpox.

CERTIFICATION IN SOUTH AMERICA

The last case of smallpox in South America was reported from Brazil in April 1971; South America was certified free of smallpox in August 1973.

Recent History of Smallpox

The history of smallpox in South America since the late 1950s has been described in Chapter 12. The essential features are summarized below as a background to the precertification activities and the recommendations of the Commission for the Assessment of the Smallpox Eradication Program in the Americas, which met in 1973.

After 1967, when the Intensified Smallpox Eradication Programme was initiated, only 3 countries in South America and the French Overseas Department of French Guiana reported cases of smallpox. The disease remained endemic in Brazil, which had long been reporting several thousand cases of variola minor annually, while Argentina, French Guiana, and Uruguay reported a few cases between 1967 and 1970, following importations from Brazil (Table 25.1). All the other South American countries had reported their last cases before 1967 (see Chapter 8, Fig. 8.6) and the last importation into the subcontinent from outside South America was believed to have occurred as long ago as 1920. Certification activities were therefore concentrated on Brazil and on adjacent countries in which importations from Brazil might have led to the establishment of new endemic foci.

Precertification Activities

In April 1971, the month in which the last outbreak of smallpox occurred in Brazil, it was decided that surveillance should continue

Table 25.1. South America: number of reported cases of smallpox, 1966–1972

Country	1966	1967	1968	1969	1970	1971	1972
Argentina	21	30[a]	0	0	24[a]	0	0
Brazil	3 623	4 514	4 372	7 407	1 771	19	0
French Guiana	0	0	1[a]	0	0	0	0
Peru	13	0	0	0	0	0	0
Uruguay	0	0	2[a]	3[a]	0	0	0

[a]Considered to be due to importation from Brazil.

in Brazil for 2 years after the occurrence of the last known case and that an assessment of the smallpox situation should then be made throughout South America (see Chapter 24). Over the next 2 years, country reports were prepared for submission to an independent assessment group by 11 countries (Argentina, Bolivia, Brazil, Colombia, Ecuador, Guyana, Paraguay, Peru, Suriname, Uruguay and Venezuela) and French Guiana; all of these except Brazil had been free of known endemic smallpox for at least 5 years. Chile was excluded because it had no common border with Brazil and, having a reasonably sophisticated health service infrastructure, had found no endemic smallpox to report since the early 1950s.

Brazil

The vaccination campaign carried out between 1967 and 1971 had covered over 80% of the Brazilian population of 97 million. As has already been mentioned, the last case of smallpox occurred in April 1971, in Guanabara State, but the campaign was continued until the International Commission's visit in 1973. By 1971, epidemiological surveillance units had been established in 2904 of the 3951 *municípios* (73%), and formed an important reporting network for suspected cases, the proportion of *municípios* with such units rising to 89% in 1972 and 90% by June 1973 (Table 25.2).

In 1972, health personnel conducted special inquiries aimed at collecting rumours of smallpox cases throughout the country. They interviewed personnel working in government agencies, such as political and health officials, schoolteachers and pupils, and workers in factories and businesses. More than 300 000 persons were interviewed in areas in which the risk of unreported cases of smallpox was believed to be the greatest (Table 25.3). This survey found 96 suspected cases, but none of them proved to be smallpox.

During the course of the organized surveillance programme between January 1971 and June 1973, 1293 suspected cases of smallpox were investigated (Table 25.4). Specimens

[a] Including 19 confirmed cases from the last outbreak of smallpox in Brazil.

were collected for laboratory diagnosis from 792 of them; all gave negative results except the 19 specimens collected in Guanabara State during the last outbreak, which were positive. No evidence of smallpox transmission was found after April 1971.

Argentina

The last case in Argentina occurred in April 1970, in an outbreak of 24 cases in Misiones Province, which borders on Brazil. This began with an importation from Brazil

and was contained by mass vaccination as soon as it was discovered. By the end of 1971 the vaccination campaign in the province had reached 84% of the population of 443 020 persons. During the summer of 1971 Dr Claudio Marcos da Silveira, a WHO consultant, visited Argentina to assess the smallpox situation. With Dr Juan José Hiriart, chief of the national smallpox eradication programme, he contacted schoolteachers, health officers and community leaders in areas in which cases of smallpox had been reported between 1965 and 1970, paying special attention to the community of Colonia Alicia, in which the 1970 outbreak had occurred. A survey in these areas showed that 88% of the 2819 schoolchildren examined had vaccination scars. Investigation of 26 cases of fever with rash led to the diagnosis of chickenpox in all of them. No cases of smallpox were found.

Colombia

The last cases of smallpox had occurred in Colombia in 1965. Between 1967 and 1972 more than 13 million of the 22 million people in the country were vaccinated, and a survey in 1970 found that 70% of the age group 0–4 years, 85% of the age-group 5–14 years and 77% of those aged 15 years and over had vaccination scars. Vaccination coverage was satisfactory except in 6 sparsely settled departments in the Amazon region. No evidence of recent smallpox was found during the vaccination scar survey.

In November 1971 a special survey was conducted in the Amazon basin in the Commissary of Vaupés (90 000 square kilometres), one of the more isolated areas, adjacent to the Brazilian Amazon basin. It was found that in the previous year, 8 cases of fever with rash had occurred in the San Jorge District on the bank of the Vaupés river opposite the town of Mitú. These had been diagnosed as smallpox in the hospital at Mitú, but the investigation revealed that 4 of them were in persons who had been previously vaccinated and that all were cases of chickenpox. A further search for cases of fever with rash found no evidence of smallpox in this area.

French Guiana

No cases of smallpox had been recorded in the files of the public health authorities of French Guiana since 1904. One case imported from Brazil into Cayenne had occurred in 1968 but it did not appear in the official records although it had been reported to WHO. Dr Marcos da Silveira visited the territory as a WHO consultant in 1971 and concluded that continued smallpox transmission was most unlikely for two reasons. First, the population was small (44 000), the reporting system was reasonably good and, although there was a risk of importation through persons entering illegally from Brazil, the areas adjacent to Brazil were so thinly populated that it was unlikely that an endemic focus could be established. Secondly, the vaccination programme was continuing and the records showed that in 1970 nearly half the children under 1 year of age had been vaccinated; this suggested that the coverage of the older age groups should have been reasonably good.

Paraguay

The last outbreak of 32 cases in Paraguay followed an importation from Brazil in 1965. In 1971 an investigation was conducted by a team of WHO operations officers and national personnel in the areas at highest risk, all of which bordered on Brazil. The survey team travelled 5000 kilometres, visited 88 localities, interviewed 125 health personnel and 451 teachers and educational personnel, and discovered 15 cases of exanthematous diseases, all of which had occurred during the previous 12 months. These cases and an additional 50 persons with a history of attacks of fever with rash were investigated, but no cases of smallpox were found.

Nor was evidence of smallpox found in a national survey of schoolchildren, conducted in 336 schools throughout the country in 1971. During the course of routine spraying operations in May of that year, the malaria control service personnel also conducted a search for smallpox cases among a population which comprised 4% of the national total, but found none. To determine the vaccination coverage, a special scar survey was conducted in May–June 1971 among 19 470 persons in the south of Paraguay. It was found that 78% had vaccination scars; the proportion was 43% in the age group 0–4 years and more than 82% in those aged over 4 years.

Peru

The 13 cases which occurred in Peru in 1966 were the last in a large outbreak of

variola minor that began in 1963, following an importation from Brazil. A vaccination campaign carried out between 1968 and 1970 resulted in a good coverage of the population, as was shown by a vaccination scar survey of 30 000 persons that was conducted in 1970. It was found that 82% of the age group 0–4 years, 92% of the age group 5–14 years and 91% of adults bore scars. The vaccination teams found no evidence of smallpox during the campaign.

Uruguay

The last importation of smallpox into Uruguay was recorded in 1969, before which there had been importations annually between 1960 and 1965 and again in 1968. Each case had been carefully investigated in order to determine the source of infection and each outbreak had been traced to a person exposed in Brazil. The prompt reporting and careful epidemiological investigations gave grounds for confidence that the health authorities would have detected and reported other cases had they occurred. In 1971 a small vaccination scar survey was conducted; of the 1029 persons examined, 98% had been vaccinated.

Other countries

Bolivia, Chile, Ecuador, Guyana, Suriname and Venezuela had also conducted good vaccination programmes (see Chapter 12), and the most recent cases in each country were associated with importations. Bolivia reported its last case in 1964, Chile in 1963, Ecuador in 1963, Guyana in 1951, Suriname in 1920, and Venezuela in 1962; indigenous transmission had been interrupted in most of these countries several years earlier (see Chapter 8, Fig. 8.6).

In 1971 special vaccination and search programmes were carried out in the Amazon basin areas of Bolivia, Ecuador and Venezuela, in parallel with those conducted in Brazil and Colombia. No cases of suspected smallpox were found.

Visit of the International Commission

The Commission for the Assessment of the Smallpox Eradication Program in the Americas, as it was called, first met in Rio de Janeiro on 15 August 1973, and discussed the reports that had been prepared by each of the 11 countries and by French Guiana. The Commission was charged, as were all those that followed it, with the responsibility of reaching one of two possible conclusions: that it was satisfied that smallpox eradication had been achieved, or that it would be satisfied that smallpox eradication had been achieved if a specifically described set of activities were conducted and no further cases discovered.

The Commission split up into teams which visited several areas of epidemiological importance in Brazil. They participated in the epidemiological investigation of suspected cases of smallpox and observed the operation of the existing epidemiological surveillance system. The Commission held its final meeting in Brasilia on 25 August. As has been pointed out in Chapter 24, the constitution of this first international commission was not ideal, nor did it carry out its work with the same thoroughness as later international commissions.

The Commission reviewed the situation in the various countries. Its conclusions may be summarized as follows:

(1) Although the vaccination campaigns conducted in the 1960s throughout South America were in general satisfactory, protection was generally insufficient in children under 5 years of age and in areas to which access was difficult. The Brazilian campaign was regarded as notable for having reached high levels of vaccination coverage throughout the country and in all age groups.

(2) There was a need to improve the reporting system in certain areas. However, the Commission was impressed with the excellent epidemiological surveillance throughout Brazil, where there was a widespread network of reporting posts covering 90% of the *municipios* of the country.

(3) While the larger South American countries and Uruguay maintained services for the laboratory diagnosis of smallpox and, following the last reported case in April 1971, laboratory confirmation of the diagnosis of every suspected case was important, the quality of the laboratory work was not as satisfactory as might have been hoped. The Commission drew attention to certain deficiencies in the collection, packaging and shipment of specimens, which sometimes made laboratory diagnosis difficult. It also observed that there was no interchange of information between laboratories, even within the same country. Although the WHO

collaborating centre in Atlanta, USA, had agreed to test specimens, few specimens were submitted between 1967 and 1977 and most of them were from Brazil (Table 25.5).

(4) Although vaccine production in various countries in South America was sufficient to cover local needs, some countries continued to produce liquid vaccine intended for use wholly or in part in their respective jurisdictions. Even when it was freeze-dried, the quality was often not satisfactory; this applied, in particular, to the heat stability of egg vaccine produced in Brazil (see Chapter 12). Few laboratories regularly sent vaccine specimens for quality control to the WHO Reference Centre for Smallpox Vaccine for the Region of the Americas in Toronto, Canada.

Despite the deficiencies mentioned above, the Commission concluded that smallpox transmission had been interrupted in the region, but took a cautious approach to post-eradication policy, recommending that:

(1) Countries should continue to give due attention to reporting systems and to their improvement, particularly in areas in which reporting was weak, so that consistent information was immediately available on every suspected case.

(2) A sufficient number of adequately trained epidemiologists should be made available for epidemiological surveillance services, so that each case of suspected smallpox might be thoroughly investigated by a competent epidemiologist and specimens, taken under satisfactory conditions, sent to a laboratory.

(3) Smallpox having been eliminated from the Region of the Americas, and the laboratory investigation of every suspected case being of fundamental importance to epidemiological surveillance, the Pan American Health Organization should stimulate the establishment of a system designed to ensure the technical proficiency of the laboratories performing smallpox diagnostic procedures.

(4) In order to ensure that the vaccines produced in the region were of high quality, samples of 3 consecutive lots of vaccine should be sent every 4 months to the reference laboratory for quality control tests.

In essence, the Commission recommended that vaccination and surveillance activities should be continued in much the same way as before eradication. Since it was agreed that there was little likelihood of importing smallpox from another continent, this recommendation reflects a certain lack of confidence in the decision that smallpox transmission had been interrupted. Such caution is understandable; this was the first time that smallpox eradication had been certified, and the disease had been endemic in South America for more than 400 years.

CERTIFICATION IN INDONESIA

Although Indonesia was geographically close to the endemic countries of south-eastern Asia, no importation of smallpox had been recorded from them since 1949. It was therefore considered reasonable to undertake the certification of the eradication of smallpox in Indonesia in 1974, 2 years after the last known case.

Recent History of Smallpox

Smallpox was reintroduced into Indonesia in 1947, but it remained confined to the larger islands of the western part of the archipelago

(see Chapter 13, Fig. 13.3). The numbers of cases in these islands between 1967 and 1973 are shown in Table 25.6. The last case of smallpox in the country occurred in January 1972, in a village some 30 kilometres from Jakarta, West Java.

Precertification Activities

Smallpox surveillance continued until April 1974, when the International Commission visited Indonesia. In collaboration with national staff, WHO smallpox eradication programme staff—namely, Dr Giuseppe Cuboni (May 1971–October 1974) and Mr William Emmet (August 1970–July 1974)—continued to help with precertification surveillance.

In August 1973, Dr Paul Wehrle, a WHO consultant, visited Indonesia to review the progress of certification activities and to advise on other steps to be taken in order to demonstrate convincingly that eradication had been achieved. He visited 26 provinces in North Sumatra, South Sulawesi, West Java and West Kalimantan to assess surveillance activities, using as indices the regularity with which the weekly smallpox reports were submitted, the number of notifications and the number of laboratory samples collected and tested. He reported that he was personally convinced that smallpox transmission had been interrupted in Indonesia but recommended various measures to improve surveillance.

Neither the activities of the national eradication programme nor those of the International Commission subsequently covered all the thousands of small islands in the archipelago. After 1949, no smallpox cases had been reported from any of the islands east of Sulawesi and Nusa Tenggara, although authorities on these islands routinely reported cases of other diseases. If smallpox had occurred there, rumours would have come to the notice of the health service. Experience in many islands in the South Pacific had shown that smallpox transmission could not be maintained on isolated oceanic islands because the populations were too small to provide a continuous supply of susceptible persons. The small islands of the Indonesian archipelago had apparently been free from smallpox for several decades, and the chance of continuing endemicity there was considered to be nil.

Special searches

Between March and December 1972 visits to the villages in which cases of smallpox had occurred during the period 1970–1972 were carried out by surveillance teams, consisting of national, provincial and regency smallpox eradication programme staff, in 11 provinces of Java, Sulawesi and Sumatra (Fig. 25.2). The main purpose of these visits was to ensure that the recent smallpox outbreaks had been thoroughly contained. In addition, rumours about suspected cases in localities or areas in frequent contact with those affected were investigated. Other localities that were searched were those that did not report regularly, those that were seldom visited by health personnel, and those in which frequent staff changes suggested some weakness in the local health services.

During these special searches, 1352 villages were visited and the civil authorities, religious leaders and the security forces questioned, and inquiries were made at health centres and schools. Of 650 reports of cases of suspected smallpox discovered, 629 proved to be cases of chickenpox; none was smallpox. Approximately 180 laboratory specimens were collected and tested by Indonesian laboratories, all with negative results. The

special searches failed to elicit any evidence of the occurrence of smallpox after January 1972.

Reward for smallpox detection

In May 1972, immediately after the last known case has been detected, the Indonesian government offered a reward of 5000 rupiahs (US$12) to any person reporting a case of smallpox which was confirmed by laboratory tests. A similar amount was to be given to the first health worker who investigated and confirmed the case. The reward was given wide publicity by health workers when talking to the public during field visits (see Chapter 10, Plate 10.8C) in the hope of urging people to reveal rather than hide any new case.

Routine reporting of suspected cases

The existing system for the routine weekly reporting of suspected smallpox cases was strengthened. In 1972, roughly 20% of the expected number of weekly reports were submitted, whereas in 1974 the level had risen to 50% at both the regency and provincial levels. Between 1972 and 1974, 6186 cases of suspected smallpox were reported and 8505 cases investigated (Table 25.7), the latter number including additional suspected cases discovered during the investigations of the original cases. As usual, the disease most frequently mistaken for smallpox was chickenpox, which accounted for about 70% of the total suspected cases seen, other skin diseases (scabies, measles, impetigo and dermatitis) accounting for the remainder.

Laboratory diagnosis

After what was thought to be the last case of smallpox in Indonesia had been reported in 1972, the laboratory investigation of suspected smallpox became of vital importance. The number of specimens collected in various

Table 25.7. Indonesia: routine reporting of cases of suspected smallpox, May 1972–February 1974

Year	Number of suspected cases					Source of reports (%)			
	Reported	Total investigated	Chicken-pox	Smallpox	Others	Health personnel	Civil authorities	Members of the public	Unspecified
1972	2 298	3 223	2 236	0	987	38	27	25	10
1973	3 067	4 175	2 781	0	1 394	38	31	18	13

Total	6 186	8 505	5 630	0	2 875	–	–	–	–

geographical areas was considered to be an index of the sensitivity of the surveillance system. Laboratory tests (gel precipitation and virus isolation) were carried out locally at the Biofarma Virological Laboratory in Bandung or the Central Public Health Laboratory in Jakarta, but specimens considered to be of special importance were also investigated by the WHO collaborating centres. In spite of the time required for shipment and communications—from the field to Jakarta, then to Geneva, then to a collaborating centre in the USA or USSR, and back by the same route—the results of tests carried out at the collaborating centres were available to the field staff within 5 weeks of the specimen being collected in 1972 and within 4 weeks in 1973 and 1974.

In addition to collecting laboratory specimens from all suspected smallpox cases, from September 1972 onwards health personnel were instructed to collect specimens from clinically unequivocal chickenpox in persons over 14 years of age who had no evident vaccination scar and from persons who had become ill in an outbreak of chickenpox in which a death had occurred. This type of surveillance was introduced after the last smallpox outbreak, in which cases had been reported to resemble chickenpox.

Between 1971 and 1973, altogether 1758 specimens were tested (Table 25.8), none being found positive for smallpox after 1972. Since chickenpox virus did not grow on the chorioallantoic membrane, hundreds of specimens from chickenpox viruses might be examined with consistently negative results. To encourage the laboratory workers and to test the laboratories' ability to grow poxviruses on the chorioallantoic membrane, samples were occasionally submitted from vaccinial lesions, from which vaccinia virus could be grown; this explains the positive results for vaccinia virus in 1972 and 1973 shown in Table 25.8.

Table 25.8. Indonesia: laboratory diagnosis of suspected cases of smallpox, 1971–1973[a]

Year	Number of specimens	Number positive for:	
		variola virus	vaccinia virus

[a] Biofarma, Bandung, tested 1479 specimens, the Central Public Health Laboratory, Jakarta, 247 specimens and WHO collaborating centres 32 specimens.

[b] From samples from vaccinial lesions, submitted as a means of checking the ability of the laboratory to grow poxviruses on the chorioallantoic membrane.

Local declaration of smallpox-free status

The national programme director decided that the local authorities should be responsible for confirming that smallpox was no longer prevalent in the areas under their jurisdiction. A total of 12 provinces in Java, Sulawesi and Sumatra had been defined as areas of concern, since cases of smallpox had been reported from them after 1970. In these provinces, both the civil authorities and the health service representatives of every village or area were requested to sign a document declaring that that locality was free of smallpox. Before this document was signed, every village chief and his local medical staff were given 2 weeks in which to check the area carefully and report any suspected case to the nearest health centre. However, the signing of the statement did not remove the duty to report any suspected case. On the contrary, all those involved were informed about the dangers of importation and the need for vigilance. This process was started in April 1973 and concluded in April 1974, involving 12 of the 26 provinces, as already mentioned, 158 of the 288 regencies and municipalities, 1771 of the 3203 subdistricts and about 25 000 of the 46 396 villages (*desas*) in Java, Sulawesi and Sumatra—a formidable task that required considerable organizational effort and logistic support.

These precertification efforts drew attention to smallpox and increased awareness of the reward offered both to health workers and to the general public for the notification of a case that could be confirmed.

Special survey in Kalimantan and Sulawesi

The health services in Kalimantan and Sulawesi were less well developed than those in Java and Sumatra; both islands had recently experienced smallpox and both were difficult places in which to work. In February and March 1974 special searches for smallpox, involving pockmark and vaccination scar surveys in the age group 0–14 years, were therefore carried out in these islands. South Sulawesi, in which the last endemic cases had

been reported, was not visited, since an intensive eradication programme had been conducted there, followed by intensive surveillance. Primary schools and health centres were visited in the towns and large villages of 7 provinces of Kalimantan and Sulawesi, and inquiries made about smallpox rumours. It was considered that the epidemiological situation in these towns and villages, which were located in coastal areas and on rivers and served as communication centres for remote areas, would reflect that in the inland part of the islands which, because of limitations of time, funds and manpower, could not be searched.

A total of 27 538 children aged 0–14 years were examined in 22 selected localities. No facial pockmarks were found in the age group 0–4 years, while there were 27 pockmarked children in the age group 5–14 years, none of whom had had smallpox during the previous 2 years. This strengthened confidence that both Kalimantan and the selected provinces of Sulawesi had been free of smallpox since 1970. Vaccination scars were found in 26% of children in the age group 0–1 year, 58% in the age group 1–4 years, and 83% in the age group 5–14 years. These levels of vaccination coverage were not satisfactory but, in view of the low population density in these islands and their isolation from the main endemic areas of Java, it was thought likely that smallpox transmission there had been interrupted in 1969.

Visit of the International Commission

On 15 April 1974, 26 months after the last case of smallpox had been reported from Indonesia, the International Commission for the Certification of Smallpox Eradication (Plate 25.1) met in Indonesia. Dr Wehrle, who was well informed about the activities that had been undertaken in Indonesia and was thus in a position to guide the deliberations of the Commission, acted as chairman. After some discussion among the other members of the Commission, Dr Julie Sulianti Saroso, Director-General for the Control and Pre-

WHO

Plate 25.1. Participants in the meeting of the International Commission for the Certification of Smallpox Eradication in Indonesia, 25 April 1975. *Left to right, front row:* **J.J. Dizon (Philippines), J. Sulianti Saroso (Indonesia), P.F. Wehrle (USA)**, A. Karyadi (Indonesia); *middle row:* B. Cantayuda (Indonesia), **I. Tagaya (Japan), N.McK. Bennett (Australia), J.S. vention of Communicable Diseases in the Indonesian Ministry of Health, was included as a member. This arrangement might be thought to have reduced the objectivity of the Commission's assessment but, on the other hand, her presence provided additional assurance that no areas of the country would be barred to members of the Commission (see Chapter 24). After the first meeting in Jakarta, the members of the Commission, accompanied by programme staff, left for the areas judged most likely to harbour smallpox cases—namely, Jakarta, North Sumatra, South Sulawesi and West Java, which were visited during a period of 2 weeks (Fig. 25.3). In their field work, the members concentrated on assessing the extent and sensitivity of the surveillance activities and reporting system, as well as on examining health records and interrogating health service staff and the public. They visited as many localities as possible, searching for patients suffering from fever with rash, whom they examined to ensure that they did not have smallpox. The Commission then held its final meeting in Jakarta on 24 and 25 April 1974. Having concluded that there was no evidence that smallpox had occurred in Indonesia since January 1972 and that surveillance activities appeared to have been adequate to identify cases had they occurred, it approved the certification of the eradication of smallpox in Indonesia as a whole.

Because of the continuing high incidence of smallpox in the Indian subcontinent and the consequent risk of importations, the Commission strongly emphasized that "continuing vigilant surveillance and evaluation are necessary for all persons with illnesses suspected as smallpox", and recommended that "primary vaccination of infants and children against smallpox should be continued until global eradication of smallpox has been achieved".

CERTIFICATION IN AFRICA SOUTH OF THE SAHARA

The organization of certification in Africa south of the Sahara constituted a special challenge for a number of reasons. The region contained 42 countries which had previously been endemic, or whose neighbours had previously been endemic, and had become smallpox-free between 1967 and 1977 (Fig. 25.4). Communication within and between many of these countries was difficult, and the health service infrastructure in most of them was at a rudimentary stage of development. The certification programme was implemented by grouping countries together geographically and on the basis of similar histories of the elimination of smallpox. One such grouping, western Africa, comprising 15 countries, was the first in which the feasibility of certification of a regional group was tested (see Chapter 24); this was followed by the certification of 9 countries in central Africa.

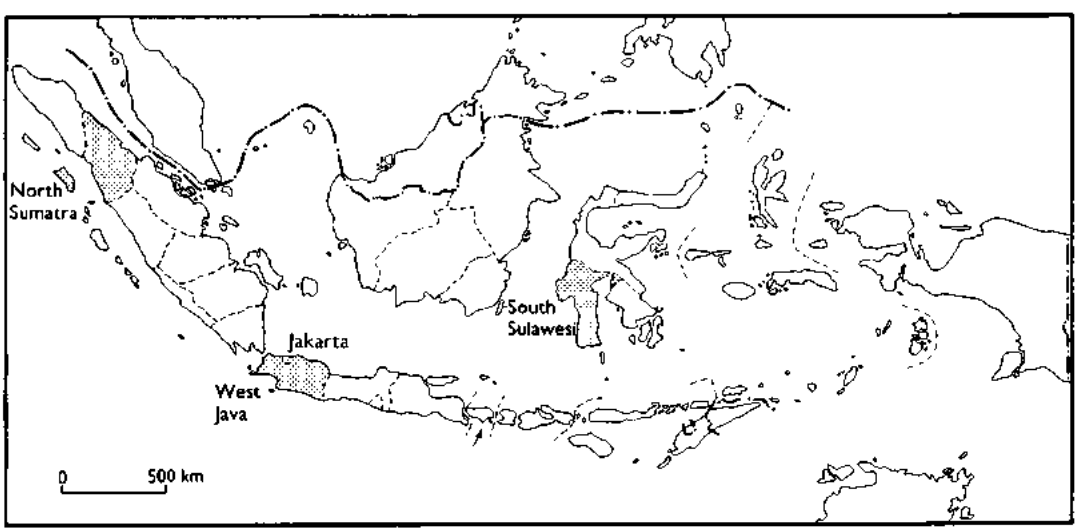

Fig. 25.3. Provinces of Indonesia (shaded) visited by members of the International Commission, 15–25 April 1974.

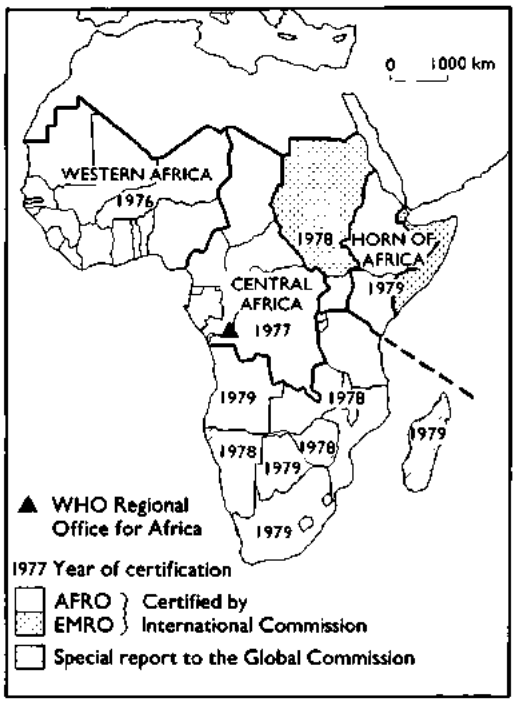

Fig. 25.4. Organization of certification in Africa south of the Sahara. A total of 42 countries were the subject of special certification procedures, 39 of them being in the WHO African Region and 3 (Djibouti, Somalia and Sudan) in the WHO Eastern Mediterranean Region. During 1976–1979 the certification programme was implemented by grouping countries together on the basis of geographical and epidemiological criteria.

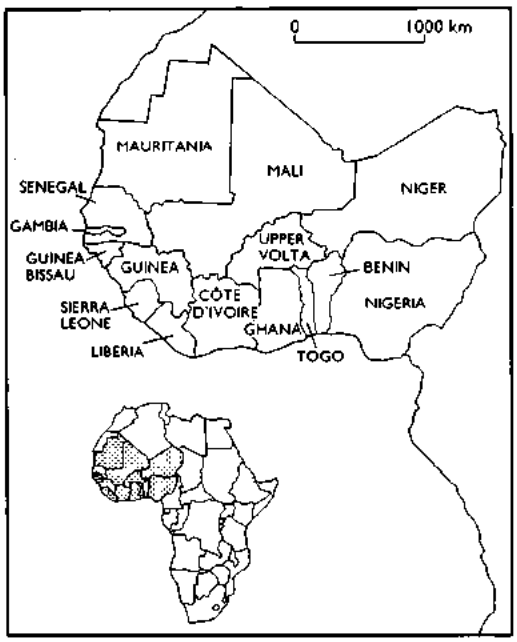

Fig. 25.5. The 15 countries of western Africa which were certified free of endemic smallpox by the International Commission in April 1976. Upper Volta is now Burkina Faso.

Arrangements based on the epidemiological and political situation in another 14 countries in eastern and southern Africa led to their certification in 1978 and 1979, by a variety of methods (see Chapter 26). The 4 remaining countries in the Horn of Africa, as the last group, were eventually certified by international commissions in October 1979 (see Chapter 27).

WESTERN AFRICA

In western Africa, 15 countries—Benin, Côte d'Ivoire, Gambia, Ghana, Guinea, Guinea-Bissau, Liberia, Mali, Mauritania, Niger, Nigeria, Senegal, Sierra Leone, Togo and Upper Volta (now Burkina Faso) (Fig. 25.5)—shared many features which made it logical to group them for the certification of smallpox eradication.

As has been described in Chapter 17, smallpox eradication and measles control programmes had been carried out in the region with United States support, and the last known outbreak of endemic smallpox had occurred in April 1970. Intensive surveillance had continued, with bilateral assistance, for more than 2 years thereafter, but both surveillance and the extent of vaccination had declined sharply after the assistance ceased. By 1976, when the International Commission for the Certification of Smallpox Eradication was scheduled to visit the region, the staff who had worked in the campaign had become involved in other activities or gone elsewhere, records were scattered or lost and smallpox surveillance activities had diminished. Because smallpox had been absent from these countries for more than 5 years, and because health services in western Africa were much less well developed than those in South America and Indonesia, it was decided that the surveys and documentation required before the Commission's visit could be—and, indeed, would have to be—simpler and adapted to the local situation.

Recent History of Smallpox

The eradication campaign in these countries has been described in Chapter 17. Data on the numbers of cases reported between 1966 and 1971 are shown in Table 25.9. Unlike certain other regions of Africa, western Africa had experienced only variola major, usually associated with a somewhat lower case-fatality rate than in the Indian subcontinent. Hence facial pockmark surveys provided a valuable means of assessing the past prevalence of the disease.

Variolation had formerly been widely practised in many countries in the region (Herbert, 1975), but in the 1960s it was observed only in a few localized areas, the last being in Dahomey (Benin) in 1969.

Preparations for Certification

Planning meeting, 3–6 February 1975

In order to plan a strategy for the certification of smallpox eradication in Africa, a meeting was held at the WHO Regional Office for Africa in Brazzaville, Congo, from 3 to 6 February 1975. It was attended by Dr Celal Algan, Regional Adviser on Communicable Diseases, Arita from the Smallpox Eradication unit at WHO Headquarters, and Dr Wehrle, the WHO consultant mentioned earlier in this chapter who had assisted with the planning of certification activities in Indonesia, together with other WHO staff.

The meeting agreed with the proposal that certification should start with the 15 countries of western Africa, since importations were very unlikely from Ethiopia, the only African country in which smallpox was then still endemic, as it was 1500 kilometres away and there was little communication between the two areas.

Decisions were reached on 3 matters: local funding, coordination of precertification activities and the preparation of country reports. For most countries, WHO agreed to provide funds to cover the local travelling expenses (living allowances, petrol and oil) of mobile teams carrying out pockmark surveys. The other matters required continuing attention, as described below.

Coordination of precertification activities

During 1975–1976 the WHO Regional Office for Africa had medical epidemiologists stationed in Brazzaville (Dr Ziaul Islam), Côte d'Ivoire (Dr Alexander Dobrescu, Dr André Delas), and Nigeria (Dr Leva A. Arevshatian) to assist in epidemiological surveillance in western Africa. To coordinate the activities, Arita travelled throughout the area twice in 1975. During these trips a detailed manual describing how to carry out a pockmark survey was prepared and various technical and administrative problems were solved in discussions with the WHO epidemiologists and national health staff. At the request of WHO, Dr Joel G. Breman, at that time an epidemiologist from the United States Center for Disease Control working for the Organisation de Coordination et de Coopération pour la Lutte contre les Grandes Endémies en Afrique de l'Ouest (OCCGE), also assisted in promoting prep-

arations in the OCCGE countries (Benin, Côte d'Ivoire, Mauritania, Niger, Senegal, Togo, and Upper Volta).

Preparation of country reports

In preparation for certification, each country was requested to provide, by the end of 1975, a formal country report documenting its smallpox eradication activities. Simple forms indicating the essential information required in the country report were distributed to all countries in the region in order to ensure uniformity in the documentation.

Pockmark surveys. Each of the countries was asked to organize pockmark surveys, carried out by special mobile teams operating for a period of 3–6 months. In order to simplify the operation, towns or villages with more than about 1000 inhabitants were to be selected, based on the demographic data for the country concerned, so that their combined population should be not less than 20% of the total population. In these localities, schools, maternal and child health clinics, hospitals and markets were to be visited to search for facial pockmarks in infants and children up to 15 years of age. Special instructions and forms describing how to select localities, how to conduct pockmark surveys and how to record the results were distributed to all the countries by WHO.

The surveys were completed by December 1975, and reports on the results became available in January 1976. As has already been mentioned, the localities surveyed were limited to large towns or villages, well distributed

Rationale for Pockmark Surveys in Western Africa

The rationale for conducting large-scale pockmark surveys in the countries of western Africa was outlined in 1976 in a memorandum by Henderson. In it, he discussed how best to provide the information that would allow an international commission to decide whether smallpox transmission had ceased in countries in which the last reported case had occurred several years earlier, and in which intensive smallpox surveillance had ceased some 5 years before the visit by the commission. He suggested that extensive facial pockmark surveys might be useful:

"For smallpox to have persisted during the past 4 years in the 15-country African area concerned, it is evident from what we know of the epidemiology of the disease that a large number of people living in a fairly large geographical area would have had to experience illness if the chain of transmission were to persist. Two-thirds of those afflicted would still bear facial scars of the disease and most of these would be children. To determine whether or not smallpox had been absent from this area, over this extended period, it would seem to me that one might examine a large number of children in many different geographical areas. If none had facial scars resembling those caused by smallpox which had been acquired during the past 4 years, one should be able to state with reasonable confidence that continuing smallpox transmission had not occurred in the 15-country area.

"To conduct such a study on a village-by-village basis would be ideal but expensive in terms of time and manpower. Practically, however, one might undertake to examine all those up to perhaps 15 years of age who attend school. Such an examination could be quickly performed as the children are already assembled in groups and children from a wide geographical area would be represented. Some, undoubtedly, would bear facial scars acquired more than 4 years before. If these children were identified, enumerated and the information confirmed that the disease had indeed been acquired more than 4 years previously, this would be further evidence that facial scars would be identified if present.

"An assessment which would be much simpler than this would be hard to visualize. The difficulties in undertaking such an appraisal would need to be carefully considered and, as well, whether the evidence obtained (with such other data as might be compiled) would be sufficient to permit an international commission to endorse the view that smallpox had been eliminated from the 15-country area concerned."

throughout the country; small villages in remote and inaccessible areas were excluded because of the considerable time and resources that would have been required to reach them. The view was taken, and later accepted by the International Commission, that, if smallpox transmission had continued, the disease should have reached larger towns or villages at some time between 1971 and 1976, and pockmarked persons would have been seen there.

The selection of localities can be illustrated by the arrangements made in Nigeria, the largest and most populous country in the region and the major focus of smallpox during the eradication campaign (see Chapter 17). Table 25.10 shows the numbers of localities of various sizes selected for assessment and their total population; 9.5% of all inhabited localities were surveyed, accounting for 37.7% of the total population of Nigeria. The localities were widely scattered throughout the country; their geographical distribution is shown in Fig. 25.6.

The field survey teams in the 15 countries examined a total of 6.5 million persons, made up of 1.6 million preschool children, 3.7 million primary-school children and 1.2 million over primary-school age, representing over 25% of schoolchildren up to 13 years of age and 5% of the total population of 122.4 million of western Africa (Table 25.11).

Table 25.10. Nigeria: number of localities selected for facial pockmark surveys, by population size

[d] Now Burkina Faso.

During these surveys, over 8000 individuals with facial pockmarks were identified among persons of primary-school age or older. Almost all of them had had smallpox before 1971; in a few, the lesions were due to other causes. In no case did the interrogation reveal a missed case of smallpox. There were no pockmarks among children below the age of 6 years.

Suspected smallpox cases. During the pockmark surveys the teams visited hospitals and dispensaries to ascertain whether there were any rumours of smallpox. If suspected cases were seen, specimens were taken for laboratory examination.

Between 1972 and 1976, 11 countries in the region had reported 127 cases of suspected smallpox, none of which was confirmed on investigation. In contrast to the extensive laboratory investigations in Indonesia (see Table 25.8), between 1971 and 1973, only 75 laboratory specimens had been sent to the WHO collaborating centre in Atlanta, USA, from western Africa (Table 25.12), because no special searches for suspected smallpox had been carried out. None of these specimens yielded variola virus, but in 41 of them herpesvirus particles were seen by electron microscopy.

Visit of the International Commission

The International Commission met first in Abidjan, Côte d'Ivoire, from 23 to 26 March 1976, to review the country reports and survey data. Western Africa was divided into 5 zones, each of which was visited by a team consisting of members of the International Commission accompanied by temporary advisers and WHO personnel. Each team visited all the countries in the zone allocated to it. Their investigations included a review of additional records available at the national and local levels, interviews with personnel involved in various aspects of the programme, and visits to selected localities to verify the sensitivity and effectiveness of the smallpox surveillance effort, including verification of the recently completed facial pockmark surveys. The Commission finally met in Brazzaville from 12 to 15 April to consider the additional data obtained during the field visits.

A number of questions had been clarified during the field visits. Overall, the reports showed that in all the countries excellent vaccination and surveillance programmes had been conducted in 1967–1972 and good pockmark surveys in 1975. Although the surveillance and reporting systems in most countries were better than those in operation before the eradication programme began in 1967, no cases of smallpox had been reported from any country in the region since 1970. In addition, between 1970 and 1976, 8 cases of human monkeypox had been discovered in Côte d'Ivoire, Liberia, Nigeria and Sierra Leone. The disease resembled smallpox clinically but not in its epidemiology (see Chapter 29). The fact that these cases, which had occurred in remote areas, had been discovered was evidence of the efficiency of the surveillance systems.

The long period (6 years) of apparent freedom from smallpox in western Africa predisposed the Commission to believe that transmission had been interrupted, a view that was strongly supported by the fact that the very extensive pockmark survey had produced no evidence of smallpox transmission after 1971.

The Commission concluded that there was no evidence that smallpox had occurred in the 15 countries of western Africa since 1970, and certified the region as being free of smallpox. Bearing in mind that smallpox transmission persisted in Ethiopia, however, it recom-

mended that vaccination programmes should continue, particularly for preschool children. Continued careful surveillance, and especially the reporting and investigation of all chickenpox outbreaks in which deaths had occurred, was most important, so as to make certain that these outbreaks were not caused by smallpox introduced from an endemic area or by monkeypox or related viruses.

CENTRAL AFRICA

Following the certification of smallpox eradication in the 15 countries of western Africa, preparations for certification were organized over the period June 1976 to June 1977 for 9 countries of central Africa: Burundi, Cameroon, Central African Republic, Chad, Congo, Equatorial Guinea, Gabon, Rwanda and Zaire (Fig. 25.7). Apart from forming a geographical unit, these countries shared several features which made it reasonable to group them together for certification. As in western Africa, the USA had supported a smallpox eradication and measles control programme in certain countries in the region between 1967 and 1972—namely, Cameroon, the Central African Republic, Chad, the Congo, Equatorial Guinea and Gabon. WHO-assisted smallpox eradication programmes had been in operation in Burundi, Rwanda and Zaire. Zaire, the largest of these 9 countries, with a population of 26 million in 1977 (half the entire population of the group), developed a WHO-assisted smallpox eradication programme in 1967. The last case of smallpox in Zaire—the last in this group of countries—was recorded in June 1971, and active surveillance was continued throughout Zaire, with WHO support, until 1977.

Fig. 25.7. The 9 countries of central Africa certified free of endemic smallpox by the International Commission in June 1977.

French was the official language of 8 of these central African countries,[1] making it much easier to prepare documentation and arrange meetings than in western Africa, in which both English and French had to be used.

Recent History of Smallpox

Smallpox had been endemic in most of these countries until the mid-1960s (Table 25.13). In the 1950s and early 1960s outbreaks

[1] Both English and French are official languages in Cameroon, while Spanish is that of Equatorial Guinea.

of both variola major and variola minor had been reported in Zaire, but there was some uncertainty about the validity of diagnoses (see Chapter 18). After 1962 the usual African type of variola major was the only variety of smallpox seen in all these countries, hence pockmark surveys promised to be as useful here as they had proved to be in western Africa.

Preparations for Certification

Coordination of precertification activities

It had been agreed that, in preparing for certification, activities similar to those found satisfactory in western Africa should be carried out—namely, the preparation of standardized, relatively simple country reports and the organization of pockmark surveys. Work on the preparation of country reports was begun in July 1976, and from 11 to 15 October 1976 a coordination meeting was held in Brazzaville to discuss the preliminary results and the procedures to be followed.

Representatives from the 9 countries, together with consultants and staff from the WHO Smallpox Eradication unit, attended the meeting, at which the preliminary country reports submitted by country representatives and the methodology of pockmark surveys were reviewed. WHO agreed to provide funds to cover the local travelling expenses (living allowances, petrol and oil) of mobile teams carrying out pockmark surveys. June 1977 was agreed as the date for the visit of the International Commission, since it was thought that by then all country reports and pockmark surveys would have been completed.

Dr Islam provided each country with the statistical data available at the WHO Regional Office for Africa in Brazzaville. Since such data were not always easily available in the countries concerned, this greatly facilitated the preparation of the country reports.

Zaire was treated differently from the other countries. A detailed country report was requested, but it was agreed that pockmark surveys would be carried out only in the epidemiologically critical border areas, since country-wide active surveillance for smallpox had continued ever since the discovery of the last case in 1971. A special monkeypox survey was planned as part of the precertification activities, since monkeypox was clinically indistinguishable from smallpox. It consisted of a search for unreported human monkeypox cases or smallpox-like disease in areas within a 25-kilometre radius of villages in which human monkeypox cases had occurred in the past.

Preparation of the country reports

Pockmark surveys. The field survey teams examined over 1.3 million persons, constituting 2.5% of the total population of the central African countries (Table 25.14). In all, 1.5% of preschool children and 8.8% of schoolchildren were examined. Pockmarks were found in 1420 schoolchildren and 146 adults, but there were none in the preschool age group (0–5 years).

Table 25.14. Central Africa: results of pockmark surveys, 1976–1977

Country	Population (millions)[a]	Number of persons examined

[a] Population data for 1977 from United Nations (1985).
[b] Number of persons with facial pockmarks shown in parentheses.
[c] . . = data not recorded.

Laboratory diagnosis. The number of specimens sent to WHO collaborating centres between 1972 and 1976 varied from one country to another (Table 25.15), but the great majority were collected in Zaire. Variola virus was not found in any of the 748 specimens examined, but 14 specimens collected in Zaire were found to contain monkeypox virus.

Visit of the International Commission

The first meeting of the Commission was held in Brazzaville from 6 to 8 June 1977. Subsequently, the Commission formed 6 teams, which between them visited all the countries in the region. The type of investigation undertaken by these teams can be illustrated by the report of the subgroup that visited Zaire, which consisted of Dr A. M'Baye and Dr J. G. Breman, Commission members from Senegal and the USA respectively, assisted by Dr Pierre Ziegler and Dr Edilberto Zanotto, former WHO staff from the Zaire smallpox eradication programme.

Between 8 and 26 June 1977 the subgroup reviewed the country report, the results of the facial pockmark survey and the special report on monkeypox, and visited 28 zones in Zaire, including some in each of the 9 regions of the country. In addition, the detailed locally prepared survey reports were reviewed and 57 government and private health units visited.

The subgroup also visited 35 schools, 16 markets and a refugee camp in order to examine preschool children and schoolchildren for facial pockmarks caused by smallpox. In all, 13 450 children were examined or re-examined. No child of less than 7 years of age showed facial pockmarks attributable to smallpox. The vaccination coverage of schoolchildren was satisfactory (about 90%). Investigations by national staff of 33 suspected cases were reviewed by the subgroup; no evidence of recent smallpox was found.

The Commission met again in Brazzaville from 28 to 30 June 1977 and, after discussing the findings of the field visits, concluded that there was no evidence that smallpox had occurred in any of the 9 countries of central Africa since August 1971. Specific questions by the teams about variolation and laboratory stocks of variola virus elicited the information that variolation was not practised in any of these countries, nor were stocks of variola virus held in their laboratories. Since smallpox was still endemic in Somalia, the Commission recommended that careful surveillance should be continued and vaccination campaigns maintained, particularly for preschool children, in all countries until such time as the global eradication of smallpox could be certified. The Commission also recommended that active surveillance of human monkeypox should be maintained.

Table 25.15. Central Africa: number of specimens from suspected cases of smallpox submitted to WHO collaborating centres for laboratory diagnosis, 1972–1976

Country	Number of specimens[a]	Monkeypox virus present

Rwanda	2	0
Zaire	691	14
Total	748	14

[a] All negative for variola virus.

CERTIFICATION IN AFGHANISTAN AND PAKISTAN

Afghanistan and Pakistan, which share a border of about 1000 kilometres, were the first countries on the Asian mainland from which the eradication of smallpox was certified. In both, the national eradication programmes were started in 1967; the last cases were recorded in 1973 and 1974 respectively. The geographical features and ethnic make-up of the border areas were similar on both sides of the frontier and cases had been imported across it into Afghanistan. Smallpox was still endemic in India in 1975, but Pakistan's long border with India was closed, and population movements across it were infrequent.

In contrast to the situation in western and central Africa, in which the last outbreaks occurred in 1970 and 1971 respectively and many countries in both regions had been free of endemic smallpox for several years previously, the disease had been endemic in Afghanistan and Pakistan recently enough for the intensified surveillance of the later

stages of the eradication programme to be carried over into the preparations for certification. For this reason reliance was placed on active surveillance and searches, rather than on the pockmark surveys used in Africa. The same international commission dealt with the certification in both countries in the latter part of 1976, a few months after the certification of western Africa and before that of central Africa.

AFGHANISTAN

The last case in Afghanistan was recorded in July 1973 but, because of the prevalence of smallpox in neighbouring Pakistan and the concern that foci of unreported smallpox might remain in remote areas of the country, surveillance was reinforced. Dr Arcot G. Rangaraj, a WHO epidemiologist, remained in Afghanistan until certification had been completed. Dr Abdul Mohammad Darmanger of the Ministry of Health played an important role in the 12-member National Committee for Smallpox Eradication, which took responsibility for the preparations for certification.

Analysis of the sources of outbreaks occurring during the last 4 years of endemic smallpox (Table 25.16) showed the need to pay particular attention, in the precertification surveillance activities, to variolation and nomadic groups.

Precertification Activities

Surveillance: 1973–1975

For operational purposes, Afghanistan was divided into 4 zones (see Chapter 14, Fig. 14.3) and subsequently into 3 zones—namely, Kabul, Kandahar and Kunduz (see Fig. 25.8). To search for and investigate suspected cases, special surveillance teams had continued work after the last case, 3 teams being located in the Kabul zone, 3 in the Kandahar zone, and 1 in the Kunduz zone. Special surveys

Table 25.16. Afghanistan: outbreaks of smallpox, 1970–1973

Source of outbreaks	1970		1971		1972		1973	
	Number	%	Number	%	Number	%	Number	%

were organized in areas in which smallpox outbreaks had occurred after 1967, either through natural transmission or through variolation, and in border provinces, as well as those in which nomads were concentrated during the summer. During the period 1974–1975, 255 of the 327 administrative units of the country (78%) were visited by surveillance teams, but no new focus of smallpox infection, indigenous or imported, was detected.

About 700 villages were identified in which variolation had been practised in the past, and 90 of them—those in which it had been performed most recently—were repeatedly checked and visited. Neither practising variolators nor fresh variolation scars were detected. In addition, 155 nomad encampments were visited and searched in the Kabul, Kunduz and Kandahar zones, with the same result.

Special active search in 1976

A special active search for suspected cases in rural areas was carried out in 1976 by 7 smallpox surveillance teams and 15 combined BCG/smallpox vaccination teams. These teams checked all villages with more than 250 persons and, regardless of the size of the population, all previously affected villages and those in which variolation had been practised. The teams moved from province to province, arranging their operations according to the climatic and geographical conditions of the area to be searched. Of the 28 provinces, 22 were covered, an average of 6–8 villages being visited daily by each team. Over 8000 villages were searched, accounting for 93% of the villages with a population of more than 250 in the country. Teams also visited and interviewed people in 1548 markets, 2100 tea-shops and 1192 schools throughout the country. Two months later, the same areas were visited by assessment teams which interviewed villagers and assessed the work of the search teams in 10% of these villages. It was found that many villagers had seen searchers and 88% knew where and to whom to report suspected cases. During the search, 262 suspected cases of smallpox were found; 135 (51%) of them proved to be cases of chickenpox and 110 (42%) measles; the remaining 17 were cases of other skin diseases such as eczema, scabies and dermatitis.

A special pockmark survey was conducted among the 0–4-year-old children of nomads. Altogether, 5107 of these children were examined in 8 provinces inhabited by nomads during the summer. Only 2 children with pockmarks were found, both of whom had contracted smallpox more than 3 years earlier while travelling between Pakistan and Afghanistan.

Collaboration of the malaria control programme in the active search

During the period April–June 1976, in addition to the active searches carried out by surveillance and mobile vaccination teams, about 1000 malaria control programme workers carried out another search in densely populated areas below an elevation of 2000 metres—i.e., where malaria transmission occurred. About 13 000 villages were visited, 680 000 households searched and about 3 million people interviewed. Not only were suspicious cases detected, none of which proved to be smallpox, but the search also assisted in increasing the awareness of the

population of the need to notify suspected smallpox cases.

Hospital searches

In April June 1976, local health staff in provincial hospitals, maternal and child health clinics and basic health centres made inquiries among visiting outpatients about any suspected cases present in their home villages or towns. The search resulted in the detection of 223 suspected cases; 55% proved to be measles and 28% chickenpox, the remaining 17% including a variety of skin diseases. Furthermore, staff of the provincial hospitals participated in searches in the towns and in villages located within a 5-kilometre radius. As an incentive, from 1976 onwards a reward of 3000 afghanis (US$51) was offered for every report of a confirmed case of smallpox. Despite these activities, no evidence was found of recent smallpox. All the results indicated that smallpox had not been present in the country during the previous 3 years.

Variolation

From the inception of the Intensified Smallpox Eradication Programme in Afghanistan, there was concern that variolators, who were especially active in the central and eastern parts of the country, might play an important role in smallpox transmission (see Chapter 14). In fact, 47 of the 237 outbreaks recorded between 1970 and 1973 could be specifically attributed to variolation (see Table 25.16). The last known variolation in Afghanistan was recorded in Dand Area of Kandahar Province in April 1976. However, none of the 57 children variolated at that time had developed any skin lesions at all. Evidently the variolation material used contained no viable virus.

Throughout the eradication programme, staff had attempted to identify variolators, to learn about their practices, and to persuade them to give up variolation. Whenever possible, they collected specimens of variolation material so that it could be assayed for the presence of viable virus. Also, intensive efforts were made to educate the population about the dangers of variolation and to vaccinate systematically throughout the country in order to demonstrate that vaccination was available to all. These measures proved to be remarkably successful.

The remaining question of concern was whether it might be possible for a variolator to retain over a period of many years scabs containing viable variola virus of sufficiently high titre to permit successful variolation. Variolators who were interviewed in 1976 claimed to have given up the practice during the previous few years, partly because villagers had gradually ceased to seek their services and partly because of pressure from the government. Most variolators asserted that the variolation material they had used was not effective for more than 1 or, at most, 2 years. Since smallpox had been absent from the country during the past 2 years it was therefore thought unlikely that many persons would attempt variolation because of the lack of effective material. Of 9 specimens collected from variolators in Afghanistan from 1969 to 1976, none had yielded viable virus since 1970, when smallpox was still endemic (Table 25.17).

Specimens were studied by virus isolation and electron microscopy, virus being isolated

Table 25.17. Afghanistan: results of laboratory tests of specimens of variolation material obtained from variolators

Age of specimen	Type of material	Date collected	Results	
			Poxvirus particles by electron microscopy[a]	Virus isolation
?	Fluid	March 1969	..	+
9 months	Scabs	May 1969	..	+
4 months	Scabs	September 1969	..	+

6 years	Scabs	May 1976	+	−
10 years	Scabs	May 1976	+	−

[a] Virus particles may be visualized by electron microscopy, even though not viable; .. = not done.

from 4 of them. Three of the isolations were made from relatively fresh samples, 2 being between 4 and 9 months old; the third was fluid and would have dried up if it had been stored for more than 12 months. The fact that, as Table 25.17 shows, in 4 other specimens numerous poxvirus particles could be demonstrated by electron microscopic examination but virus could not be isolated suggested that viable variola virus probably did not survive under normal conditions for more than 2 years, or perhaps a much shorter period.

However, in the cold mountainous regions of Afghanistan in particular, the possibility could not entirely be ignored that one or more variolators might have been able to preserve for years material which contained variola virus with a titre sufficient to produce successful takes. One variolator from Kunar Province had stated in an interview that he (as well as a colleague in Peshawar, Pakistan) usually preserved scabs in a screw-capped container which was buried in the ground in a mountainous area. He considered this material to be effective for up to 10 years. On further questioning, however, he stated that fresh material had to be added to the basic stock each year.

Visit of the International Commission

The International Commission visited Afghanistan between 22 and 29 November 1976. After a preliminary meeting in Kabul, members of the Commission visited the 3 national smallpox eradication programme zones (Fig. 25.8) before their final meeting in Kabul.

They found that good records had been kept of smallpox control activities and that the work of the zonal smallpox eradication programme staff was of a high order. The basic health service units played a valuable role in investigating suspected cases of smallpox, but the recording and reporting of such activities was not standardized and was deficient in places. A number of recent suspected cases were reinvestigated and confirmed not to have been smallpox. The pockmark surveys of children showed that no outbreaks had occurred after the time when the zone concerned had been considered to be free from smallpox. No pockmarks were observed in children under the age of 5 years.

Checks for vaccination scars confirmed that a very high proportion of children had been vaccinated, as reported by national smallpox eradication programme staff, the major exceptions being in some nomad camps, where small groups of families were found to have been missed. The Commission teams were most impressed with the level of knowledge about smallpox, vaccination and the importance of reporting suspected cases found among all sections of the community. Knowledge of the reward was widespread in most of the provinces visited.

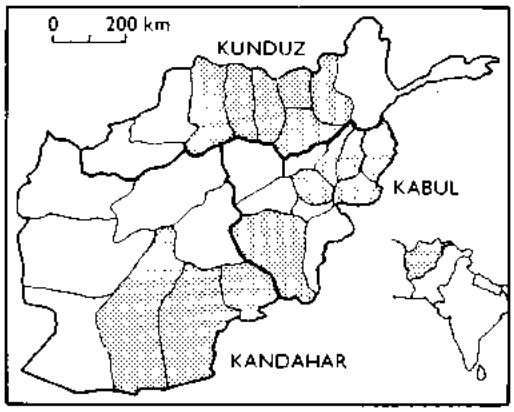

Fig. 25.8. Provinces (shaded) in the 3 zones of Afghanistan visited by members of the International Commission in November 1976.

Variolation scars, which could be distinguished from scars due to vaccination since they were on the wrists or the dorsum of the forearm (see Chapter 14), were common in adults, but there was no evidence of recent variolation other than that reported in Kandahar Province in April 1976, already mentioned.

The Commission certified smallpox eradication in Afghanistan on 30 November 1976, noting that the energetic and thorough surveillance activities carried out since 1972 would have been adequate to disclose cases of smallpox if they had occurred. Because some parts of Asia had still to be certified and the transmission of smallpox was still occurring in the Horn of Africa, the Commission recommended that surveillance and vaccination should be continued until global eradication had been certified.

As far as variolation was concerned, the Commission concluded that, although it was unlikely that scabs containing live virus remained in the possession of variolators, the possibility that variolation might cause future outbreaks could not be completely

excluded. The Commission was concerned about this prospect and strongly recommended that vigilance should be maintained. In fact, a further 3 years elapsed after the Commission's visit before the Global Commission finalized its report, during which time no case of smallpox was reported. This strengthened the belief that viable variola virus did not survive in variolators' material.

PAKISTAN

The last case of smallpox occurred in Pakistan in September 1974 (Table 25.18) and eradication was certified in December 1976.

Precertification Activities

As in Afghanistan, surveillance measures were further strengthened in all provinces after eradication because of the concern that foci of unreported cases might still be present, especially in "problem areas"—i.e., areas not easily accessible for geographical or political reasons. First priority was given to active search operations.

Country-wide searches

In 1975 several active searches were carried out by various categories of staff: vaccinators, searchers, malaria and family planning field staff and other health workers. In 1976 the searches were extended to the entire country, covering the majority of the rural areas. Three complete search operations were carried out in January, May and August 1975, usually for periods of 2 weeks each, although this was extended to 21 working days in many areas to ensure the best results. After each search operation, an independent assessment was made by the district and provincial surveillance teams, covering 5% of randomly selected localities in the territory already searched.

Similar search operations were carried out in urban areas throughout Pakistan. The administrative organization and health services available in the towns made it necessary for these searches to be carried out independently of those in rural areas. In general, municipal vaccinators and general health staff, supported by volunteers, carried out house-to-house searches in all slums, sweeper colonies (areas to which migrants normally went), other poor socio-economic areas, cantonment areas, railway settlements, the areas in which the last 20 outbreaks of smallpox had occurred, and the areas on the outskirts of towns in which nomads usually settled. In June and July 1976 a special all-Pakistan urban search was carried out in towns with a population of over 50 000, and in all district headquarter towns, regardless of their size. An intensified health education campaign was also carried out in these towns before search activities commenced.

Searches in problem areas

Provincial and district surveillance teams, assisted by local health staff, organized repeated special searches in the problem areas previously mentioned, which might not have been properly searched in the course of eradication activities. As a rule, randomly selected villages and settlements in such areas were visited, and information on the occurrence of smallpox cases during the past 2 years was collected and checked; in addition, vaccination scar and pockmark surveys were carried out among children under 5 years of age.

These special searches were intensified during the first half of 1976, when particular attention was paid to parts of Azad Kashmir, the areas bordering on China, remote areas of Baluchistan inhabited by nomads, mountain-

ous parts of Punjab, flood-affected riverine areas in Sind and on the border with India, and the Thar desert (Fig. 25.9).

Active searches in areas in which the last outbreaks occurred

During 1975 and again in March–April 1976, a special team composed of the most competent vaccinators, sanitary inspectors and health assistants, together with district surveillance teams, visited the areas in which the last 20 outbreaks had occurred in each district, reassessed the previous reporting, case-finding and containment activities, and carried out an active case search in all the localities within a 5-mile (8-kilometre) radius of the previously affected areas. Pockmark surveys were conducted on a large scale, particularly among children under 2 years of age, in an effort to find undisclosed cases, but none was found in that age group.

In the districts in which smallpox incidence had been low and the number of outbreaks small, all localities which had had smallpox outbreaks in 1974 were visited and the epidemiological situation rechecked in an effort to disclose possible continuing transmission.

To assess surveillance independently, surveillance teams from one province visited another province or area for periods varying from a few weeks to 2 months. Thus, in 1976, provincial and district teams from Punjab assessed the efficacy of the programme operations in Azad Kashmir, Baluchistan, and North-west Frontier Province; Sind provincial and district teams did the same in Baluchistan and Punjab.

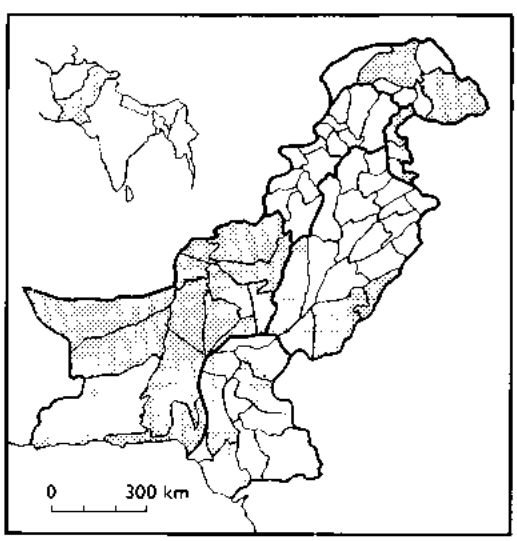

Fig. 25.9. "Problem areas" in Pakistan (shaded), in which special searches were carried out during pre-certification activities in 1976.

Rewards

The cash reward offered for finding smallpox cases was increased from 100 rupees (US$10) to 200 rupees, and in July 1975 to 500 rupees. The reward was publicized as widely as possible by means of the radio, press and wall posters in order to encourage the public to report suspected cases.

In November 1975, the following new system of rewards was introduced:

— 1000 rupees to anyone who reported an active case of smallpox;

— 100 rupees to any health worker who discovered a child with facial pockmarks that originated from a smallpox-like disease which had occurred after October 1974;

— 1 rupee to search workers for every chickenpox case visited and recorded during the all-Pakistan search operation in January 1976.

The participation of the local administrative authorities was sought. A special postcard, signed by the Deputy Commissioner, was sent to each *numberdar* (village leader), asking him to question, within a week, all the inhabitants of his village as to the presence of smallpox cases and, if any existed, to report them immediately to the district authorities.

Results

As a result of all these activities, 49 874 cases of fever with rash were detected, reported and investigated by November 1976. The reporting of cases of chickenpox during the search periods was encouraged (Table 25.19), on the assumption that a surveillance system sufficiently sensitive to detect them would almost certainly detect smallpox outbreaks. Altogether, 27 703 chickenpox cases were reported. Laboratory specimens were collected from 157 cases in which the diagnosis was in doubt and tested by WHO collaborating centres for the presence of variola virus, with negative results. No focus of smallpox infection, indigenous or imported, nor any recent case of smallpox was detected. All the information obtained in

Table 25.19. Pakistan: number of cases of fever with rash investigated and number of cases of chickenpox reported between October 1974 and September 1976, by province or area

Province or area	Number of cases of fever with rash	Number of cases of chickenpox
Azad Kashmir and northern areas	608	524

Total	49 874	27 703

1975–1976 served to confirm that the disease had not been present in the country since October 1974.

Variolation

Variolation had been practised in Pakistan both in North-west Frontier Province and to a lesser extent in Punjab, but on nothing like the scale found in Afghanistan. Material was collected from several variolators during 1975. In 1976, local health staff throughout the country were asked to inquire about variolations performed in the last 12–18 months, to visit the areas concerned, and to try to locate the variolators and collect variolation material from them. Examination of 11 specimens by electron microscopy revealed poxvirus particles in 9, none of which yielded viable virus (Table 25.20). One specimen collected in 1975 showed numerous herpesvirus particles, suggesting that a professional variolator, desperate to find a smallpox patient from whom he could replenish his material, took specimens from a chickenpox patient, either deliberately or after misdiagnosis.

Visit of the International Commission

The International Commission for the Certification of Smallpox Eradication in Afghanistan was also responsible for certification in Pakistan. It travelled to Islamabad after completing its visit to Afghanistan, and remained in Pakistan from 6 to 18 December 1976, members visiting 37 of the 71 districts or agencies in the country (Fig. 25.10).

Field visits

Evidence of the recent occurrence of smallpox was sought by means of pockmark surveys, especially among children, and by questioning people. A number of recent suspected cases were reinvestigated and confirmed not to have been smallpox. The areas selected for special searches included some of those in which smallpox had occurred late in 1974. Scar surveys were carried out to assess vaccination coverage and the extent of variolation. Where possible, known variolators were traced and interviewed and sites of outbreaks due to variolation were revisited. Inquiries were made among different sections of the population to determine the extent of

their knowledge of smallpox and of the reward offered for its detection.

Results of searches

The Commission's teams found pockmarks in 99 out of more than 7000 children under the age of 15 (1.4%). Only 5 children under 5 years of age were found to have pockmarks; all were recorded cases from outbreaks which had occurred before October 1974. No undisclosed outbreaks were discovered during the Commission's surveys. A substantial number of recent outbreaks were reinvestigated and details of the cases verified in the records. No missed cases were discovered. The checks for vaccination scars showed that a very high coverage had been achieved among adults and older children, somewhat less satisfactory levels being found in some areas among children under 5 years of age.

The evidence of variolation scars in adults confirmed that this practice had been common many years previously in parts of Baluchistan, in certain of the tribal areas of North-west Frontier Province and in a few communities in other provinces. Variolation scars were seen in children in 2 of the areas associated with documented episodes in 1974 but, despite careful searches, not in children elsewhere. Ten former variolators were interviewed. They stated that variolation material did not remain potent for more than a year at the most and that the practice had been abandoned. Signs advertising the reward for

reporting smallpox were seen in many of the places visited and, although their distribution was uneven, knowledge of the reward was widespread.

Conclusions

The Commission concluded that the smallpox eradication programme had achieved its goal in October 1974 and that there had been no smallpox transmission in Pakistan since that time. Although population movements across the long border between Pakistan and India were very limited, the Commission recommended that primary vaccination should be continued at least until the whole of Asia had been certified to be free of smallpox.

CERTIFICATION IN THE REST OF THE INDIAN SUBCONTINENT AND BURMA

Bangladesh, Bhutan, Burma, India and Nepal, contiguous countries in a vast area (Fig. 25.11) in which smallpox had been endemic for centuries, with frequent transmission across the international boundaries, were dealt with next. The last case of smallpox in India was reported in May 1975. Nepal and Bhutan experienced a number of importations from northern India as late as 1974 and 1975. In Bangladesh, freed from smallpox in 1971, major epidemics developed from 1972 onwards as a consequence of importations from West Bengal and Bihar. The last outbreaks of smallpox in Burma occurred in 1969, when an importation from Bangladesh resulted in 68 cases. Thus, in these 5 countries, continuing freedom from the disease depended very much on whether the adjacent country was smallpox-free. Because of India's large size and vast population, the smallpox situation in that country greatly influenced that in the others. Bhutan recorded its last smallpox case in February 1974, Nepal in April 1975 and India in May 1975 (Table 25.21). For certification purposes, these 3 countries were treated as a group and certified by international commissions in April 1977. Bangladesh recorded its last case in October

1975 and was certified in December 1977. Because of its contiguity, Burma was certified together with Bangladesh.

INDIA, NEPAL AND BHUTAN

India

The last case of smallpox in India occurred in May 1975 and the country was certified to be free of smallpox in April 1977. Precertification activities were recognized as an essential follow-up to eradication, and WHO support in terms of personnel and funds (provided by Sweden) was continued. About 60 epidemiologists (20 international and 40 national) participated in the 2-year preparation for certification, a detailed account of which is given in Basu et al. (1979). Ježek, Dr Lev Khodakevich and Dr Nicholas Ward were responsible for coordinating the activities on behalf of WHO. At the national level, Dr R. N. Basu took full responsibility for certification preparations. Detailed planning was discussed at an informal workshop held in Kathmandu, Nepal, from 29 January to 2 February 1977 (Plate 25.6).

Precertification activities

A thorough programme was undertaken, consisting of the following components: intensified surveillance for cases of fever with rash, active searches for possible cases of smallpox, laboratory testing of suspected cases of smallpox, and finally a comprehensive assessment of all this work by a national assessment commission.

Surveillance of outbreaks of fever with rash. A system for the surveillance of all cases of fever associated with a rash was introduced throughout India in January 1976. This required each health worker to report all such cases, as well as cases of and deaths from chickenpox, in addition to all cases suspected of being smallpox. Special registers for cases of fever with rash were established at each basic reporting unit—namely, 5323 primary health centres, 1005 municipal health offices, 1050

Monnier (WHO), A.M. Scardaci (WHO), J.S. Friedman (WHO).

selected hospitals and 797 other peripheral notification posts, as well as 428 smallpox eradication programme offices based in district and state health establishments.

Active search operations. Active search operations, initiated as part of the eradication campaign in the autumn of 1973 (see Chapter 15), continued throughout the period from May 1975, when the last case was discovered in India, until April 1977, when the International Commission visited the country. The frequency of these active search operations is shown in Fig. 25.12.

Compared with the searches in 1973 and 1974 during the eradication programme, those carried out in 1975 and 1976 were both much more extensive and more intensive, and included 3 country-wide searches conducted in the autumn of 1975, the spring of 1976 and the autumn of 1976. These involved some 110 million households in more than half a million villages and 2600 urban areas. The major national search operations aimed at recording not only suspected cases of smallpox, but also any cases of fever with rash, including chickenpox, measles and certain skin diseases. In addition, individual states intermittently carried out their own searches. Diagnoses were verified only by higher-level health officers. A reward of 1000 rupees (US$100), introduced in July 1975, was offered to both searchers and health officers and the general public, and provided a strong incentive for the searchers to discover cases of smallpox, if they did occur (Plate 25.7).

More than 95% of all the villages in India were searched during each country-wide search. No smallpox cases were found although tens of thousands of cases of chickenpox were seen. The results of the subsequent assessment of some 10% of the villages already searched indicate that about 70% of the families knew about the smallpox reward and where to report the disease should they find it. Fig. 25.13 shows the percentages of households assessed as having seen the searchers in each survey, by district. The coverage by searchers was good in the 1975 search and improved still further in those carried out in 1976 (Table 25.22).

Percentage that saw searchers	94.0	79.3	86.0
Percentage that knew of reward	73.0	80.4	83.0

During 1976, altogether 1 951 487 cases were recorded in the registers for cases of fever with rash, 60% of them following active searches, 36% following routine village visits by health staff, reports by members of the public or through the secondary surveillance system, and 4% as a result of market searches. All cases were examined by experienced health supervisors and none was found to be smallpox. The data on cases

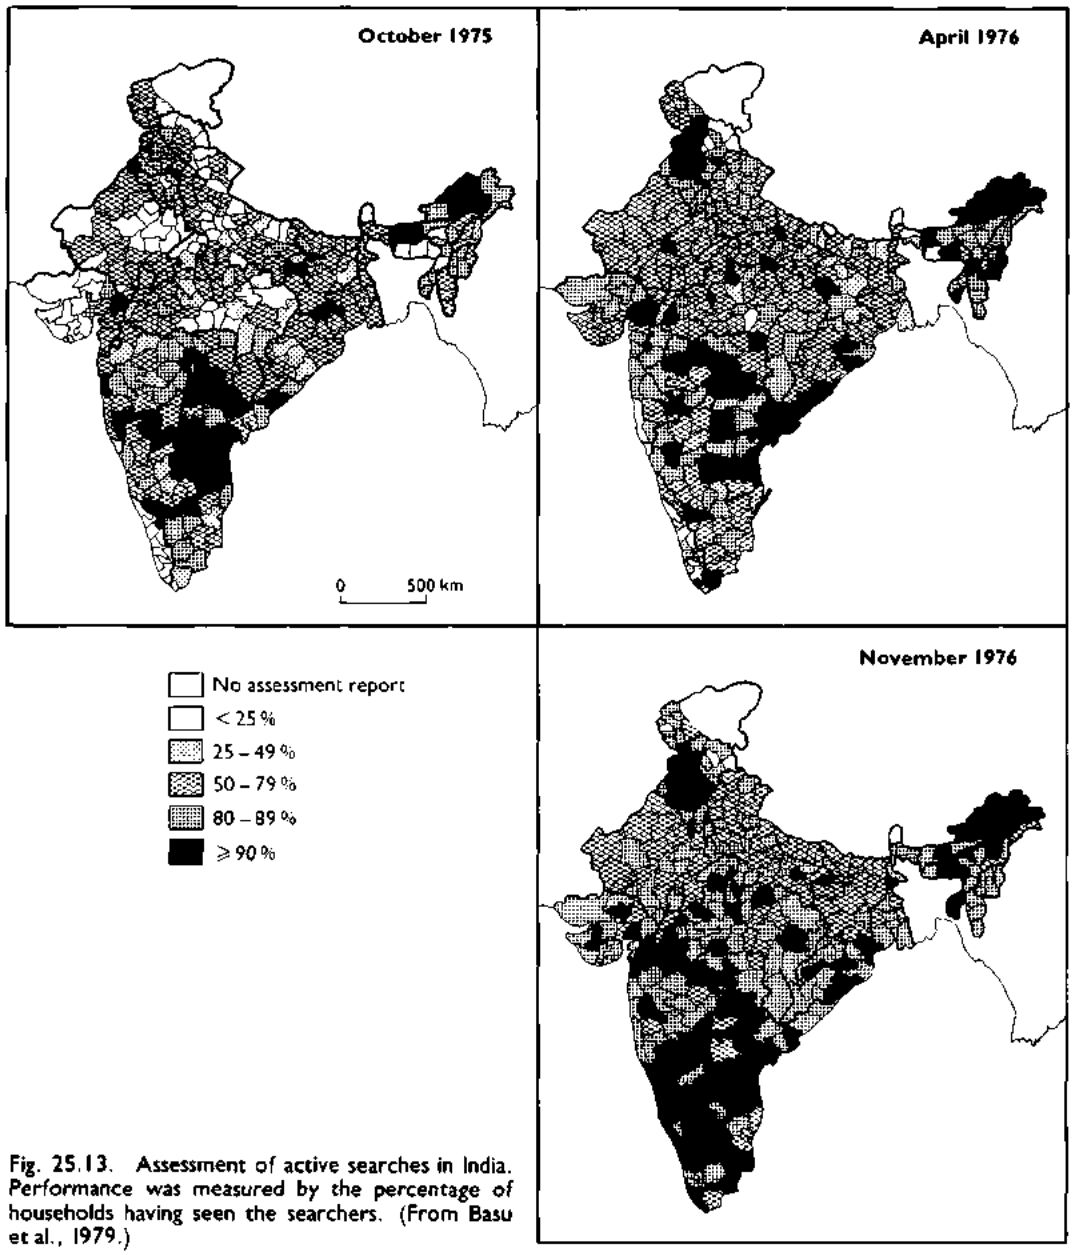

Fig. 25.13. Assessment of active searches in India. Performance was measured by the percentage of households having seen the searchers. (From Basu et al., 1979.)

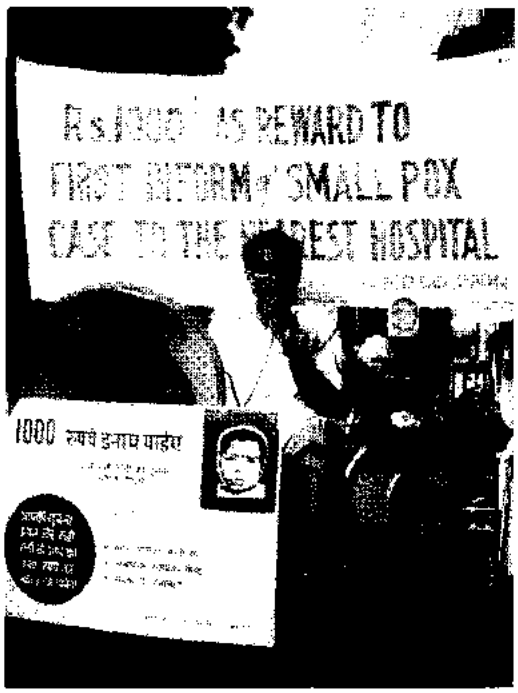
entered in the registers are analysed in Table 25.23. In the same year, 519 651 localities in which these cases had occurred were visited by experienced senior health workers (37% of them by medical officers); in the first quarter of 1977, a further 322 526 localities were visited. The number and thoroughness of these investigations made it difficult to believe that smallpox could have persisted in India for 2 years without being detected.

Furthermore, 520 cases (102 suspected clinically to be smallpox and 418 deaths in chickenpox outbreaks) were investigated in 1976 by experienced epidemiologists associated with the smallpox eradication programme (Ježek et al., 1978e) and 63% of the suspected smallpox cases were found to be due to chickenpox; none was smallpox.

As would be expected from the known seasonal incidence of the disease, by far the largest number of chickenpox outbreaks and cases occurred during the spring search (March–April 1976). In April 1976, a special study was carried out in the state of Kerala,



Z. JEŽEK

Plate 25.7. During the eradication programme in India the reward had gradually been increased from 10 to 100 rupees by the end of 1974. In July 1975, after smallpox was believed to have been eradicated from India, the reward was increased to 1000 rupees.

in which chickenpox deaths appeared to be unusually frequent, especially in adults (White, 1978). The investigation revealed that deaths attributed to chickenpox had been correctly diagnosed.

Special searches. In addition to the search operations just described, special searches were carried out in certain parts of the country which, for geographical reasons, were relatively inaccessible. These had posed problems for surveillance during the eradication campaign and required special attention during the precertification activities. First, surveillance activities were reinforced in the Andaman and Nicobar Islands, Ladakh, Mizoram and Sikkim (Ježek & Kanth, 1978; Ježek et al., 1978b). Secondly, 353 sites of outbreaks at the end of 1974 and in 1975, dispersed over 55 districts located in 20 states or Union territories, were systematically reinvestigated in the latter part of 1976 (Ježek et al., 1978c). Investigations that included interviews with more than 128 000 households and the physical checking of over a quarter of a million persons yielded no evidence of hidden foci or missed outbreaks.

Laboratory diagnosis. During the Intensified Smallpox Eradication Programme, the diagnosis of smallpox had been confirmed by laboratory investigations mainly in suspected cases which had occurred *in* smallpox-free areas or areas of low incidence. The number of such investigations was substantially increased during the precertification activities, especially in the first quarter of 1977 (Table 25.24). From January 1976 onwards, special instructions were issued calling for specimens to be collected from a representative patient in every outbreak of suspected smallpox, from every chickenpox outbreak in which deaths occurred, and from every outbreak of a vesicular disease in which containment action was taken, even if by mistake. The last instruction was based on the fact that, before the active searches in 1973, vaccinators and health officials had occasionally concealed smallpox cases but carried out containment vaccination in the hope that the outbreak would subside.

In January 1975, the government of India arranged that the National Institute of Communicable Diseases should take sole responsibility for testing smallpox specimens from India; for this purpose, the Institute used both gel precipitation and virus isolation on the chorioallantoic membrane. The WHO collaborating centres in Atlanta and Moscow also tested many specimens and carried out electron microscopic examinations in addi-

	Total	Variola virus	Vaccinia virus	Varicella–zoster virus	Herpes simplex virus
1975	702	141	2	45	1
1976	640	0	4	106	4
1977 (end end of April)	1 385	0	..	..	..

[a] .. = data not recorded

tion to the other two methods. In principle, duplicate specimens were collected from each suspected case, one being tested by the National Institute of Communicable Diseases and the other by one of the WHO collaborating centres. For virus isolation, the results obtained were in full agreement. Laboratory investigations of 2025 specimens provided no evidence of smallpox in India during 1976 and 1977.

Variolation and laboratory stocks. In contrast to the situation in Afghanistan and Pakistan, variolation had not been a problem in India during the past few decades and no special inquiries were required. However, the situation with regard to laboratory stocks of variola virus was carefully evaluated and steps were taken in 1976 to ensure that all such material was destroyed.

The national commission

Before the International Commission's visit to India, scheduled for April 1977, the Indian government organized a national commission for the assessment of the smallpox eradication programme in India (Basu & Khodakevich, 1978a). This consisted of 32 members from the Union government of India and 12 state governments and from WHO (Plate 25.8). Both Dr Jan Kostrzewski (who was to be chairman of the International Commission shortly to be set up) and Arita also attended a coordination meeting of the national commission in January 1977, since successful certification of smallpox eradication in India by the International Commission was clearly an important milestone in certification in the world as a whole and thorough preparation was essential. The national assessment took place over the period from 13 December 1976 to 8 January 1977.

After a preliminary assessment of the situation, teams from the national commission investigated selected districts to assess their surveillance activities (Fig. 25.14). Although their observations might not be seen as completely impartial by observers outside India, the members of the national commission teams were extremely critical in assessing what had been accomplished since, if they failed to discover any deficiencies, they would be held responsible.

The national commission found no evidence of continuing smallpox transmission and India was considered ready to receive the International Commission in April 1977.

Nepal

After what was regarded as the last case of smallpox in Nepal had been recorded in April 1975, surveillance was continued until the International Commission visited the country in April 1977. During the eradication programme, the country had been divided into 3 areas (see Chapter 15): (1) densely populated areas of low altitude adjacent to the Indian states of Uttar Pradesh and Bihar—i.e., the areas most vulnerable to smallpox importations; (2) high Himalayan mountainous areas with sparse populations and the least likely to experience importations; and (3) areas intermediate between (1) and (2). This subdivision was retained throughout the precertification surveillance period.

A similar surveillance strategy was adopted in all areas, active searches being carried out by means of house-to-house visits. The 3 main groups of surveillance workers were: smallpox eradication programme staff, malaria control staff, and health workers assigned to integrated health activities. Dr P. N. Shrestha, director of the national smallpox eradication programme, ensured that the best use was made of available health workers in order to strengthen the surveillance activities. Mr Jay Friedman, a WHO technical officer who had been located in Nepal since 1972, remained there until the International Commission visited the country, and contributed to the success of the undertaking. No evidence of smallpox transmission was found at any time during the precertification activities.

In 1975 a special pockmark survey was conducted among 2350 Tibetan refugees; this found no evidence of smallpox transmission in Tibet (Xizang Autonomous Region) more recently than 1961 (see Chapter 27). This was extremely important, since little was known of the incidence of smallpox in China at that time. The survey indicated that the chance of smallpox importation from Tibet was extremely small.

Bhutan

The last known case of smallpox in Bhutan occurred in February 1974, when 3 cases were introduced from Assam, India. In 1976 the

governments of Bhutan and India began discussions on the development of a special surveillance programme in preparation for certification. In August 1976 an Indian team, headed by Dr Basu, visited Bhutan to finalize the surveillance plan. An active search by means of house-to-house visits was carried out between September and December 1976, concentrated on the southern part of the country, where people moved freely across the border with India. A total of 23 surveillance workers visited about 800 villages; out of 45 000 persons seen, 11 were pockmarked. However, there was no indication of smallpox transmission after the last case in 1974.

Visit of the International Commission

An International Commission consisting of 16 members from 16 countries visited Bhutan, India and Nepal in March–April 1977; groups of Commission members visited Bhutan from 28 to 30 March, Nepal from 6 to 13 April and India from 6 to 20 April. For political reasons, Bhutan and India were certified separately. Since at that time only persons of Indian nationality were allowed to visit Bhutan, Lieutenant General R. S. Hoon, an epidemiologist serving in the Indian Defence Forces and a member of the International Commission, visited Bhutan together with Dr Basu, after which he participated in the investigation of the adjacent Indian state of Arunachal Pradesh.

All 16 members of the International Commission met first in New Delhi to assess the situation and plan field visits. During the field visits, each member was accompanied by national and WHO personnel who had either been members of the Indian national commission or were WHO epidemiologists who had worked in India during the precertification activities. In order to achieve maximum coverage, each member visited different areas in one or two states or union territories over a period of some 2 weeks (Fig. 25.15) before all the members of the Commission reassembled in New Delhi. Dr Kostrzewski with 2 members of the Commission and Ježek, who had been engaged in certification activities in India, visited Nepal, and then resumed their Indian field investigations. During the field visits, the Commission members concentrated on assessing the extent

and quality of the search and surveillance activities by examining records and interrogating several categories of staff at state, district, municipal, primary health centre and subcentre levels. They independently assessed the validity of statements about community awareness of smallpox by visiting villages, schools, urban areas, bazaars, places of pilgrimage and international ports. Brief reports were produced by the various Commission members or teams and these were discussed by the Commission at a plenary session from 21 to 22 April 1977.

In Nepal, 2 teams were formed, one covering the east and the other the west, special attention being paid to areas bordering on India. The members of the Commission were unable to visit the Tibetan border, but information collected from nearby mountainous areas indicated that Tibet was smallpox-free.

On 13 April 1977 Nepal was certified by the International Commission to be free of smallpox; this was followed, on 23 April, by the certification of Bhutan and India.

Plate 25.10. J. Kostrzewski, Chairman of the International Commission, presents the Commission's report to the Minister of Health and Family Welfare of India, Shri Raj Naraian, on the occasion of the certification of eradication in that country on 23 April 1977. Shri Rajeshwar Prand, Secretary of the Ministry, is in the centre.

BURMA AND BANGLADESH

Burma

Indigenous transmission in Burma had been interrupted in 1966 by a systematic mass vaccination campaign that began in 1954 and was intensified in 1963, using locally produced vaccine of acceptable potency and heat stability. Smallpox was then reintroduced from the Chittagong Hill Tracts in Bangladesh (then East Pakistan) into the neighbouring Burmese state of Arakan, in which it caused an outbreak with 181 reported cases in 1968 and 68 in 1969. This was controlled by intensive vaccination. In 1970 a WHO team had declared Burma to be free of endemic smallpox, and no further cases had been reported since then.

Between 1968 and 1975, 51 suspected cases of smallpox were investigated by field staff and specimens examined for variola virus in the laboratory, with negative results. In 1976–1977 the government of Burma established 4 national assessment teams, which visited every state and division in Burma, carried out pockmark surveys among children in the age group 5–14 years, and assessed the vaccination coverage and evidence relating to cases of suspected smallpox. The reports of these national assessment teams provided the basis for the investigations by the International Commission. In order to coincide with certification in Bangladesh, the Commission's visit was arranged for November 1977.

Bangladesh

The last case of smallpox in the Asian continent occurred in Bangladesh in October 1975; it was also the last case of endemic variola major in the world. As in India, the smallpox eradication programme retained its personnel and organization for the next 2 years in order to continue surveillance and determine whether the supposed last case really was the last one. Precertification activities in Bangladesh have been described by Joarder et al. (1980). Between October 1975 and May 1976, a large number of international and national staff were engaged in the search operations (Table 25.25). Among the many dedicated persons who contributed to the certification activities in Bangladesh, special mention may be made of Dr A. M. Mustaqul Huq, who had promoted the eradication programme since 1967, initially as programme manager and later as Director of Health Services (Preventive), and Dr Daniel Tarantola, a WHO epidemiologist, who stayed in Bangladesh until certification had been completed.

Active searches

Between October 1975 and October 1977 active country-wide searches for unreported cases, based on house-to-house visits, were organized on 8 occasions (Fig. 25.16). In each search, 50 000–60 000 health workers were mobilized. In the searches in December 1976–January 1977 and May–June 1977, deaths from chickenpox or measles were also investigated by interviewing a family member and/or taking specimens from other cases in the outbreak. A total of 56 deaths from chickenpox and 480 deaths from measles were investigated, as well as 63 deaths known only to have been caused by a disease in which there was fever with rash (Table 25.26). None of the fatal cases was due to smallpox.

After the search had been completed, the assessment team visited villages selected at random. They found that coverage by the search team varied between 78% and 87% (Table 25.26). More than 80% of the people interviewed knew about the smallpox reward.

Special searches were organized in the Chittagong Hill Tracts. The area was differ-

Table 25.25. Bangladesh: numbers of international and national epidemiologists engaged in surveillance, 1975–1977

Period	Number of WHO staff in Dhaka	Number of international field epidemiologists	Number of national epidemiologists	Total

January 1977	3	7	32	42
July 1977	3	9	31	43

ent from other parts of Bangladesh in that the population was sparse, communications were poor and the health infrastructure was rudimentary. No evidence of smallpox was found.

Surveillance in Dhaka and urban areas

The active searches just described were carried out mainly in rural areas. However, it was in the major urban areas, including Dhaka in which housing was extremely congested and into and out of which tens of thousands of rural inhabitants flowed daily, that smallpox transmission had been maintained in the past, unknown to the central health services (see Chapter 16). In Bangladesh, moreover, the municipal health services were administratively independent of the district or regional health authorities, those responsible for smallpox eradication being no exception.

Surveillance in the municipalities therefore became an extremely important pre-certification operation. The methods employed were daily visits to infectious diseases hospitals and cemeteries to check on the causes of recent admissions, deaths and burials, and the use of surveillance teams, of which there were 2 in Dhaka and 1 in each of the other 5 major municipalities. They made regular visits to high-priority areas, including the bustees (the shanty towns, whose inhabitants were usually unfamiliar with the urban health facilities and, of course, with the reporting of information on rashes), areas of low literacy in which written publicity probably failed to reach the people, and places where the population congregated daily or intermittently in large numbers. House-to-house searches were conducted periodically in all municipalities, usually immediately after the national house-to-house searches in rural areas.

This schedule allowed surveillance teams and epidemiologists to devote additional time to the supervision and assessment of urban searches. None of these search activities disclosed evidence of continuing smallpox transmission after the case in October 1975.

Pockmark survey

A facial pockmark survey of 465 892 persons aged 0–19 years, based on 1550 sampling sites all over Bangladesh, was conducted in July–December 1976. None of the 939 persons with facial pockmarks who had

contracted smallpox after 1971 had been infected after 1975 (Table 25.27).

Laboratory diagnosis

Between January 1976 and November 1977, 2462 specimens were investigated by the smallpox diagnostic laboratory in the Institute of Public Health, Dhaka, and 698 were tested by WHO collaborating centres in Atlanta and Moscow (Table 25.28). In none was variola virus found, although vaccinia virus was recovered from vaccination scabs and herpesvirus particles were seen in many of the specimens examined by electron microscopy in the WHO collaborating centres.

The national commission

A national commission of 52 members met in August 1977 to assess the smallpox eradication programme in Bangladesh. Teams from the national commission visited all districts, 54 subdivisions, 81 *thanas* and each of the 4 major municipalities in Bangladesh. After meeting again in Dhaka, the national commission expressed its satisfaction with the evidence that had been assembled to support the contention that there had been no smallpox transmission in Bangladesh after October 1975.

Visit of the International Commission

After a briefing session at the WHO Regional Office for South-East Asia, in New Delhi, a 9-member International Commission visited Burma from 21 to 30 November 1977 and Bangladesh from 1 to 14 December 1977. One representative from Burma and one from Bangladesh were included in the Commission because two politically disturbed areas—Chin State in Burma and the Chittagong Hill Tracts in Bangladesh, with a common border—could be visited only by nationals of the country concerned. In addition, the representative of each country was expected

to be particularly vigilant about the evidence of eradication in the other country.

Burma

Field trips by Commission members covered an area with a population of more than 4 million in addition to the city of Rangoon (population 3.2 million). Together, International Commission members and national teams covered all the states and divisions of Burma. One of the main activities of the Commission members during their field visits was a pockmark survey, in which more than 58 000 persons were seen (5000 preschool children, 29 000 schoolchildren and 24 000 adults), among whom 399 pockmarked persons were identified. The majority of these (96.5%) had suffered from smallpox before 1963, the most recently infected being a person who had contracted the disease during the outbreak in Arakan in 1968. Extensive questioning found no evidence of the occurrence of smallpox in Burma after 1969.

Earlier in 1977 national assessment teams had examined 1.97 million children aged 5–14 years without finding any with facial pockmarks. That the International Commission found 399 and the national commission none is explained in part by the fact that only 14 of those with facial pockmarks were under 14 years of age. It is also possible, however, that the definition of pockmarks was misunderstood during the national survey so that it did not give a truly representative picture of the prevalence of pockmarked persons.

Apart from this inconsistent result, the Commission was satisfied with the surveillance activities carried out by the Burmese health staff and found no evidence of smallpox transmission after 1970. Burma was certified to be free of smallpox.

Bangladesh

After completing its work in Burma, the Commission met in Dhaka for 2 days at the beginning of December for briefing, then divided into 9 teams, each consisting of a Commission member, a WHO smallpox eradication programme officer, a national

epidemiologist and the local officers concerned. These teams travelled extensively throughout Bangladesh (Fig. 25.17) and made thorough investigations, particularly in vulnerable areas in which transmission of smallpox might be continuing. Extensive questioning revealed that the people's knowledge of the reward and of where to report suspected cases was very good. Pockmark surveys of some 50 000 persons under 20 years of age, of whom 2000 were less than 2 years old, found 575 pockmarked persons, none of whom had contracted smallpox later than 1975.

Scrutiny of documentation and supporting records showed that, with few exceptions, a high level of surveillance had been maintained by the national authorities throughout the period since the last known case.

The results of the field visits by the Commission were consistent with the national records, and on 14 December 1977 Bangladesh was certified to be free of smallpox. This action formally set the seal upon the end of endemic variola major in the world.

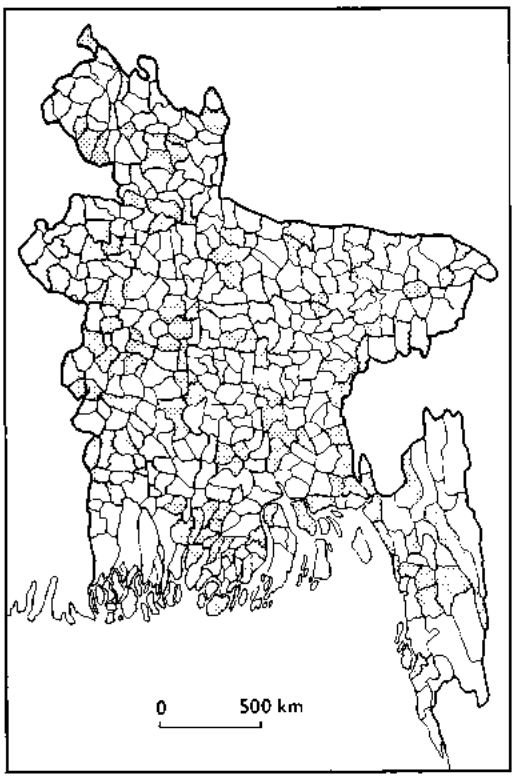

Fig. 25.17. *Thanas* in Bangladesh (shaded) visited by members of the International Commission, 1–14 December 1977. (From Joarder et al., 1980.)

CONCLUSIONS

These certification activities, which dealt with several of the former major endemic countries in the world, provided detailed information about the elimination of smallpox in the countries concerned and the methodologies for obtaining the data required by international commissions so that they could properly evaluate the likelihood that smallpox had been eliminated, both from countries in which it had recently been endemic and from those in which the last outbreak had occurred several years earlier. At the time the Consultation on the Worldwide Certification of Smallpox Eradication was held, in October 1977, preparations were well advanced for international commissions to visit other regions of Africa and Asia. It was on the basis of the knowledge and experience of certification gained between 1973 and 1977 that the Consultation was able to plan a logical series of operations that would ultimately provide the World Health Assembly with the information that would allow it to declare that smallpox had been eradicated from the world.

Conclusions	1226

INTRODUCTION

By June 1977 international commissions had already visited or were preparing to visit all the previously endemic countries and countries at special risk. However, as has been explained in Chapter 24, there was a need to determine what measures should be taken in order to certify that the transmission of smallpox had been interrupted for at least 2 years in other countries, in several of which the staff of the WHO Smallpox Eradication Programme needed outside advice on how best to deal with the situation. In addition, advice on whether global eradication could be certified needed to be, and to be seen to be, independent of the special interests of WHO personnel who were intimately involved in the global eradication programme.

These problems could be solved by establishing a global commission of respected scientists which, as one of its functions, would

advise the staff of the WHO Smallpox Eradication unit as to what data should be collected, for clearly this was a matter of judgement. Eventually, when these experts were fully satisfied that global eradication had been achieved, this conclusion would have been reached, not by WHO itself, or on the basis of the reports of a series of international commissions each dealing with one or a few countries, but by an international group of senior scientists and administrators capable of taking a global view of the problem. For this reason, the Consultation on the Worldwide Certification of Smallpox Eradication was set up in October 1977 and subsequently converted into the Global Commission for the Certification of Smallpox Eradication. This chapter and the next deal with activities undertaken at the suggestion of the Consultation and the Global Commission throughout 1978 and 1979; it was hoped that these would provide data on which the Global Commission could ultimately base its opinion that the transmission of smallpox had been interrupted everywhere in the world.

In this chapter, various operations carried out in 29 countries situated in widely separated parts of Africa and Asia (Fig. 26.1) are described. Not all were certified by formal international commissions such as those referred to in Chapter 25; other procedures—a visit by a WHO-designated expert or consultant and subsequent report, or the provision of a detailed country report—had to be used for some countries (Fig. 26.2).

Fig. 26.1. The 29 countries of Asia and Africa (including Lesotho and Swaziland) in which certification was carried out in 1978 or 1979 by international commissions, by visits by a WHO-designated expert or by the provision of a detailed country report (see Fig. 26.2).

In Africa, by mid-1977, formal certification had been successfully completed in 24 countries in western and central Africa (Chapter 25). At that time, smallpox was still occurring in Somalia, so that certification of the Horn of Africa lay in the future (Chapter 27). There remained 14 countries requiring certification, extending from the Sudan in the north to South Africa in the south, and from Angola in the west to Madagascar in the east. The strategy of certification by international commissions, as recommended by the 1977 Consultation, was followed for 10 of them (Fig. 26.2, No. 1–10), but for political and logistic reasons it was not possible to follow the Consultation's recommendations for South Africa, Namibia or Southern Rhodesia (Fig. 26.2, No. 13–15). Instead, certification by the Global Commission was based on reports prepared by Global Commission members and WHO consultants after visits arranged by the Smallpox Eradication unit. As recommended by the Consultation, eradication in Madagascar was certified by the Global Commission after receipt of a detailed country report, followed up by a visit by a WHO staff member.

For 11 countries in south-western Asia, certification by various procedures was recommended. Democratic Yemen, Yemen, Iraq and the Syrian Arab Republic (Fig. 26.2, No. 11, 12, 18 and 19) were visited by international commissions. Iran was visited by experts and certified by the Global Commission on the basis of their reports. The 6 Arab countries of the Gulf area (Fig. 26.2, No. 20–25) were required to submit a country report. At their request a more searching inquiry was made; each country carried out an intensive surveillance programme designed and supervised by a WHO epidemiologist.

For 5 countries in eastern Asia, the Consultation had recommended special certification activities. China, because of its vast size and population and its lack of contact with WHO for many years, required the special measures described in Chapter 27. There remained Thailand and the war-torn countries of Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. The fact that there had never been a WHO-sponsored smallpox eradication programme in the 3 last-mentioned countries, and that their health systems had been compromised by prolonged

warfare, made it difficult to collect data or arrange visits by WHO consultants or staff members. Thailand was visited by a member of the Global Commission; for the other countries reliance had to be placed on reports compiled from a variety of sources.

In this chapter, the certification of 14 countries in Africa is first described, then that of the 11 countries in south-western Asia and finally that of Thailand, Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. All these operations were undertaken while, at the same time, the most intensive search activities of the whole eradication programme were being carried out in the Horn of Africa. The operations mounted to certify eradication in Ethiopia, Somalia, Djibouti and Kenya, and in China, are described in Chapter 27.

SOUTHERN AFRICA

The progress of certification in the 12 countries of southern Africa (Angola, Botswana, Lesotho, Madagascar, Malawi, Mozambique, Namibia, South Africa, Southern Rhodesia, Swaziland, the United Republic of

Tanzania, and Zambia) is shown in Fig. 26.3. No smallpox had been reported in any of these countries since 1972, except for an outbreak of variola minor in Botswana in 1971–1973, following an importation from South Africa late in 1971 (Table 26.1).

Civil unrest and, indeed, open warfare had been occurring in Angola, Mozambique and Southern Rhodesia since the mid-1970s. South Africa, Namibia (which was controlled by South Africa) and Southern Rhodesia (then regarded by the United Nations as a British colony) were not represented at the World Health Assembly. This complicated the organization of certification by international commissions. Eventually such commissions were able to visit Angola and Mozambique, where they met with no difficulties. However, there were political difficulties in organizing WHO-sponsored international commissions to certify smallpox eradication in Southern Rhodesia and Namibia, and attempts to arrange for an international commission to visit South Africa (which provided the only route of entry to Namibia) were thought unlikely to be successful or at best unduly time-consuming, owing to political factors. The recommendation of the Consultation on the Worldwide Certification of Smallpox Eradication that an international commission should visit these 3 countries (see Chapter 24) was therefore not followed. Instead, arrangements were made to obtain country reports and other necessary data by organizing visits by a Global Commission member and WHO consultants who were acceptable to the respective national governments. This proved to be quite straightforward in Southern Rhodesia and Namibia, but several visits to South Africa were needed before the requisite data could be obtained.

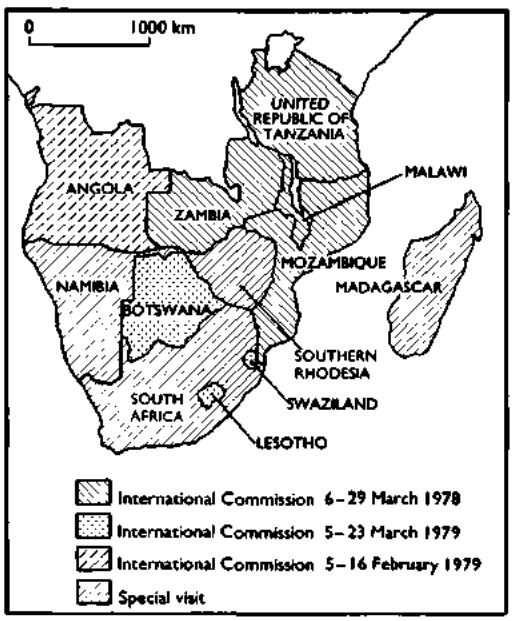

Fig. 26.3. Countries of southern Africa certified free of smallpox by international commissions or visited by a member of the Global Commission or WHO-designated expert before certification by that Commission.

Logistics

Experience in western and central Africa had shown clearly the difficulties faced by the small staff of the Smallpox Eradication unit and the relevant personnel in the WHO Regional Office for Africa in arranging simultaneous precertification activities in many countries. Furthermore, it was impossible to find experts of sufficient experience to

Madagascar	0	0	0	0	0	0	0	0

form the international commissions if members were required to travel too often and to too many different countries. To simplify certification, 2 groupings were therefore made of small numbers of countries, as follows: (1) Malawi, Mozambique, the United Republic of Tanzania, and Zambia; and (2) Botswana, Lesotho and Swaziland. The remaining 5 countries were dealt with separately. Angola, in particular, was a large country in which there had been serious civil disturbances both before and after it achieved independence in 1975 so that it was uncertain whether commission members would be able to travel extensively enough for certification to be possible. For this reason, a separate international commission was established for Angola so as not to prejudice the certification of any other country that might be grouped with it. The political problems associated with Namibia, South Africa and Southern Rhodesia have already been mentioned, while Madagascar, as an island, was a special case.

For the first time since certification in South America in 1973, the problem had to be faced that the variety of smallpox most recently present in some of these countries was mainly variola minor. In this situation, pockmark surveys, which had proved so useful in the countries of western and central Africa, were much less likely to reveal recent transmission of smallpox, because facial scars persisted in less than 10% of patients. To supplement such pockmark surveys as were performed, intensive surveillance for cases of chickenpox was carried out, and specimens were collected for laboratory examination—a procedure which reached its apogee in certification operations in the Horn of Africa (see Chapter 27). Surveillance for cases of chickenpox provided a measure of the sensitivity of the reporting system and permitted specimens to be collected from cases and outbreaks over a wide area. If cases had mistakenly been diagnosed as chickenpox instead of variola minor, this would be revealed by laboratory studies. Moreover, by obtaining material from outbreaks in which a patient had died, presumably of chickenpox, the likelihood of detecting smallpox, if it were present, was increased.

Time Schedules for Certification

Since there were so many countries for which certification was required by the end of 1979, all certification activities had to meet a strict time schedule. Further, if one of a group of neighbouring countries failed to achieve certification, none of the countries in that group could be certified. Various measures were taken to accelerate certification and maintain uniform progress—c. g., countries were requested to send information on the progress made in preparations for certification to the WHO Regional Office for Africa by cable every month. An example of such a request is reproduced below. Although formal communications were with the Regional Office, it was important that the epidemiologists in Nairobi and the Smallpox Eradication unit in Geneva should be kept informed of the situation; hence a copy of the cable was sent to each of them.

Outgoing cable:

"Reference progress SME [smallpox eradication] certification activities from now onwards please deliver to AFRO [Regional Office for Africa] a monthly cable to monitor status commission preparation including AAA cumulative totals pockmark surveys since surveys began BBB total number localities chosen for field surveys CCC total number localities visited by teams DDD total number of persons seen in schools or elsewhere EEE number of persons with facial pockmarks FFF number of specimens collected for laboratory study stop Please begin this cable report thirty October and forward thereafter on day thirty of subsequent months to AFRO with copy SME HQ [Smallpox Eradication unit] and ICP ES 005 [Epidemiological Surveillance of Diseases Intercountry Project] epidemiologists Nairobi and Maputo."

Malawi, Mozambique, United Republic of Tanzania, and Zambia

Precertification activities

These countries had recorded their last cases of smallpox between 1969 and 1971 (Table 26.1). Dr Ziaul Islam, a WHO epidemiologist based in Nairobi, who had worked on both the western and central African certification programmes, took the major role in precertification activities in this group of countries.

The preparation of country reports started early in 1977 while the certification of central Africa was in progress. In July 1977, a coordination meeting attended by WHO regional and Headquarters staff was held in Brazzaville, Congo, to assess progress. It was decided at this meeting that, in addition to pockmark surveys, a programme for the surveillance of chickenpox cases, with emphasis on the collection of specimens for laboratory examination, should have a high priority in the preparations for certification. It was proposed that at least 100 specimens from chickenpox patients should be collected in each country, from outbreaks separated in both space and time. By October 1977, Dr Islam had visited Malawi, the United Republic of Tanzania, and Zambia at least once to assist with the pockmark surveys and chickenpox surveillance. It was estimated that by December 1977 all the preparations for visits by an international commission would be completed.

Pockmark surveys. As part of the preparations for certification, pockmark surveys were carried out in each country, covering 3.2% of their combined population of 38.2 million (Table 26.2). No pockmarked children were seen among 70 621 children of preschool age, nor had any person with facial pockmarks suffered from smallpox later than 1970.

Chickenpox surveillance. In accordance with the decision made at the coordination meeting at Brazzaville in July 1977, all countries had collected a number of specimens from cases clinically diagnosed as chickenpox (Table 26.3). When examined at the WHO collaborating centres, no specimens showed poxvirus particles by electron microscopy and cultures for orthopoxviruses were uniformly negative. Herpesvirus particles were seen in 26% of the specimens.

Continued transmission in Malawi. During preparations for certification in Malawi, evidence was obtained which showed that smallpox transmission had continued for a long period of time without being recognized by the health services. The last reported case occurred in December 1969. In April 1972, Dr Islam discovered in a remote part of southern Malawi 48 individuals with facial pockmarks who had contracted their infections between April 1970 and February 1971—i.e., up to 14 months after the last reported case (see Chapter 20). Subsequently, during the precertification surveys, a joint Malawi–WHO team discovered a pockmarked girl and 2 other possible cases in the same area who gave a history of having been infected in September 1972. The exact status of these cases was never determined, but it was eventually concluded that, among the illiterate rural population, information given as to

Laboratory Diagnosis of Chickenpox

During precertification activities in many countries, large numbers of specimens from cases of chickenpox were submitted for laboratory testing to WHO collaborating centres. The varicella–zoster virus, which causes chickenpox, does not grow on the chorioallantoic membrane and grows only slowly in special kinds of cultured cells. However, typical enveloped herpes virions can be seen with the electron microscope in preparations made with fresh vesicular fluid (see Chapter 2, Plate 2.16).

Most reports from WHO collaborating centres showed a rather low percentage of sightings of herpes virions with the electron microscope in material that came from cases of chickenpox, compared with the very high percentage of positive results for pox virions from cases of smallpox. This is explained by the fact that the enveloped herpes virions are much more fragile than pox virions and often failed to survive intact during the process of shipment from the field to the laboratory.

Zambia	86	0	36	50
Total	528	0	136	392

the year of illness was unreliable, and that the last case in Malawi had occurred in an outbreak that terminated spontaneously in 1971 without being detected by health staff.

Difficulties in precertification activities. WHO-assisted national smallpox eradication programmes had operated in Malawi, the United Republic of Tanzania, and Zambia, but the sensitivity of the surveillance system for smallpox had diminished in each of these countries since 1974. WHO had not been involved in smallpox eradication work in Mozambique. The precertification surveys just described were made possible only by detailing a WHO epidemiologist to work with designated national health workers in each country. Some logistic problems arose—e.g., in Mozambique, in which available resources were insufficient to permit the carrying out of a pockmark survey and extra funds had therefore to be provided to cover petrol costs and living allowances. Three new vehicles were also needed, but only for 2–3 months, so that it would have been wasteful to purchase them. Furthermore, they could not have been obtained in time, since procurement usually took 12 months. This problem was solved when the vehicles were made available by the WHO Expanded Programme on Immunization and money to cover local expenses was provided by WHO.

Visit by the International Commission, 6–29 March 1978

An International Commission for the Certification of Smallpox Eradication met in Maputo, Mozambique, from 6 to 9 March 1978. After reviewing the data from all 4 countries, the Commission set up 4 teams, one for each country, and reassembled for its final meeting in Lusaka, Zambia, 27 to 29 March.

After extensive travel throughout each country and examination of the reporting networks and of the data provided in the country reports, the Commission decided that, if smallpox transmission had continued after the date of the last known case, it would have been detected. The circumstances of the missed outbreak in Malawi were carefully scrutinized, but the epidemiological evidence indicated that the last case had occurred in 1971. The Commission noted that, even if the disease had persisted until September 1972, this was over 5 years ago, and the local situation had been examined in detail both by the joint Malawi-WHO team in precertification activities and by the Commission member during his visit. At its final plenary meeting in Lusaka the Commission agreed

that the 4 countries should be certified to be free of smallpox.

Botswana, Lesotho and Swaziland

Coordination meeting

During the International Commission's visit to Lusaka in March 1978, mentioned above, a coordination meeting was held to discuss strategies for the certification of the remaining countries in southern Africa. It was attended by Dr Celal Algan and staff from the WHO Regional Office for Africa, Dr Joel Breman, formerly of the Center for Disease Control, Atlanta, USA, who had recently joined the Smallpox Eradication unit, and Arita. Apart from the Horn of Africa, where smallpox remained endemic until 1977, the last case in Africa had been reported in Botswana in November 1973. The small landlocked countries of Lesotho and Swaziland had experienced their last outbreaks in 1962 and 1966 respectively.

Although the 6 adjacent countries of Botswana, Lesotho, Namibia, South Africa, Southern Rhodesia and Swaziland formed an epidemiological unit (see Fig. 26.3), the coordination meeting decided that it would be very time-consuming and perhaps politically difficult to arrange for simultaneous precertification surveys and the certification of these countries by one or even several international commissions. Botswana was the only one of them in which WHO had been involved in a smallpox eradication programme when, after the outbreak there in 1971, a WHO team had assisted an augmented national programme. It was decided that arrangements should be made for the visit of an international commission to Botswana, Lesotho and Swaziland in March 1979, and that preparations for precertification activities in those 3 countries should begin immediately. Other measures were to be taken to obtain the information necessary to certify smallpox eradication in Namibia, South Africa and Southern Rhodesia (see below).

[b] Due to smallpox contracted before 1971.

Precertification activities

The last outbreak of smallpox in the region had been due to very mild variola minor in Botswana in 1971–1973 (see Chapter 20), and variola minor was the predominant variety of smallpox recently prevalent in South Africa, by which Lesotho was completely and Swaziland almost completely surrounded. However, outbreaks of variola major had occurred in all these countries in the past, and it was decided to carry out both pockmark surveys and chickenpox surveillance. Dr Moíses Altmann, a WHO epidemiologist stationed in Maputo, Mozambique, assisted the national health authorities in their preparations for the commission's visit. Progress was initially rather slow, but by January 1979 all 3 countries had prepared country reports and completed pockmark and chickenpox surveys.

Pockmark surveys. The pockmark surveys covered a large proportion of the small populations of the 3 countries (Table 26.4). No facial pockmarks were seen in 44 985 children of preschool age and only 6 cases (all in Botswana) were found among 291 612 schoolchildren. Pockmarks were somewhat more common in adults, being seen in 0.26% in Botswana and a smaller proportion in Lesotho and Swaziland, and heavy facial scarring was found only in adults, reflecting the outbreaks of variola major in the 1950s and 1960s.

Chickenpox surveillance. Specimens were collected from cases of chickenpox during precertification surveillance, care being taken to obtain specimens from as many separate outbreaks as possible. They were examined at WHO collaborating centres. None contained poxvirus, but herpesvirus particles were seen with the electron microscope in 28% of the specimens (Table 26.5).

Visit by the International Commission, 5–23 March 1979

The first meeting of the International Commission was held in Gaborone, Botswana, from 5 to 7 March 1979. In addition to examining the country reports for these 3 countries, the Commission reviewed the data available at that time on smallpox eradication in the 3 neighbouring countries, Namibia, South Africa and Southern Rhodesia, because these 6 countries formed an epidemiological unit. The Commission then divided into 3 groups, which visited Botswana, Lesotho and Swaziland respectively, and reassembled for final discussions in Mbabane, Swaziland, between 21 and 23 March.

During their visits, Commission members themselves carried out pockmark and vaccination scar surveys, though necessarily on a much smaller scale than in the national

surveys (Table 26.6). They discovered a higher proportion of pockmarked schoolchildren and adults than had been found in the national surveys in Botswana and Swaziland, but fewer in Lesotho. In any case, even these higher frequencies were quite low (0.26% and 0.29% in schoolchildren in Botswana and Swaziland respectively) and no pockmarked children under the age of 6 were found, out of a total of 2533 examined.

There was some doubt among Commission members in Botswana whether smallpox transmission there had been interrupted in 1973 or had extended into 1974. Two suspected cases of smallpox in children had occurred in 1974, but it was impossible to confirm or disprove the diagnosis.

The vaccination scar survey conducted by Commission members revealed a high vaccination coverage of the population in all 3 countries; in the age group under 15 years, for example, it was 96% in Botswana, 85% in Swaziland and 72% in Lesotho. In Botswana, refugees, bushmen and a religious sect whose

[b] Due to smallpox contracted before 1971.

members objected to vaccination on principle were considered as high-risk groups among whom the transmission of smallpox was more likely to continue. However, national vaccination surveys and visits by Commission members showed satisfactory vaccination coverage in each of these groups.

Because the variety of smallpox most recently prevalent in these 3 countries had been variola minor, the absence of pockmarks in children was less significant than in the majority of other countries, but the absence of variola virus in specimens taken from cases diagnosed as chickenpox and the high level of vaccinial immunity were persuasive. Noting that there had been no evidence of confirmed smallpox since 1973 or of suspected cases since 1974, the Commission certified that smallpox had been eradicated from Botswana, Lesotho and Swaziland.

South Africa

With a population of 22.8 million in 1970, South Africa was the most populous country in southern Africa. Variola major and variola minor had been endemic up to the Second World War, but thereafter only variola minor had persisted as an endemic disease, and was not regarded very seriously by the health authorities. Apart from a visit to South Africa in 1972 by Henderson (see Chapter 20), the country had had no contact with the WHO smallpox eradication campaign and had not established a national smallpox eradication programme. Smallpox was regarded as one of the diseases for which vaccination should be provided, but was considered to be of minor importance compared with poliomyelitis, measles, diphtheria, and other diseases.

Arrangements for certification

Following the Consultation on the Worldwide Certification of Smallpox Eradication in October 1977, the Director-General of WHO wrote to the South African Minister of Health and Welfare to propose that the South African government should participate in the global certification of smallpox eradication. In his letter he suggested that a visit early in 1978 by Fenner, who had been the chairman of the Consultation, would be a useful way to begin this activity. Within 10 days of the dispatch of this letter, South Africa informed WHO by cable of its willingness to participate in these certification activities and to provide every assistance during Fenner's visit.

Visit by Fenner, 19 January–19 February 1978. The purpose of the visit was threefold: (1) to advise South African health officials on how to prepare a country report for submission to the Global Commission; (2) to emphasize the importance of chickenpox surveillance and make arrangements for the collection of specimens for laboratory examination by WHO collaborating centres; and (3) to obtain an impression of the recent history of smallpox and rural health services in South Africa (including some of the "black homelands"). Fenner's itinerary is shown in Fig. 26.4. With the help of the South African government, the trip was extended to include Namibia (see below). He was cordially received by government and provincial health officials (see box) and visited infectious disease hospitals, university medical schools, diagnostic laboratories in Johannesburg and Cape Town, and rural health centres in northern Transvaal and 3 of the "black homelands", Bophuthatswana, Lebowa and Transkei.

The laboratory services were found to be of high quality and a network of diagnostic laboratories covered most of the country. However, their practice of testing for ortho-

Collaboration between South Africa and WHO on Smallpox Eradication

The following note prepared by Fenner on his return from South Africa illustrates that country's willingness to cooperate with WHO's global certification activities:

"Everywhere I went I was received with great cordiality, and there were frequent expressions of satisfaction that WHO had arranged the visit. No effort was spared to enable me to see what I regarded as the 'vulnerable' areas, the more heavily populated parts of Namibia near the Angolan border and the northern parts of Transvaal (Lebowa) and Bophuthatswana, near Botswana.

"I was driven around the countryside and to clinics and hospitals by senior health officials, health inspectors or nursing sisters over a distance of more than 3000 km, and a chartered plane was made available for 3 days. Such travel afforded opportunities for extensive informal discussion of the health conditions and the complex politics of these parts of Africa, as well as observation of the countryside and living conditions in the rural areas, and the rural hospitals and clinics."

poxviruses by growth in tissue culture rather than on the chorioallantoic membrane, and reporting positive results as indicating a "member of the vaccinia–variola group" was confusing (see Chapter 20). Variola virus stocks were held in the National Institute for Virology, but the South African Director-General of Health would not agree to a request by Fenner that they should either be transferred to a WHO collaborating centre or destroyed. In fact, it was not until December 1983 that they were finally destroyed (see Chapter 28).

Vaccine was produced in a laboratory in Cape Town for use locally and in some neighbouring countries—e.g., Southern Rhodesia. Tests on freeze-dried vaccine carried out in 1970 by the WHO Collaborating Centre for Smallpox Vaccine in Bilthoven, Netherlands, showed that it met WHO standards.

Preparation of the country report. It was suggested that South Africa should submit its country report by 1 June 1978 and complete the chickenpox survey in October 1978, so that the situation could be reviewed at the Global Commission meeting in December 1978. However, when no material had arrived by 12 September, Arita sent a cable to Pretoria requesting the submission of a country report documenting smallpox eradication as soon as possible. To avoid further delay, Fenner revisited South Africa briefly in mid-October, and Dr Nicole Grasset, formerly the regional smallpox adviser in the WHO South-East Asia Region, who had lived in South Africa in her youth, visited the country in November and brought data and a draft report back to Geneva, where it was finalized by staff of the Smallpox Eradication unit.

The delay in sending the results of the chickenpox surveys was due to the seasonal character of the disease; outbreaks occur in spring and, in the Southern Hemisphere, this starts in September, so that, by October, there had been too few to enable the stipulated 100 specimens to be collected.

Review of country report by the Global Commission, December 1978

The country report and the results of an incomplete chickenpox survey were presented to the Global Commission at its meeting in Geneva from 4 to 7 December 1978. The Commission noted that South Africa had relatively well developed health services, as shown by the overall doctor to population ratio of 1:1806 and registered nurse to population ratio of 1:573. In addition, 5660 health stations were responsible for reporting communicable diseases. After the last known outbreak in 1971, when special efforts were made to achieve high vaccination rates in the northern Transvaal (see Chapter 20), smallpox vaccination was being performed as part of a well-organized immunization programme which also provided poliomyelitis, BCG and diphtheria–pertussis–tetanus vaccination.

The results of facial pockmark and vaccination scar surveys carried out in widely separated rural and urban areas during 1978 are shown in Table 26.7. An additional survey of 17 064 children under 15 in Bophuthatswana and Transkei revealed none with facial pock-

Transvaal	62	0	25	37
Total	127	0	42	85

marks and 67.6% with vaccination scars. Four adults with facial pockmarks gave histories of attacks of variola major many years earlier.

When the Global Commission met in December 1978, no data were available on the laboratory examination of specimens from cases of chickenpox, and it was therefore decided to delay certification pending the arrival of the results of this survey. By June 1979, 127 specimens had been submitted for examination, the majority coming from the northern Transvaal (see Fig. 26.4), where the last outbreak of smallpox had occurred in 1971. All were negative for poxvirus, but herpesvirus particles were seen in 33% of the specimens (Table 26.8).

After receipt of the results of the examination of the first 100 specimens, Arita wrote to members of the Global Commission, who, on the basis of their review of the situation in December 1978 and the results of the chickenpox survey, agreed on 17 April 1979 that smallpox eradication had been achieved in South Africa.

Namibia

Although the United Nations had terminated the South African mandate over Namibia in 1966 and the South African presence there had been declared illegal by the International Court of Justice in 1971, the country was in fact controlled and administered by South Africa, under the name "South West Africa". In this sparsely populated country, the highest population density being 7.5 persons per square kilometre in Ovamboland, adjacent to the border with Angola, endemic smallpox was said never to have been present, though there had been occasional importations from Angola, most recently in 1956. Endemic smallpox had been eliminated from Angola in 1959 (see below) and although cases had occurred as recently as 1973 in Botswana, these were in the eastern part of that country, separated from Namibia by the Kalahari desert. The South African Institute for Medical Research operated a branch laboratory in Windhoek, the capital, and small laboratories in some other towns in Namibia.

Visit by Fenner, 5–9 February 1978

During his trip to South Africa early in 1978, Fenner also spent 5 days in Namibia (see Fig. 26.4). He met health officers and staff in hospitals and laboratories, obtained information on health services, especially the surveillance and control of communicable diseases, visited schools and conducted a limited vaccination scar survey. After his departure, a country report was prepared by the South African health authorities and sent to the Global Commission.

Review of the country report by the Global Commission, December 1978

The country report was considered at the meeting of the Global Commission in December 1978. It followed the usual lines, describing the geography and demography,

health administration, history of smallpox and records of vaccination activities. Between 1969 and 1978, 10 specimens had been examined for suspected smallpox at the National Institute for Virology in Sandringham; all were negative. Pockmark and vaccination scar surveys had been conducted throughout the country in April–November 1978 (Table 26.9). The 3 pockmarked adults found were Angolans who said that they had suffered from smallpox in childhood.

During 1978 and 1979, 18 specimens collected from cases clinically diagnosed as chickenpox (see Fig. 26.4) were examined in a WHO collaborating centre; none contained poxvirus but 9 showed herpesvirus particles.

On the basis of the history of smallpox in Namibia, the low probability of importations from adjacent countries during the previous decade, the results of the facial pockmark surveys and the high vaccination rate in individuals over 5 years of age, the Global Commission certified that smallpox had been eliminated from Namibia.

Southern Rhodesia (Zimbabwe)

Southern Rhodesia was a British colony until 1980, when it attained independence and was renamed Zimbabwe. In 1965 the white colonists had made a unilateral declaration of independence and since then the country had been in a state of civil war. Legally, in 1978, it remained under the jurisdiction of the United Nations Sanctions Committee. In order to obtain information on the smallpox situation, the Director-General of WHO wrote to the Southern Rhodesian authorities requesting that 2 WHO consultants should be allowed to visit the country to assess whether smallpox had been eliminated. A favourable reply having been received, Dr Nicole Grasset and Dr Gordon Meiklejohn, both highly experienced in smallpox eradication activities, visited the country in January 1978.

Visit by Dr Grasset and Dr Meiklejohn, 10–30 January 1978

Since Southern Rhodesia was a much smaller country, the objectives of this visit differed from those of Fenner's visit, mentioned above, to South Africa and Namibia. The consultants' aim was to obtain enough information, by travel and inquiry, and supported by subsequent investigations by local personnel, to be able to submit to the Global Commission a definitive report on the smallpox situation in Southern Rhodesia.

The consultants were warmly received by the local authorities (see box) and after initial consultations in Salisbury (Harare), they travelled separately around the 5 provinces, carrying out extensive pockmark and vaccination scar surveys as well as evaluating the level of surveillance of infectious diseases by health personnel. Subsequently, national health personnel carried out further and more extensive studies. The consolidated results of all these surveys are shown in Table 26.10.

In their inquiries, the consultants observed that there was a remarkable lack of knowledge about smallpox among persons under 25 years of age. Almost without exception they failed to recognize the smallpox pictures on the recognition cards and stated that they had never seen or known of the presence of the disease. On the other hand, many older persons knew about smallpox from their childhood, and 0.26% of adults surveyed had facial pockmarks, the most recent being said to date from an illness in 1966.

In addition to their field survey, the consultants commented on the health services, which they described as extensive, well

Attitude of the Southern Rhodesian Authorities to the Visit by WHO Consultants

Dr Grasset reported as follows: "Dr G. Meiklejohn and myself were everywhere received with great cordiality and everything was done to facilitate our work in Rhodesia ... Maps, charts and tables concerning the smallpox programme in Rhodesia since 1954 were given to us, and the smallpox activities and other health programmes were freely discussed.

"... In order to carry out surveys in as many localities as possible, half the country's territory was covered by Dr Meiklejohn and the other half by myself ... The Chief Health Inspector accompanied Dr Meiklejohn throughout his travels, and I was escorted by different European and African provincial health officials.

"As the majority of localities we had to visit for epidemiological reasons were in areas bordering Mozambique, Zambia and Botswana, where few or no civilians travel due to civil warfare, special arrangements were made to bring us as near as possible to the villages by chartered or government four-seater planes. From the rough air strips, we were usually provided with a metal-protected lorry accompanied by armed African soldiers. In particularly dangerous areas, two military jeeps with soldiers escorted us throughout the day and soldiers were placed on the airstrips to assure our security at the departure of the charter plane.

"As every day we had to examine a few thousand children in one to four localities, advance planning was made by the authorities, i.e., the population was grouped at gathering points, and up to 8 African health assistants were made available to assist us in our work.

"On no occasion was any information requested kept from us."

planned and supported by excellent communications. There was a medical school in Salisbury; the health personnel included many European nurses and physicians, a large proportion of whom had undergone training in public health and tropical medicine; and an extensive network of 83 mission hospitals existed. Because of the civil war, health staff were working under extremely difficult circumstances, often at the risk of personal injury or death. Although smallpox was at the top of the list of notifiable diseases, the country had never set up a separate smallpox eradication programme. Mobile vaccination teams sought to vaccinate the entire population against smallpox in a 3-year cycle, using liquid smallpox vaccine purchased from South Africa. There were no systematic search operations and, apart from reporting during an outbreak, no routine "nil" reports. Reliance was placed on the extensive and well-distributed network of health units and on the alertness of staff in high-risk areas. This approach appeared to have been reasonably successful in detecting almost all outbreaks, and transmission was interrupted in 1970. The instability in some border areas raised doubts as to the ability of this health structure to detect outbreaks rapidly in those areas if there should be an importation, but the neighbouring countries—Botswana, Mozambique, South Africa and Zambia—had been free of smallpox since 1973 or earlier.

The consultants found no evidence of smallpox transmission within Southern Rhodesia or of importations since the last reported outbreak there in 1970. It was their opinion that, because the health units were numerous, geographically well distributed and staffed with well-trained and alert personnel, any case of smallpox that might have occurred after 1970 would have been detected. Facilities for laboratory diagnosis, including electron microscopy, were available in Salisbury and many specimens had been tested between 1970 and 1977, all with negative results. After the consultants' visit, a further 23 specimens obtained from patients with what was diagnosed clinically as chickenpox were examined in a WHO collaborating centre. Herpesvirus particles were found in 10 of them but poxvirus in none.

Review by the Global Commission, December 1978

At its meeting in December 1978 the Global Commission reviewed the consultants' report and the results of the pockmark and

vaccination scar survey supplied by the government, and certified that Southern Rhodesia was free of smallpox.

Angola

The only countries remaining for assessment in southern Africa were Angola and the island of Madagascar. At the coordination meeting held in Lusaka in March 1978, it had been decided that the certification of Angola should be carried out by an international commission in February 1979.

The last reported cases of smallpox in Angola had occurred in 1966. Although the country had suffered from political instability since 1961, there had been a good vaccination programme, in which freeze-dried vaccine had been used, until 1975. Variola minor was endemic up to 1959, and outbreaks of variola major had occurred following importations from Zaire during the 1960s, the last taking place in 1966. Each of these was investigated by state epidemiologists and confirmed by virus isolation at a laboratory in Luanda. The extensive national vaccination campaign extended through 1974 but was then sharply curtailed because of the civil war, which culminated in national independence in 1975. By then, more than 3 years had elapsed since the last outbreak in Zaire, which had been the source of earlier importations. However, in 1978 many areas were regarded as inaccessible and it was thought that it would be difficult to carry out pockmark surveys and obtain specimens from cases of chickenpox in those parts of the country.

Precertification activities

Dr Joel Breman of the Smallpox Eradication unit helped to plan the precertification programme and Dr René F. M. Collas, a WHO epidemiologist, and Mr José F. Verani, a WHO technical officer, who were stationed in Angola in connection with other WHO projects, assisted the national health officials. In August 1978 Dr Clovis H. Tigre, a Brazilian epidemiologist, visited Angola to review the progress of field surveys and the preparation of the country report. He found that little had been done.

In November 1978, at Arita's request, Dr Francisco J. C. Cambournac, a former resident of Angola who had been Director of the WHO Regional Office for Africa but had retired to Portugal, provided valuable data on smallpox in Angola before 1975, the year of independence. The country report was finally prepared later that month, by which time 79 specimens had been collected from chickenpox patients. However, the field survey had been delayed because of poor communications and lack of resources, and it was doubtful whether all the data would be available for the visit of the International Commission scheduled for February 1979. Early in December, after a meeting at the Ministry of Health between government officials and the WHO programme coordinator in the country, the survey proceeded more rapidly and by early January 1979 all preparations had been completed.

Pockmark survey. The pockmark survey carried out by the national health authorities covered all the provinces (Fig. 26.5) and 11% of the total population. About 0.8% of the adult population and 0.04% of school-age children had facial pockmarks, but only 1 pockmarked child was found in the preschool age group (Table 26.11), and it was decided that the scarring had been caused by chickenpox.

Chickenpox surveillance. Variola minor had virtually replaced variola major in Angola in

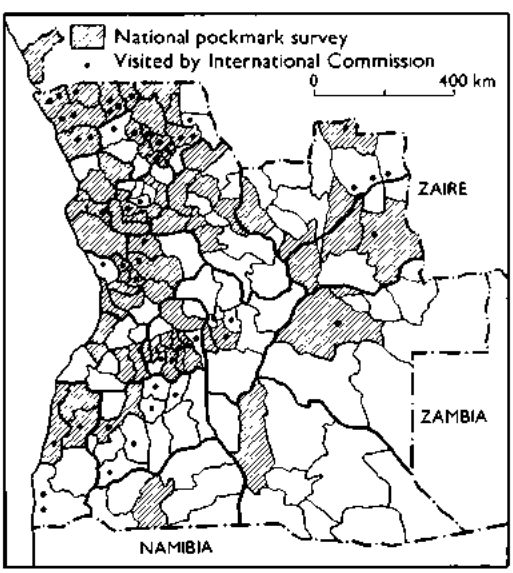

Fig. 26.5. Certification activities in Angola: municipalities covered by the national pockmark survey, July–December 1978, and those visited by members of the International Commission for the Certification of Smallpox Eradication in Angola, 5–16 February 1979.

Table 26.11. Angola: results of facial pockmark survey in July–December 1978, by age group

Age group	Persons examined		
	Total number	With facial pockmarks	
		Number	%
Preschool children	81 572	1[a]	0
School-age children	444 401	177[b]	0.04
Adults	218 454	1 807[b]	0.83

[a] One child had facial scarring which resembled pockmarks caused by smallpox, but after further examination it was decided that the scarring had been caused by chickenpox.
[b] Due to smallpox contracted before 1974.

the 1950s and had been present together with variola major in neighbouring countries (Zaire and Zambia) until the late 1960s. A total of 122 specimens collected from outbreaks of chickenpox occurring in various provinces (Fig. 26.6) were examined in a WHO collaborating centre; none contained poxvirus but 12 were found to contain herpesvirus particles. This unusually small proportion of herpesvirus-positive specimens was due to a breakdown of the electron microscope during the period concerned, so that much of the material had only been cultured.

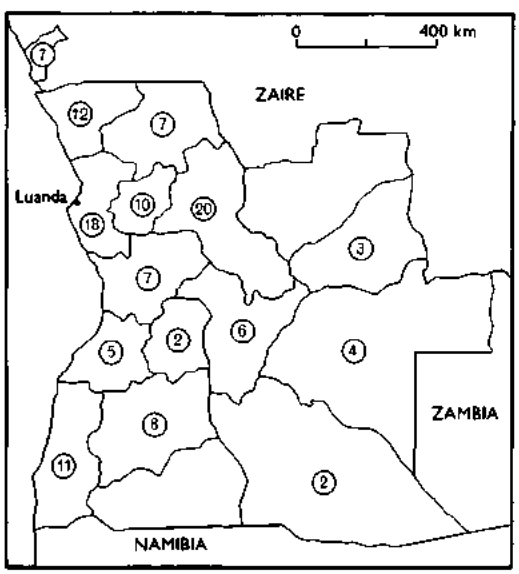

Fig. 26.6. Numbers of specimens collected from chickenpox cases in various provinces of Angola between July 1978 and February 1979.

Visit of the International Commission, 5–16 February 1979

After reviewing the data supplied by the Angolan authorities in Luanda, the Commission formed 5 teams, which travelled widely throughout the country (see Fig. 26.5) before meeting again in Luanda on 15 and 16 February to review the situation. Contrary to the opinion prevailing earlier, members were able to visit most parts of Angola, except the south-east, which bordered on Namibia, a country that had been free of smallpox for decades. During their visits they conducted a facial pockmark survey that covered 28 167 persons, of whom 495 had pockmarks; these were all persons of school age or older and all had contracted the illness causing the pockmarks prior to 1966.

Between 1966 and 1974 there had been a good vaccination programme, 1.5–2.8 million people out of a population (in 1974) of about 6.3 million having been vaccinated annually with freeze-dried vaccine of good quality purchased from a number of European countries. There were 144 reporting units in the 16 provinces and, on average, one-third of them were sending in monthly epidemiological reports. Taking into consideration the absence of smallpox from Angola since 1966 and from neighbouring countries since the late 1960s, the field investigations carried out by the Angolan authorities, and the results of the chickenpox survey, the International Commission certified Angola to be free of smallpox.

Madagascar

Because Madagascar was an island with a relatively small population, it had been possible to interrupt smallpox transmission there during the First World War, and to control effectively the few importations that occurred between 1925 and 1931 (see Chapter 8). The Consultation on the Worldwide Certification of Smallpox Eradication, meeting in October 1977, decided that all that was needed from Madagascar was a country report, which was presented by the government to WHO in December 1977.

An unusual feature of this report was the large number of recorded deaths from chickenpox (Table 26.12). The data for 1972–1975 were supplied in the country report, the other figures by correspondence. These data could

Table 26.12. Madagascar: number of reported cases of and deaths from chickenpox, 1972–1978

Year	Number of cases	Number of deaths	
		Original figures[a]	Revised figures[b]
1972	11 069	7	7
1973	19 408	26	26
1974	27 322	187	8
1975	33 076	108	5
1976	22 213	97	11

1978	20 204	20	20

[a] From the Ministry of Health of Madagascar.
[b] After investigations by Dr Z. Islam in March 1979.

have been interpreted as the result of an unrecognized importation of variola major into Madagascar in 1974 and its subsequent spread and misdiagnosis as chickenpox during 1975 and 1976. The likelihood that this was so was increased when the data by province for 1976 showed that the case-fatality rate for "chickenpox" in the province of Antananarivo was almost 1% (8572 cases; 83 deaths). Correspondence between the Smallpox Eradication unit and health officials and the WHO programme coordinator in Madagascar failed to elicit a satisfactory explanation for the reported high death rates from chickenpox, and in December 1978 the Global Commission deferred certification pending the provision of further information.

It was arranged that Dr Ziaul Islam should visit Madagascar and investigate the situation. Working there from 26 February to 9 March 1979, he checked the original records for 1972–1978 and discovered that measles deaths had sometimes been attributed to chickenpox, typing errors had been made, and confusion had resulted from using reporting forms for mortality when those intended for reporting morbidity had run out; sometimes no explanation for the figure reported could be found. His final assessment of the numbers of deaths from chickenpox, also shown in Table 26.12, is consistent with the occurrence of chickenpox only.

Dr Islam's report, which also provided some additional information on the health structure and vaccination programme in Madagascar, was distributed to members of the Global Commission on 10 May 1979. They accepted the explanation that the high mortality attributed to chickenpox was due to reporting and/or recording errors and eradication in Madagascar was certified by correspondence on 29 June 1979. Had the Global Commission not made such a decision, arrangements between the Smallpox Eradication unit and the government of Madagascar were in hand to carry out an intensive pockmark survey in the areas in which large numbers of chickenpox deaths had been originally reported, but this did not prove necessary.

UGANDA AND THE SUDAN

In parallel with the certification activities in the countries of southern Africa, arrangements were made for international commissions to visit the 2 African countries (other than those of the Horn of Africa) for which certification was still required—namely, Uganda and the Sudan. Uganda had reported its last endemic case of smallpox in

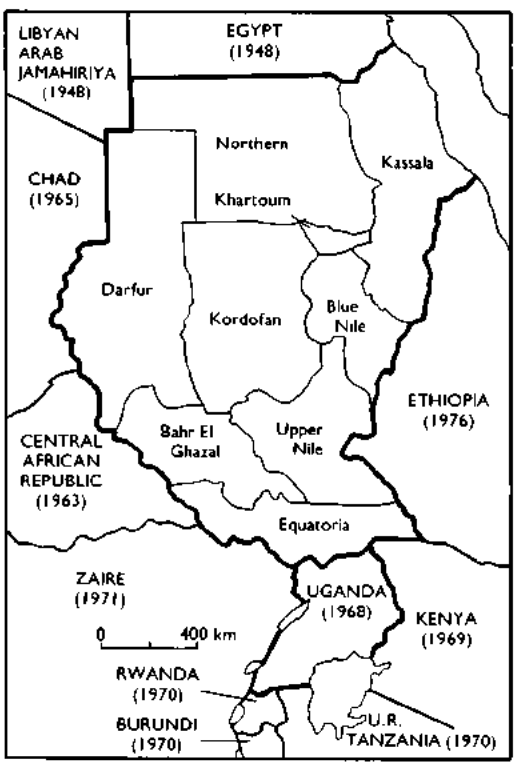

Fig. 26.7. Sudan and Uganda, showing the provinces of the Sudan at the time of the precertification activities and the years in which smallpox ceased to be endemic in neighbouring countries. Uganda was visited by an international commission from 11 to 27 October 1978 and the Sudan by another international commission from 15 to 29 November 1978.

1968, but imported cases had occurred each year between 1969 and 1972, originating from the neighbouring Equatoria Province of the southern Sudan (Fig. 26.7), in which there had been civil disturbances until 1972. The certification of eradication in Uganda was therefore dependent on that in the Sudan. However, certification could not be undertaken in the Sudan until 1978 because of the risk of importations from Ethiopia, in which smallpox remained endemic until August 1976. Plans were therefore made for the certification of the Sudan and Uganda in October–November 1978, by separate international commissions.

Uganda

Precertification activities

Preparations for certification in Uganda followed the pattern that had been developed in western Africa, where a similar long interval had occurred between the last reported case and certification (see Chapter 25). Dr Chu In Ho, a WHO epidemiologist stationed in Kampala, assisted the Ugandan health authorities in the preparation of the country report and in conducting pockmark surveys and chickenpox surveillance. For the pockmark survey (Table 26.13), 622 localities widely dispersed over Uganda's 10 provinces were selected and over 1.5 million persons, representing 12.2% of the total population of Uganda, were examined. Most of the more recent outbreaks of smallpox in Uganda had been due to variola minor (see Chapters 8 and 19), so it was not surprising that facial pockmarks were rare, being found in only 0.005% of persons of school age or older. None was ascribed to smallpox infection contracted after 1970.

A WHO-supported virus laboratory in Entebbe had confirmed diagnoses of smallpox in 1970 and 1972, but thereafter had gradually ceased to function. In preparation for

Plate 26.3. The President of Uganda took a personal interest in the certification of smallpox eradication in his country. The eradication programme transcended personal and political barriers in a global effort towards a common goal.

Table 26.13. Uganda: results of facial pockmark surveys by national authorities, April–September 1978, and by International Commission members, October 1978, by age group

Age group	Survey	Number of persons examined	
		Total	With facial pockmarks
Preschool children	National	85 504	0
	International Commission	4 932	0
School-age children	National	900 115	47[a]
	International Commission	25 926	11[a]
Adults	National	572 266	19[a]
	International Commission	29 629	2[a]

[a] Due to smallpox contracted before 1971.

certification, 118 specimens were collected from cases of chickenpox occurring in all provinces during the period April–September 1978. On examination at WHO collaborating centres, none was found to contain poxvirus particles.

Visit of the International Commission, 11–27 October 1978

After an initial 3-day meeting in Kampala, the Commission was divided into 3 teams, which between them visited all the provinces. As well as inspecting health units and the reporting system, they carried out facial pockmark surveys (see Table 26.13) which confirmed the results of the larger national survey.

Before certifying that smallpox transmission had been interrupted in Uganda, members of the Commission made a special visit to the Virus Research Institute in Entebbe and confirmed that all stocks of variola virus previously held there had been destroyed on 27 July 1976, after receipt of the letter dispatched from the Smallpox Eradication unit earlier that month (see Chapter 30).

Sudan

A WHO-assisted smallpox eradication programme had been carried out in the Sudan, geographically the largest country in Africa, from 1969 onwards but was not very effective until 1972 (see Chapter 18). The last endemic case of smallpox had occurred in Bahr El Ghazal Province in December 1972. The requisite 2-year surveillance period after the last known case had been completed by the end of 1974, but the eradication of smallpox was not certified in the Sudan by an international commission until November 1978.

Certification was delayed because the Sudan was at the crossroads of movements by seasonal agricultural workers and pilgrims, some of whom came from western Africa on their way to Mecca, and some from Ethiopia, in which smallpox had been endemic until 1976 (see Chapter 18, Fig. 18.6). The movement of refugees from Ethiopia into the southern Sudan also caused problems. The certification of smallpox eradication in the Sudan could be undertaken with confidence only after transmission had been interrupted in Ethiopia.

The delay in certification caused considerable problems for the Sudanese health authorities, since they had to maintain surveillance for a further 5 years after the last case. However, the fact that they had done so meant that smallpox eradication in the central and eastern parts of the African continent could be certified with much greater confidence. In addition to Ethiopia, the Sudan had borders with the Central African Republic, Chad, Kenya, Uganda and Zaire, from which cases had regularly been imported in the 1950s and 1960s. The absence of importations from these countries into the Sudan between 1972 and 1978 provided additional assurance that transmission had ceased in these countries as well.

Precertification activities

After the last case occurred in December 1972, surveillance continued in the Sudan, more than 600 staff being employed for the purpose, including 48 supervisors, 18 assessors and 369 vaccinators, who were distributed throughout the 13 provinces. During this period 1 or 2 WHO epidemiologists or consultants assisted in developing and implementing surveillance. The smallpox eradication staff who contributed in this way included Dr Abdel Hamid el Sayed, as the national director of the programme, and the WHO epidemiologists Mr David Bassett, Dr Donald P. Francis and Dr Satnam Singh.

While the reporting system was being strengthened, programme staff conducted a

systematic search for hidden foci of smallpox, particularly in the southern provinces and the areas bordering on Ethiopia. Active searches were conducted in villages, health establishments, schools, police stations and markets to seek information on cases of diseases with a rash, and a reward was offered. The vaccination programme was also maintained.

Pockmark survey. Between 1975 and 1977 smallpox eradication programme staff examined a total of nearly 2 million persons, out of a total population of 14 million, for facial pockmarks (Table 26.14). The few people found with them (0.04% of those examined, all of school age or older) had contracted smallpox before 1972.

Chickenpox surveillance. Because of possible diagnostic confusion between variola minor and chickenpox, the latter was made a notifiable disease and, wherever possible, outbreaks were investigated by smallpox eradication programme staff. Between 1973 and 1977, 17 690 cases, including 10 deaths, were reported (Table 26.15). Each year, specimens for laboratory investigation were taken from a number of cases, usually those with unusual features. Of 74 specimens examined in WHO collaborating centres none contained poxvirus.

Special searches in the southern provinces. Because of the difficulties of access before 1972, special searches were conducted in Upper Nile and Equatoria Provinces. During two searches in Upper Nile, in 1972 and 1974, 718 000 out of 798 000 inhabitants of the province were vaccinated. A vaccination scar survey revealed a coverage of 85% in the age group 0–4 years and 98% in the age group 5–14 years.

In Equatoria Province, the special surveillance team operating in January 1974 dis-

Z. JEŽEK

Plate 26.4. The collection and testing of material from skin lesions in cases of fever with rash, especially in countries where variola minor had recently been endemic, provided assurance that the surveillance system would have detected smallpox if it had occurred.

covered evidence of possible smallpox transmission as late as November 1973. The last confirmed case in the province had occurred in November 1972, in the most densely populated part of Kapoeta District, some 80–100 kilometres from the Lafit mountains, where evidence of possible continued transmission was discovered. Intensive investigations suggested that there had been a number of cases, the last in a 15-month-old boy with facial pockmarks. However, it was impossible to determine precisely the date of onset of the disease. The surveillance team revisited the Lafit mountains 3 times in 1974, and repeatedly thereafter, but failed to find any further evidence of smallpox. During a visit to the area in 1976 evidence was obtained suggesting that the supposed last case in the focus had been infected late in 1972, not late in 1973.

Special surveillance in areas on the Ethiopian border. In September 1973, an interregional WHO smallpox eradication programme seminar was held in Addis Abeda. Border surveillance was discussed, and the Ethiopian and Sudanese governments made arrangements after the seminar for surveillance teams from each country to investigate rumours of smallpox on the other side of the border (see Chapter 21). For example, at the request of Ethiopia in November 1973 and February 1974, a Sudanese team investigated smallpox rumours and vaccinated the inhabitants in the Gabba and Metabel areas of Gojam Province in Ethiopia, which were not easily accessible from the Ethiopian side of the border.

Visit by a WHO consultant. In August–September 1977, Dr Gordon Meiklejohn, a WHO consultant, visited Khartoum and assisted in documenting the work of the smallpox eradication programme and subsequent surveillance activities. In May 1978, a further stimulus was given to the discovery of cases of smallpox by the announcement by the World Health Assembly that a reward of US$1000 would be offered to any person who reported a smallpox case which was confirmed by laboratory investigations in a WHO collaborating centre.

Visit of the International Commission, 15–29 November 1978

After a brief meeting in Khartoum, field visits were made by 9 separate teams over a period of 12 days. Because of the large size of the Sudan, an aeroplane was made available by the United Nations Development Programme to help to cover critical areas in the northern and eastern provinces (Fig. 26.8). During their visits, Commission members carried out facial pockmark (see Table 26.14) and vaccination scar surveys.

The International Commission found nothing to cause them to doubt the claim that smallpox transmission had been interrupted in the Sudan at least 5 years earlier, and certified the country to be free of smallpox.

SOUTH-WESTERN ASIA

Several countries in south-western Asia required certification by international commissions or other special measures (Fig. 26.9). They fell into 3 groups.

Yemen and Democratic Yemen were geographically close to the last remaining endemic countries in the world, Ethiopia and Somalia, and certification activities were delayed there until nearer the time when the Horn of Africa would itself be visited by international commissions. Because of political differences between the two countries, they were visited by separate international commissions in June 1979.

To the north-east lay Saudi Arabia and the Gulf states of Bahrain, Kuwait, Oman, Qatar and the United Arab Emirates. Because of the intensity of the traffic between these countries and the Indian subcontinent and the vast annual pilgrimages to Mecca, the Consultation on the Worldwide Certification of Smallpox Eradication had recommended in October 1977 that WHO should obtain special country reports from each of them for review by the Global Commission in December 1978.

Iran, Iraq and the Syrian Arab Republic were not included in the Intensified Smallpox Eradication Programme in 1967 because they had eliminated endemic smallpox in 1963, 1959 and 1950, respectively. However, it was known that a major epidemic of variola major had spread through these countries in 1970–1972, after an importation from Afghanistan (see Chapter 23). Few of the many cases which occurred had been reported to WHO—29 from Iran in 1971 and 2 in 1972, 37 from Iraq, all in 1972, and 54 from the Syrian Arab Republic in 1972 (Fig. 26.10). Unofficial

The disease spread to Iraq and the Syrian Arab Republic, and from Iraq to Yugoslavia. Numbers indicate the cases officially reported to WHO by month. In both Iran and Iraq, the numbers of cases which actually occurred and were known to the respective governments were far larger (see Chapter 23).

reports suggested that there was good reason to believe that transmission had persisted for almost 2 years in Iran, 8 months in Iraq and 4 months in the Syrian Arab Republic, with many more cases than had been reported.

The last cases of smallpox in these countries were believed to have occurred in 1972, some 5 years earlier but the Consultation believed that it was important to confirm with greater certainty that smallpox was not persisting in any of them and had not been present for at least the last 2 years. It therefore recommended that visits should be made to Iran, Iraq and the Syrian Arab Republic by Global Commission members, consultants and/or WHO staff, to verify and document smallpox eradication and present their findings to the meeting of the Global Commission in December 1978.

Certification did not proceed exactly as suggested by the Consultation. Iraq and the Syrian Arab Republic were visited and certified in succession by an international commission, of which the chairman, Dr Robert Netter, was a member of the Global Commission. In Iran, however, although extensive precertification activities were conducted, political events made it impossible to arrange the planned visit of an international commission to that country.

Yemen

A WHO-assisted smallpox eradication programme had been initiated in Yemen in 1969 in the course of which the primary vaccination of 0.7 million children and the revaccination of 1 million persons, out of a population of 4.8 million, were carried out. Surveillance activities had discovered 23 possible smallpox cases between 1970 and 1977, but when specimens from these cases were examined in WHO collaborating centres no poxvirus particles were found.

In 1978 and 1979, a special search was conducted with the assistance of Mr Robert C. Steinglass, a WHO operations officer. This included the investigation of suspected cases of smallpox, the collection of specimens from every chickenpox outbreak discovered in the country, and facial pockmark and vaccination scar surveys in a large number of selected localities. Altogether 920 localities were visited in 146 of the 162 districts. The WHO reward of US$1000 for information on new smallpox cases that could be confirmed was widely publicized to stimulate the reporting of suspected cases. In contrast to African countries, in which variola minor had been most recently endemic, variola major had been the prevalent form in Yemen, and a facial pockmark survey covering some 20% of the total population revealed 1920 pockmarked persons, all of whom were over 10 years of age (Table 26.16). None of them had had smallpox more recently than 1967. None of the 42 specimens collected from cases of fever with rash was found by WHO collaborating centres to contain poxvirus.

A vaccination scar survey revealed that only 22.9% of children aged 0–4 years had vaccination scars, a proportion that rose to 65.6% among those aged 5–9 years.

Visit of the International Commission, 2–10 June 1979

After preliminary discussions in Sana'a, the Commission members formed 3 teams and travelled widely throughout the country, except in the sparsely populated eastern desert area of the Marib, which was closed for political reasons. The results of the surveys confirmed those presented in the country report, and the Commission concluded that there was no evidence that there had been any endemic cases of smallpox since the last recorded cases in 1969. Accordingly, Yemen was certified to be smallpox-free.

Democratic Yemen

Although Democratic Yemen had not reported a confirmed case of smallpox since 1961, the government undertook a smallpox eradication programme, beginning in 1970. In a mass vaccination campaign combining smallpox and BCG vaccinations, 4 mobile vaccination teams had performed 1.7 million smallpox vaccinations between 1970 and 1977, among a population of 1.7 million; 578 000 were primary vaccinations, and the take rate was over 90%.

Precertification activities

Special search operations were carried out between February 1978 and February 1979, with the assistance of a WHO epidemiologist, Dr Mohamed El Naggar. The offer of a reward of 50 Yemeni dinars (approximately US$150) for the notification of a case of smallpox was publicized by newspapers, radio and television. During a year-long operation, active searches were conducted in 55 of the 83 subdistricts in the country, including 2 subdistricts on the island of Socotra. Dr R.N. Basu and Dr Holger Lundbeck, members of the Global Commission, visited the country in November 1978 to study and advise on preparations for certification.

Pockmark survey. Facial pockmarks were seen only in persons over 14 years of age (Table 26.17). From the replies to questions put to those with pockmarks, it emerged that the most recent infection among them in Democratic Yemen had occurred in 1958. A vaccination scar survey recorded 59.8% with scars in the age group 0–4 years, the corresponding proportion reaching 96.9% in the age group 5–14 years. Of 36 specimens collected from cases of fever with rash during 1978–1979 and examined by WHO collaborating centres, 8 showed herpesvirus particles and none poxvirus.

Visit by the International Commission, 3–11 June 1979

After a briefing meeting in Aden, 3 teams, each including a Commission member, a WHO consultant and a national representative, visited 18 districts and carried out limited surveys for facial pockmarks (Table 26.17) and vaccination scars. The results obtained corroborated the evidence presented in the country report.

The Commission concluded that there was no evidence that the endemic transmission or importation of smallpox had occurred in Democratic Yemen since the smallpox eradi-

[a] Due to smallpox contracted before 1959.

cation programme had begun there in 1970. It certified the country to be free of smallpox.

Arab Countries of the Gulf Area: Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, United Arab Emirates

The health services of these 6 countries had been greatly strengthened since the increase in income from oil production in the early 1970s. Indigenous transmission of smallpox was thought to have ceased in all of them in the 1960s, but there were numerous opportunities for importations to occur (see Chapter 23, Table 23.10) and the inadequacy of the surveillance system at that time meant that a report of zero incidence of smallpox could not be regarded as completely reliable. The 1977 Consultation on the Worldwide Certification of Smallpox Eradication had therefore requested that detailed country reports should be supplied to the Global Commission (see Chapter 24).

One of the members of the Consultation, Dr Jalal M. Aashi, who was at the time Secretary-General of the Secretariat-General of Health for the Arab Countries of the Gulf Area, arranged for a member of the Smallpox Eradication unit, Dr Ehsan Shafa, to attend the meeting of the Secretariat-General in Riyadh, Saudi Arabia, from 30 October to 2 November 1977. Dr Aashi and Dr Shafa had drawn up a plan of action for the Gulf states, to be implemented during 1978, and this was approved by the assembled ministers of health. In fact the plan was more thorough than the Consultation's suggestions had indicated. Under its terms each country was requested: (1) to carry out chickenpox surveillance and collect specimens from selected cases; (2) to establish and maintain rumour registers of suspected cases of smallpox; (3) to carry out facial pockmark surveys; and (4) to prepare a country report. Specimen collection kits and forms for each section of the plan of action were provided.

Dr Arcot G. Rangaraj, a veteran of the smallpox eradication campaign in Afghanistan, was appointed as a WHO consultant for 6 months (1 March–31 August 1978) to help to implement the plan of action. He visited each country 3 times, contacting public health laboratories, hospitals, health centres and clinics, medical officers of oil companies, missionary and other private institutions, and private practitioners.

Table 26.18. Arab countries of the Gulf area: results of precertification investigations, January–July 1978

Country	Estimated population (1977)	Facial pockmark survey in children < 10 years old		History of children with facial pockmarks	Number of cases of chickenpox reported	Laboratory investigations[a]	
		Number examined	Number with pockmarks			Number of specimens tested	Number positive for herpesvirus
Bahrain	270 000	25 623	1	Contracted in Pakistan	3 154	50	16
Kuwait	1 130 000	80 791	0	—	1 766	78	35
Oman	810 000	67 060	1	9-year-old child, skin infection in infancy	480	39	10
Qatar	190 000	15 242	0	—	566	35	8
Saudi Arabia	7 630 000	158 075	0	—	831	105	46
United Arab Emirates	670 000	85 994	4	3, each infected 7 years earlier in Bangladesh, India and Pakistan; 1, a 9-year-old boy, infected in 1971 outbreak	1 871	52	32

[a] Specimens examined at WHO collaborating centres; all were negative for poxvirus.

The results of the special investigations are shown in Table 26.18. There was no evidence that smallpox had been present in any of the 6 countries since 1971.

After reviewing the excellent data provided in the reports of these countries, the Global Commission, meeting in December 1978, had no hesitation in certifying all of them to be free of smallpox.

Iran

Preparations for certification

Shortly after the Consultation in October 1977, Dr Shafa visited Iran from 2 to 14 December 1977, during which time, in collaboration with the health authorities, a plan of operations for the confirmation of smallpox eradication was prepared. In view of the large epidemic of smallpox in Iran in 1970–1972 (see Chapter 23), government health officials agreed to carry out a comprehensive programme. This was to last for 6 months, starting on 21 March 1978 (the Iranian New Year), and include: (1) chickenpox surveillance with the compulsory reporting of cases, and epidemiological and laboratory investigation of chickenpox outbreaks associated with deaths; (2) the maintenance of a rumour register and reports on the investigation of suspected cases of smallpox; (3) facial pockmark surveys; and (4) the preparation of a comprehensive country report.

Dr Parviz Rezai, Deputy Director-General of Communicable Diseases Control and Malaria Eradication, was put in charge of the programme, and by the end of February 1978 sanitary inspectors from every province in Iran, who were responsible for specimen collection, had attended a seminar in Teheran and been issued with specimen collection kits. A seminar was also held, attended by the chiefs of the communicable disease departments of all the provinces, to discuss the plan of action and their role in its execution.

Activities went on until 23 September. Dr Shafa continued to follow their progress closely and visited Iran again in August 1978. In October, he and Dr Lawrence Brilliant, who had worked as a WHO staff member in the smallpox eradication programme in India, visited Iran to assist in the analysis of the data and the preparation of the final report for the Global Commission. They also paid brief visits to the provinces of Ilam, Fars and Isfahan. It had been planned that Dr Aashi and Henderson, members of the Global Commission, would visit Iran between 1 and 15 November, during which time they would be provided with a supplementary report giving epidemiological details of the 1970–1972 outbreak. However, their visit had to be cancelled owing to increasing civil unrest, which culminated in the deposition of the Shah and the proclamation of an Islamic Republic on 1 April 1979.

Pockmark survey. The object of the facial pockmark survey was to confirm the absence of smallpox during the previous 5 years (1973–1978); hence only children under 5 years of age were examined. The areas to be surveyed were selected in the following order of priority: (1) the environs of the last known smallpox outbreaks; (2) districts in which deaths from chickenpox had been reported; (3) districts in which suspected cases of smallpox had been reported; and (4) border territories and remote areas.

Of 72 337 children examined (1.2% of all those under the age of 5 years), 15 were reported to have apparent pockmarks. On investigation, the scarring was found to be due to chickenpox in 11 cases, to boils in 3 cases, and to the secondary infection of chickenpox vesicles in 1 case. The survey was conducted in 160 of the 162 districts, in all 23 provinces. Dr Brilliant visited the provinces of Fars and Isfahan during October 1978 and confirmed that the facial pockmark survey was well designed, the sampling frame was carefully chosen, and the survey procedures were understood by the health workers.

Chickenpox surveillance. Weekly reporting of chickenpox from each district by telegram was made compulsory for the 6-month period 21 March–23 September 1978. In all, 4076 cases were reported, giving an incidence of 12.2 per 100 000 population over a 6-month period, which was similar to incidence rates in other countries in which extensive chickenpox surveillance programmes had been undertaken. Of these reported cases, 88% were verified by senior health officials and epidemiologically analysed; 85% of the persons in question had vaccination scars. Laboratory specimens were taken from 46% of the 459 cases in unvaccinated subjects and from 140 chickenpox cases which, although the persons concerned had been vaccinated, were either severe or atypical or had occurred in an adult. Specimens were collected from every province except Boyer Ahmadi-ye Sardsir va Kohkiluyeh, Kerman, Ilam, and Lorestan.

Ilam Province, which had reported the poorest chickenpox surveillance, was visited and checked by Dr Shafa in October 1978. All 349 specimens tested by WHO collaborating centres proved negative for poxvirus.

Special investigation of suspected smallpox cases. Four unusual cases of skin disease were investigated by physicians from the Communicable Disease Unit in Teheran. Two were found to be cases of molluscum contagiosum and the other 2 were severe chickenpox. Routinely, all cases of fever with rash were regarded as suspected cases of smallpox until proved otherwise by clinical, epidemiological and laboratory findings. Between 1973 and mid-1978, 309 such cases were investigated. All proved negative for variola virus on laboratory examination by the Pasteur Institute in Teheran, an establishment which had demonstrated a good laboratory capability for smallpox diagnosis in 1971–1972.

Review by the Global Commission, 7 December 1978

Dr Rezai presented a detailed country report entitled *Smallpox Eradication in Iran*, and Dr Brilliant an additional document, *The Special Programme to Confirm Smallpox Eradication in Iran.* In addition, 2 confidential reports—*Smallpox in Iran 1970–72*, prepared by the Iranian government, and *Smallpox in Fars Province, Iran, 1970–72*, prepared by Dr Brilliant—were made available to a special group of Commission members. These 4 reports provided very comprehensive data on the smallpox situation in Iran. The confidential government report gave details of 1996 cases of smallpox that had occurred in 400 outbreaks between November 1970 and September 1972 (see Chapter 23, Fig. 23.4), of which 1349 had been confirmed as positive for variola virus in the laboratory in Teheran.

The epidemic had originated from an importation from Afghanistan and was eventually controlled by mass vaccination. Its long duration (23 months) was due to the use of poor-quality liquid vaccine, and it was rapidly controlled as soon as potent freeze-dried vaccine became available (see Chapter 23). The political decision not to report the actual number of cases to WHO did not prevent the health services from being fully operational within the country and from being committed to eliminating the disease. There was no reason to believe that any cases had occurred after September 1972.

As has been mentioned above, political circumstances had led to the cancellation of the planned visit to Iran in November 1978 by members of the Global Commission, as recommended by the October 1977 Consultation, but on the detailed evidence before it the Global Commission had no hesitation in certifying that Iran was free of smallpox.

Iraq

Smallpox had been eliminated from Iraq in 1959, so that there had been no WHO-assisted smallpox eradication programme in the country. Vaccination, and subsequently certification activities, were undertaken by the regular health services. Late in 1971, smallpox had spread from Iran to Iraq (see Fig. 26.10) but, as in Iran, the authorities had been reluctant to report it. Evidence obtained subsequently suggested that there had been at least 800 cases (see Chapter 23), but that the outbreak had been finally contained by June 1972.

Preparations for certification

In May 1978 Dr James Tulloch, a consultant with the Smallpox Eradication unit, visited Iraq to assist with the preparation of a country report and the organization of a facial pockmark survey. The basic report was prepared in collaboration with Dr Felix Jurji, the national Director of Epidemiology and Quarantine. In June, the Director-General of the Public Health Administration sent forms to all departments in the school health administration with a request that all schoolchildren should be examined for pockmarks and that the forms should be returned by mid-September for presentation to members of the International Commission, which planned to visit Iraq in October.

Visit by the International Commission, 5–15 October 1978

Because of the reluctance of the government to discuss the 1971–1972 epidemic, members of the Commission concentrated on determining whether Iraq had been free of smallpox for at least the previous 2 years. After a briefing meeting in Baghdad, Commission members and their colleagues formed 2 teams, which travelled widely through the country. They checked the quality of the

Plate 26.6. James Tulloch (b. 1949), an Australian epidemiologist who served as a consultant to the smallpox eradication programme from 1976 to 1980. He participated in the final stages of the eradication programme in Bangladesh and played an active role in preparations for certification in many countries.

reporting system, and visited hospitals, health units and the diagnostic laboratory in Baghdad. The general impression everywhere was one of competence. In the laboratory, 162 specimens collected between 1972 and 1978 from patients with a rash had been tested; all had proved negative for variola virus. Of these, 27 collected in January 1978 and 11 collected in March–June 1978 were tested in WHO collaborating centres, all with negative results.

Four out of 3825 children aged between 4 and 12 years who were examined had pockmarks, all due to smallpox contracted before or during 1972. Vaccination coverage was between 75% and 100% in primary-school children, depending on the area, and between 50% and 80% in preschool children.

The Commission concluded that there was no evidence that smallpox had occurred in Iraq since 1972 and that the health services were sufficiently reliable from the point of view of detecting, recording and reporting communicable diseases to ensure that, if a case of smallpox had occurred, it would have come to the notice of the central public health authorities. However, between their visit in October and the meeting of the Global Commission in December, the results of the facial pockmark survey had been received; these showed that 17 out of 195 665 schoolchildren had "facial pockmarks". No details were provided of the children's ages or of the dates on which they had suffered from smallpox. Certification was therefore delayed pending clarification of the situation. Subsequently, it was reported that, of these 17 children with "facial pockmarks", 16 had good primary vaccination scars, 15 cases were of chickenpox, 1 had had boils, and 1 had had another kind of skin infection. This information was sent to all Global Commission members in March 1979 and Iraq was certified to be smallpox-free by correspondence on 17 April 1979.

Syrian Arab Republic

Because endemic smallpox had been eliminated from the Syrian Arab Republic in 1950, there had never been a smallpox eradication programme in the country. All vaccinations were carried out by the regular health services. The Iran–Iraq epidemic had spread to the Syrian Arab Republic in February 1972, but appeared to have been contained by May of that year (see Chapter 23).

Preparations for certification

After his visit to Iraq, Dr Tulloch proceeded to the Syrian Arab Republic in May 1978 to help to arrange the preparation of a country report, a facial pockmark survey and the collection of specimens for laboratory testing. Dr Nouri Ramzi, Vice-Minister of Health, arranged for Dr Tulloch to visit the area of the last outbreak, in which there were 54 reported cases around Meyadin in the south-eastern part of the country, along the Euphrates river, and on the main road from Baghdad (see Chapter 23, Fig. 23.5). A survey of 507 schoolchildren in this area found 15 with facial pockmarks due to smallpox, which made it clear that more cases had occurred than were notified in 1972, as well as revealing an unreported outbreak in the period 1966–1967. For the purposes of certification it was not considered worth while to make a major effort to clarify events which had taken place over 6 years before, but the government was asked to undertake a facial pockmark survey of the 6-year-old children entering school in September. If no pockmarks were found among them, that would be considered good evidence that no cases had occurred

since 1972. Surveys carried out on 28 072 6-year-old children in 197 schools in Damascus and 11 320 children in 207 schools in Deir-ez-Zor failed to find any pockmarks. The vaccination coverage was good in schoolchildren in the higher grades—namely, 80–95%—and 50–60% among those in the first grade.

Since 1972, when 3 specimens taken from cases were found to contain variola virus by the WHO collaborating centre in Atlanta, USA, 1 specimen tested in 1974 had proved negative, as had 6 specimens tested by WHO collaborating centres between August and October 1978.

Visit by the International Commission, 15–22 October 1978

After reviewing data with the health authorities in Damascus, Commission members visited health centres and primary schools. Of 3873 children then examined, one had facial scarring reportedly due to smallpox contracted in Haffe in 1971. Four other persons with pockmarks were adults who had suffered from smallpox some 30 years previously. Commission members reviewed the reports and concluded that the detecting, recording and reporting of communicable diseases in the country were sufficiently reliable to ensure that, if an outbreak of smallpox had occurred since 1972, it would have come to the notice of the central public health authorities. Their recommendation that the Syrian Arab Republic should be certified to be free of smallpox was accepted by the Global Commission in December 1978.

SOUTH-EASTERN ASIA

At the other side of the Asian land mass were several countries in which WHO-assisted smallpox eradication programmes had never been operative because the disease had been eliminated in 1962 or earlier. The largest country, China, is the subject of detailed consideration in Chapter 27. Malaysia had eliminated endemic smallpox by the end of 1949 and effectively controlled a large outbreak that had occurred after an importation in 1959 and continued into 1960. Singapore had reported no cases since a small outbreak following an importation in 1959. Both countries had had stable governments since 1960 and the Consultation did not recommend that any special investigation should be undertaken. The remaining 4 countries were Democratic Kampuchea, the Lao People's Democratic Republic, Thailand and Viet Nam; the numbers of reported cases of smallpox in these countries during the period 1952–1963 are shown in Table 26.19.

Table 26.19. Thailand, Democratic Kampuchea, Lao People's Democratic Republic and Viet Nam: numbers of reported cases of smallpox, 1952–1963

Year	Thailand	Democratic Kampuchea	Lao People's Democratic Republic	Viet Nam
1952	43	1 740	33	2 251
1953	50	1 788	15	1 582
1954	20	443	0	3 564
1955	117	483	0	1 907
1956	4	523	0	1 008
1957	3	125	0	472
1958	28	18	0	35
1959	1 548	4	0	13
1960	32	0	0	0
1961	33	0	0	0
1962	2	0	0	1
1963	0	0	0	0

The October 1977 Consultation had recommended that, because of the prolonged hostilities and the possibility of breakdowns in the public health services, country reports should be obtained for Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam. The authorities of each of the countries concerned were to be asked to endorse these reports and, in so doing, to certify that no cases of smallpox had occurred in their country for the past 2 years. In view of the intense traffic between Thailand and India and Bangladesh, it was recommended that a member of the Global Commission or a WHO consultant should visit Thailand.

Lao People's Democratic Republic and Viet Nam

In recommending that country reports should be obtained from Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam, the Consultation had taken a cautious attitude, for there had been only 1 reported case (in Viet Nam in 1962) since 1959. Because of the fighting there during the 1960s and 1970s, large numbers of foreign soldiers had been present in these countries, but no reports of the occurrence of smallpox

had been received. Furthermore, smallpox had been absent from neighbouring countries for many years, and over the past decade there had been little communication with the endemic countries of the Indian subcontinent.

Much of the available information on Democratic Kampuchea, the Lao People's Democratic Republic and Viet Nam was in the files of the WHO Regional Office for the Western Pacific in Manila, which requested these countries in March 1978 to provide additional information. However, by August of that year no reports had been received at WHO Headquarters in Geneva. To accelerate matters, Dr Bert van Ramshorst, a medical officer in the Smallpox Eradication unit, was sent to Manila on 4 October 1978 to prepare country reports, based on the data available in the regional office, for the Global Commission meeting early in December. These were sent to the respective governments for endorsement, which was eventually received in Geneva from Viet Nam on 28 November and from the Lao People's Democratic Republic on 29 November. Thus the Lao People's Democratic Republic and Viet Nam were certified by the Global Commission on the basis of the reports prepared from the documentation available in the regional office and the official statements by their respective governments that the countries were smallpox-free. However, the certification of Democratic Kampuchea had to be deferred, because government endorsement of the country report had not been received.

Democratic Kampuchea

Formal endorsement by the government of Democratic Kampuchea of the country report prepared by the Smallpox Eradication unit proved to be very difficult to obtain because of the political turmoil in that country. Briefly, the situation was that, after a prolonged civil war, the Kampuchean National United Front for National Salvation took power in January 1979, overturning the Khmer Rouge government under Pol Pot and calling the country the People's Democratic Republic of Kampuchea. The Khmer Rouge fled, but continued to fight a guerrilla war against the new government, at the same time setting up, together with other groups, a rival coalition government. The latter was recognized by the United Nations, so that official contact with the authorities who were actually running the country, necessary in order to obtain endorsement of the country report, was not possible.

In accordance with the decision that official government endorsement of the report was essential, the Global Commission, meeting in December 1978, deferred certification. During the succeeding months WHO took a number of steps designed to break the deadlock. These included attempting to make contact with the Ambassador of Democratic Kampuchea in Beijing and approaches via Dr Robert Netter, a member of the Global Commission resident in Paris, since at that time two French groups were working in Democratic Kampuchea, as were UNICEF and the International Committee of the Red Cross.

In early autumn news came that Dr My Samody from Phnom Penh was attending a meeting at the International Committee of the Red Cross in Geneva. He was contacted and given a copy of the report. At the same time an urgent request for the endorsement of the report was addressed to the government recognized by the United Nations through its mission in Geneva, but no reply was received.

On 8 November, a letter dated 25 October 1979 was received from Dr Nu Beng, Minister of Health of the People's Democratic Republic of Kampuchea in Phnom Penh, endorsing the country report and containing a declaration of the smallpox-free status of the country. This was accepted by the Global Commission, and together with China (see Chapter 27), Democratic Kampuchea was the last country in the world to be certified, on 9 December 1979.

Thailand

In accordance with the recommendation of the October 1977 Consultation, Dr R. N. Basu, then Assistant Director-General of Health Services in India and a member of the Global Commission, visited Thailand from 8 to 27 May 1978 for an initial appraisal, field visits and the preparation of documentation. He visited Bangkok and 4 provinces, where he interviewed personnel in health offices, hospitals, clinics and schools, and also visited 2 refugee camps on the Laotian border. In the camps, he examined people for vaccination

scars, and by questioning them found that none had ever seen a case of smallpox either in the camp or in their country of origin. Dr Basu observed the way in which the communicable disease surveillance system operated in hospitals, in the 4 regional epidemiological offices, in the regional communicable disease control offices, and in remote areas, where mobile units were used for this purpose; he also evaluated the performance of the health volunteers scheme for providing primary health care at village level.

Documentation provided for the Global Commission included a comprehensive country report prepared by the government of Thailand and a paper presented by the government at the 1967 interregional seminar on smallpox eradication, which gave epidemiological details of the eradication of the disease in Thailand. The last case occurred in 1962—an importation from Calcutta, which did not give rise to any secondary cases.

On the basis of the country report and the evidence presented by Dr Basu, the Global Commission in December 1978 certified that smallpox had been eliminated from Thailand.

CONCLUSIONS

This complex series of operations, involving 29 countries in Africa and Asia over the brief period of 24 months, completed the certification of smallpox eradication in all the countries of the world in which the disease had been endemic in 1967, or countries otherwise regarded as at high risk, except for China and the countries of the Horn of Africa. Many different procedures were adopted, depending mainly on the prior history of smallpox and a variety of political considerations. There remained only the certification of China, the Horn of Africa and the adjacent country, Kenya, and the receipt from other Member States of WHO of certificates denoting freedom from smallpox for at least the preceding 2 years. These matters are discussed in the next chapter.

INTRODUCTION

As the eradication of smallpox was certified, country by country and region by region, global certification activities finally focused on the Horn of Africa and China (Fig. 27.1). For very different reasons, these were the last regions of the world to provide the detailed information required before the global eradication of smallpox could be certified by the Global Commission in December 1979.

The Horn of Africa comprises 3 contiguous countries, Ethiopia, Somalia, and Djibouti (Fig. 27.2), in the first 2 of which smallpox had remained endemic after it had been eliminated from every other country in the world. The eradication programme in these countries had been hindered by warfare and civil disturbances (see Chapters 21 and 22), which continued into the period of precertification surveillance and of certification itself. The last known case of endemic smallpox in the world had occurred in Merca,

Somalia, in October 1977. In Kenya, smallpox was related epidemiologically to outbreaks in Ethiopia and Somalia because of the common borders with those countries, and the 4 countries were therefore grouped together for certification purposes. Furthermore, because of the movements of nomads and refugees between them, it was essential that all 4 countries should be prepared for certification and visited by international commissions simultaneously. A symbolic target date was established for the final certification, 26 October 1979—exactly 2 years after the onset of rash in the last case in Somalia.

In China, it was believed that the last case had occurred many years earlier, but WHO had not been involved in either the eradication campaign or any follow-up activities, nor did WHO officials have access to China before 1972. Even then, it proved very difficult to obtain a satisfactory description of how and when smallpox had been eradicated until a visit by a WHO team was arranged by the Smallpox Eradication unit in July 1979. Because of the vast population and size of China, the Global Commission believed that the smallpox situation there should be properly documented before its smallpox-free status could be certified.

PREPARATIONS FOR THE CERTIFICATION OF SMALLPOX ERADICATION IN THE HORN OF AFRICA

With the global eradication of variola major in October 1975 and the imminent eradication of variola minor during 1977, there was pressure to complete certification of the global eradication of smallpox as quickly as possible, because of its implications with respect to the discontinuation of routine vaccination and the abandonment of the requirement of vaccination certificates for international travellers. Because Ethiopia and Somalia were the last countries in the world in which smallpox had been endemic, it was possible to focus all available WHO resources on this effort, and from 1977 onwards much larger international resources were directed to these countries than had ever been made available to the other countries of Africa.

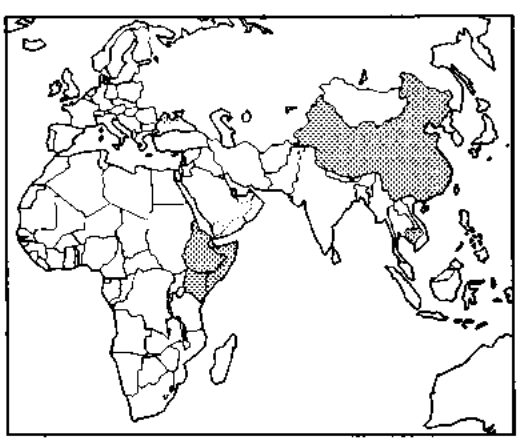

Fig. 27.1. The Horn of Africa, China and Democratic Kampuchea (see Chapter 26), the last areas in the world to be certified free of smallpox.

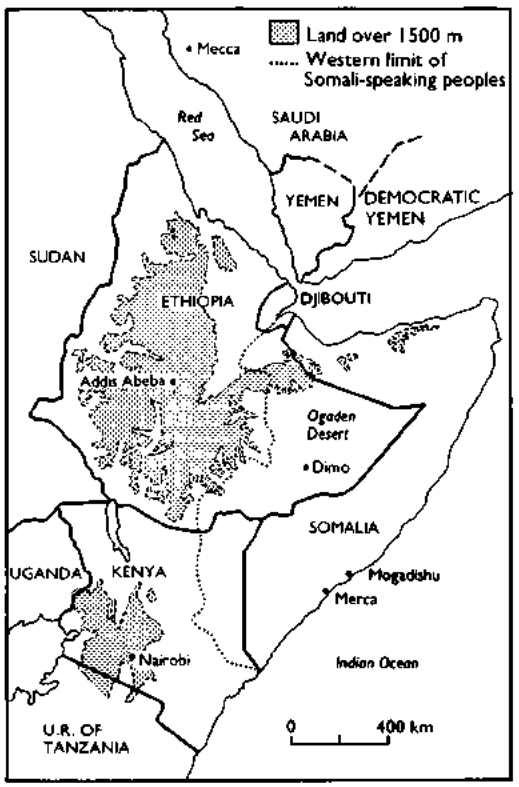

Fig. 27.2. The countries of the Horn of Africa and neighbouring parts of Africa and south-western Asia, showing land above 1500 metres. Dimo was the site of the last case of smallpox in Ethiopia, Merca that of the last case in Somalia.

The problem of certification in the Horn of Africa was further compounded by the fact that the prevalent variety of smallpox had been variola minor, and studies in the area had shown that less than 10% of patients bore persistent facial scars after recovery. Thus pockmark surveys to determine whether smallpox had recently been present were of little use, and identifying cases of chickenpox,

which might have been confused with variola minor, and obtaining specimens from them for laboratory testing, therefore became of great importance.

Coordination of Arrangements for Certification

In order to coordinate activities in the 4 countries and ensure that border areas were properly covered, the Smallpox Eradication unit organized a series of 3 coordination meetings. The first, in March 1977, was largely concerned with the completion of the eradication programme in Somalia and is described in Chapter 22; the second (September 1977) and third (April 1978) were devoted primarily to preparations for certification. Arita and Dr W. Koinange of Kenya undertook the laborious task of persuading sometimes reluctant governments to participate in these coordination activities.

Second coordination meeting, Nairobi, September 1977

In response to the emergency measures then in operation in Somalia (see Chapter 22), a second coordination meeting was held in Nairobi from 26 to 28 September 1977, 6 months after the first meeting, at a time when, as is now known, the interruption of transmission in Somalia was only a month away. It was attended by national smallpox eradication programme staff from Djibouti, Ethiopia, Kenya, Somalia, and the Sudan, together with WHO staff from the Smallpox Eradication unit and the WHO Regional Office for Africa. Despite the fact that, at the time, the Ethiopian Ogaden was occupied by the Somali army and the Western Somalia Liberation Front, a delegation from Ethiopia attended the meeting, exchanged information on surveillance activities with the participants from other countries and contributed greatly to the success of the meeting.

Discussions at the meeting were focused on how rapidly Somalia could eradicate smallpox and how the countries in the Horn of Africa could further strengthen their surveillance measures so as to prevent any further setbacks of the kind that had occurred in Somalia—namely, the establishment of new endemic foci following importations into smallpox-free areas. Important recommendations were made, among them the following:

"Smallpox surveillance activities, including specimen collection, should be increased in all priority areas of the participating countries for the next 12 months and, during this period, special attention should be paid to the possible presence of smallpox foci in both displaced populations and remote areas where search activities might have been incomplete or improperly conducted and vaccination coverage might be low.

"Special measures should be taken by all the participating countries to ensure appropriate vaccination and control of persons who travel abroad, especially those going to Saudi Arabia for the forthcoming pilgrimage. Somali medical teams going to Saudi Arabia for medical service of their pilgrims should be accompanied by experienced smallpox surveillance officers so that smallpox surveillance can be exercised during the pilgrimage period."

Third coordination meeting, Nairobi, April 1978

Since smallpox had not been reported from Somalia or elsewhere since October 1977, a third coordination meeting was held in Nairobi from 17 to 19 April 1978, specifically to discuss preparations for the certification of the Horn of Africa. It was planned that the meeting would be attended by programme staff from Democratic Yemen, Djibouti, Ethiopia, Kenya and Somalia, although at the last moment the delegates from Somalia were unable to attend owing to confusion about visas. Because of their proximity to Somalia, just across the Red Sea, it was originally intended that Yemen should also send representatives to this meeting. However, Democratic Yemen and Yemen were visited by international commissions and certified in June 1979, separately from the Horn of Africa (see Chapter 26).

The meeting decided that surveillance should continue at least until October 1979, in order to make sure that the Merca case had, in fact, been the world's last case of endemic smallpox. It was agreed that complete documentation on eradication programmes and precertification activities in the countries of the Horn of Africa should be submitted to the meeting of the Global Commission in December 1979, so as to allow it fully to appraise the progress of the programme and report its findings to the Thirty-third World Health Assembly in May 1980.

The meeting also requested WHO to offer a special reward to the first person to report an active case of smallpox anywhere in the world.

Message from the Director-General of WHO

The historical significance of the third coordination meeting in the context of the global programme was well expressed by the message of the Director-General of WHO to the meeting:

"It is now almost six months since the last case of onset of rash was recorded in the Somali smallpox eradication programme. Since that date, 26 October 1977, no further case of smallpox infection has been detected in the Horn of Africa, or anywhere in the world. This date, therefore, appears to mark the turning point in the global smallpox eradication campaign. Until then, the major objective had been to eliminate all smallpox foci. But now the situation has changed. Now it is our task to demonstrate whether we have broken the chain of smallpox transmission which has continued amongst the peoples of the world for thousands of years.

"In this respect, this meeting has a special place in the history of smallpox eradication. Proving the absence of the disease is likely to be no less difficult than containing outbreaks. There will naturally be a certain degree of doubt, since the event has never happened before in the history of medicine.

"I believe this meeting will tackle the problem of scientific credibility fully and squarely. But one point is already made clear. Surveillance, once established on a sound technical basis, should continue throughout two years following the detection of the last case. This is the only way to ensure that the international criteria of public safety have been fully met.

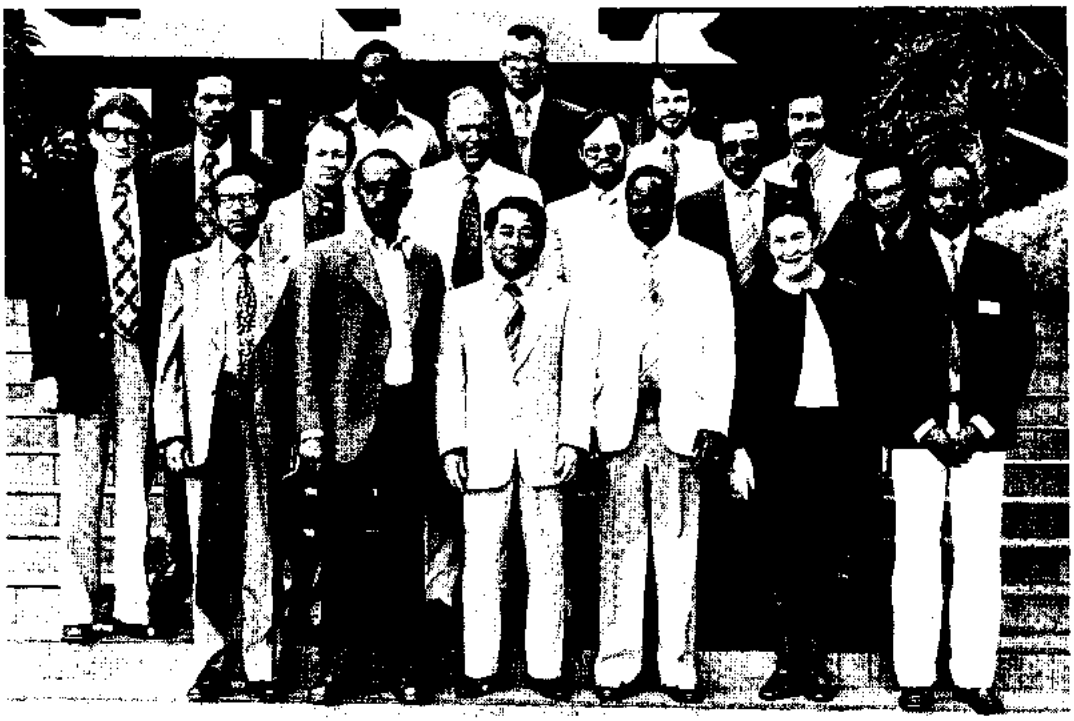
"One of the most heartening aspects of the global eradication campaign is the way the countries concerned have worked together to achieve the enormous progress made to date. Your participation in this meeting again demonstrates that sense of international solidarity, and the desire of the six countries you represent to contribute to the goal of worldwide global eradication. The most critical programmes are those in your areas. The next two years' surveillance will mark the crucial phase in the final confirmation of this worldwide achievement."

Two weeks after the Nairobi meeting, the Thirty-first World Health Assembly did establish such a reward, the amount offered being US$1000 (see Chapter 24).

Precertification activities

Intensive precertification programmes were undertaken in all 4 countries in preparation for visits by 4 separate international commissions in October 1979. The situation in each country was different. In Ethiopia and Somalia, the personnel and organization of the national eradication programmes were retained but shifted their target from the elimination of endemic foci to an active search for unreported cases. However, the ease with which these operations were accomplished differed greatly in the 2 countries. At the time, the whole of Somalia was under government control and the intensive surveillance activities developed during the eradication programme continued throughout the next 2 years. In the much larger country of Ethiopia, although active surveillance could, with some difficulty, be carried out in most of the country, the Ogaden desert, which included portions of the 3 provinces of Bale, Hararge and Sidamo, was the scene of active warfare, with armed forces moving from Somalia into Ethiopia. These disturbances greatly increased the difficulties of active surveillance. The Ogaden was clearly an area of special concern, requiring particularly intensive surveillance because, as epidemiological studies there had shown, the transmission of variola minor could be sustained for many months among comparatively small population groups (see Chapter 22).

Endemic smallpox had been eliminated from Kenya in 1969, but some importations had occurred thereafter, most recently in December 1976, in a rural area adjacent to Somalia, so that a special surveillance programme in that part of the country had had to be organized. Similarly, Djibouti had had to organize special surveillance in 1977 because of its proximity to the Ogaden, whence refugees were flowing into the country.



WHO

Plate 27.1. Participants at the third coordination meeting in Nairobi, 17 – 19 April 1978. *Left to right, front row*: Z. Islam (WHO), Yemane Tekeste (Ethiopia), I. Arita (WHO), C.L. Khamis (Kenya), B. O'Keefe (Kenya), D.W.O. Alima (Kenya); *middle row*: H.B. Lundbeck (Sweden), K.R. Dumbell (United Kingdom), S.O. Foster (WHO), V. Radke (WHO), W.M. Jaffer (Democratic Yemen), Girma Teshome (Ethiopia); *back row*: P.R. Arbani (WHO), I.P. Mwatete (Kenya), M.N. El Naggar (WHO), J.F. Wickett (WHO), R.C. Steinglass (WHO).

Precertification Activities in Ethiopia

The Ethiopian smallpox eradication programme was conducted successfully during a period of considerable political disturbance (see Chapter 21), which continued and indeed became more serious during the preparations for certification. Both the eradication campaign and the subsequent precertification operations are described in detail by Tekeste et al. (1984).

The last known case in Ethiopia occurred in August 1976 in Dimo village, El Kere *awraja*, in the Ogaden. There were then 25 WHO epidemiologists, 15 national coordinators and about 1000 Ethiopian staff in the smallpox eradication programme, using some 90 vehicles. From the end of 1976 onwards, Ato Yemane Tekeste served as the project manager of the Ethiopian smallpox eradication programme. He was assisted by 3 WHO epidemiologists (Dr Lev Khodakevich as senior adviser, Dr Claudio do Amaral and Dr Poerwokoesoemo R. Arbani) and a WHO finance officer (Mr Omar S. Ismail). Under Ato Tekeste's direction, 9 assessment officers supervised 15 programme coordinators, each responsible for one of the 15 regions, in the management, training and supervision of field staff as well as in the assessment of the programme. These coordinators employed a number of surveillance agents and intermediate supervisory staff, totalling about 1000.

With these changed staffing arrangements, the precertification activities were started early in 1977. During 1977, 1978 and 1979, when extensive searches for possible hidden foci were carried out, Eritrea as well as a number of other areas in the north and the Ogaden in the south were often partly or completely inaccessible because of civil disturbances and warfare. Accordingly, search operations were conducted or stopped as the areas became accessible or inaccessible. In border areas which became inaccessible to Ethiopian staff, rumours were investigated, wherever possible, from bases in Djibouti, northern Kenya and Somalia. This necessitated extensive coordination between the 4

countries through the exchange of reports on smallpox rumours, which was achieved by close contact between national programme directors and Arita, who frequently visited Ethiopia and the neighbouring countries.

Political events in the Ogaden

Because of military activities, precertification operations in areas under the control of the Ethiopian government were conducted differently from those in areas in which the government then had little control—namely Eritrea and the Ogaden (shown in Fig. 27.3 as a stippled area). Although the areas of limited access were geographically extensive, the majority of the population lived in the more accessible central highland areas. The last case of smallpox in Eritrea occurred late in 1972. Intensive searches in 1973–1974, before the activities of the separatist movement limited access to the rural areas, failed to reveal any evidence of further cases. The Ogaden desert, on the other hand, was the route by which smallpox had spread to Somalia in 1976 and was thus an area of great importance for surveillance.

Fig. 27.4 illustrates the changing fortunes of war in the Ogaden. Politically, the period of the smallpox epidemic in southern Somalia was marked at first by guerrilla activities in the Ogaden by the Western Somalia Liberation Front and then by the occupation of this area by the Somali army in July 1977. Eight months later the Ethiopian army recaptured the major towns, but continuing guerrilla activity prevented the resumption of normal surveillance elsewhere. By 1979 the situation had stabilized to the point where searches could be made along the western limits of the Ogaden.

Precertification activities in the accessible areas

Different parts of the politically accessible portion of Ethiopia presented somewhat different problems. Over most of the area routine surveillance was carried out through the newly established farmers' associations (see below) in the rural areas and urban dwellers' associations in the towns. In other areas special searches were organized. Certain areas were considered to be at high risk because the last cases had occurred there, access to them was difficult, or good routine surveillance had not been possible. In others, travel was safe only during a few weeks of calm between outbreaks of civil strife. Finally, there were some remote, sparsely populated areas which had been infrequently searched and which could not be reached without special logistic arrangements or transport by helicopters.

Searches in rural areas. The population of Ethiopa is predominantly rural, only 11% living in towns or villages with 2000 or more inhabitants. The search for evidence of recent smallpox in most rural areas was based on the farmers' associations, which were cooperatives comprising some 500–1000 persons. There were about 20 000 of them in Ethiopia in 1977. Because of the close contact between members of these associations and their chairmen, it was possible to acquaint them with the need for reporting smallpox cases, and during the active search operations each association became a basic unit for the collection of information on smallpox.

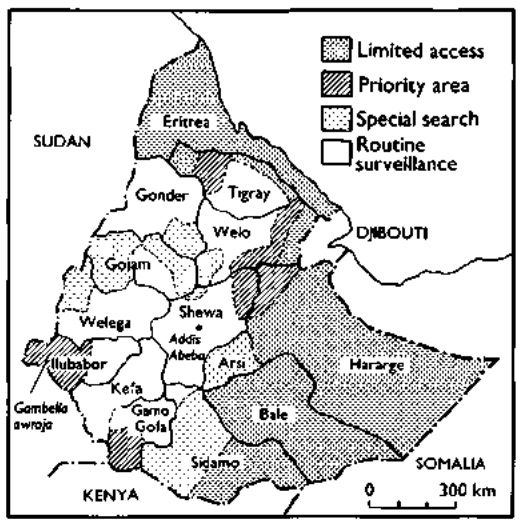


Fig. 27.3. Ethiopia: status of surveillance at the end of 1977. Throughout the programme, civil disturbances were occurring in various parts of the country so that smallpox staff were excluded from certain areas. Priority areas were defined as those difficult to reach, but where there was sometimes a calm period of a few weeks during which an intensive search could be carried out. Special searches were organized in areas which were in principle accessible, but where a satisfactory routine surveillance system could not be established. Routine surveillance was based on regular contacts with the 20 000 Farmers' Associations, whose membership accounted for two-thirds of the population of Ethiopia. For details of the search carried out in Gambella, Ilubabor, see box.

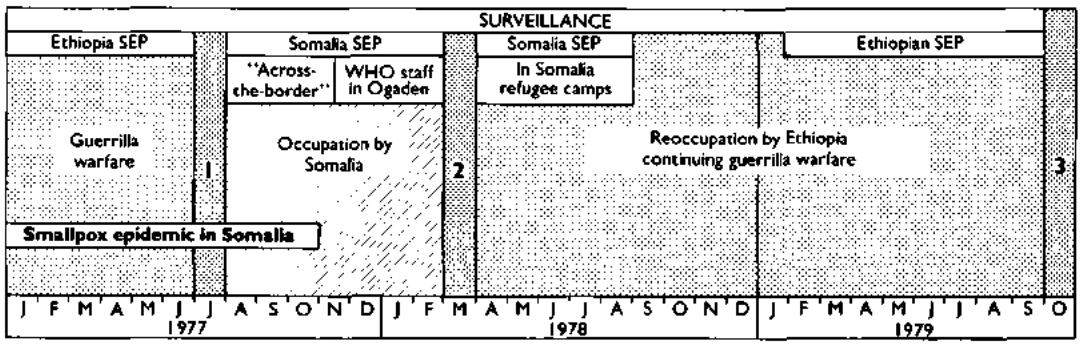

Fig. 27.4. Interplay between the changing fortunes of war in the Ogaden and smallpox surveillance activities. In July 1977 the Western Somalia Liberation Front overran the Ogaden and the Somali army established control (1). In March 1978, Ethiopian troops retook the Ogaden (2). Surveillance in varying degrees was maintained from both until eradication was certified in October 1979 (3). SEP = smallpox eradication programme.

During 1977, local surveillance teams were supposed to visit all the farmers' associations in their assigned areas 4 times a year. However, it soon became clear that coverage was erratic, 86% of the farmers' associations being visited at some time but some only once and many on several occasions. In 1978 this system was abandoned and a search for cases of smallpox was undertaken which covered some 50% of all houses in rural Ethiopia. Every month about one-fifth of all farmers' associations were visited by the surveillance workers. In this way, 20 322 out of the 20 828 farmers' associations were visited by surveillance workers between November 1978 and April 1979. The population thus contacted, either direct or through their neighbours, amounted to about 20 million—two-thirds of the total population of Ethiopia.

During the search the supervisors of the surveillance workers investigated 7260 cases of fever with rash and collected 929 specimens. A large number of cases of chickenpox and measles were seen, but no cases of smallpox.

Searches in urban areas. In addition to the searches in rural areas, the surveillance agents also searched urban areas during 1978 and 1979; thus 760 of the 929 towns, with a total population of 3.8 million, were searched, about 2500 cases of fever with rash being investigated and 189 specimens collected. Once again, no smallpox cases were found.

Second visits to the sites of the last outbreaks. During the period 1971–1976, smallpox had occurred in 99 of the 102 *awrajas* in Ethiopia. Between November 1978 and March 1979 the sites of the last outbreaks in 64 of these 99 *awrajas* were revisited by surveillance teams (Fig. 27.5). In the other 35 *awrajas*, mainly in Eritrea and the Ogaden, no such follow-up visits could be arranged because of civil strife and the resettlement of the rural population. During the visits to these 64 *awrajas*, 2 additional outbreaks were identified which had occurred before August 1976, but there were no signs of transmission after the last recorded case.

Laboratory investigations. The variety of smallpox occurring in Ethiopia in the 1970s was variola minor, which elsewhere had been found to leave facial pockmarks in less than 10% of cases. As an alternative to pockmark surveys as a way of detecting missed cases of smallpox, special attention was devoted to the surveillance of chickenpox. Large-scale collections of specimens for laboratory

Search in Gambella *Awraja*, Ilubabor Region

In Ethiopia, there were a few remote and inaccessible areas in which logistically it was extremely difficult to organize a search operation, Gambella *awraja* being one of them. This remote area (see Fig. 27.3) was inhabited mainly by primitive tribal groups. No smallpox had been reported there since the start of the eradication programme in 1971, but until 1978 the only search conducted was by a team consisting of an Ethiopian surveillance agent and a United States Peace Corps volunteer, who in April–May 1972 travelled by foot for about 290 kilometres along the Gilo river towards the Sudanese border to vaccinate and search for smallpox.

In March–April 1978, a well-planned search was conducted among the 140 000 inhabitants of this area. About 60 surveillance staff worked under the supervision of 2 Ethiopian coordinators and a WHO epidemiologist, Dr Claudio do Amaral, using helicopters and river transport. About two-thirds of all the houses in the *awraja* were visited by the team; the remainder had been abandoned because the people had moved close to the river, but the team visited them by walking along the river bank. In all, 36 suspected cases were investigated and 30 specimens were collected, but no smallpox was found.

investigation were made from cases of chickenpox or fever with rash, 2886 specimens being examined between 1977 and 1979 (Table 27.1). Fig. 27.6 shows the distribution, by *awraja*, of specimens collected during 1977 and 1978.

Variola virus was not found, but herpesvirus particles were seen in about 25% of the specimens and vaccinia virus on 9 occasions. The latter resulted from contamination, since specimens were sometimes collected while vaccinations were being performed.

Precertification activities in the Ogaden desert

The Ogaden desert, which traverses the major portion of the regions of Hararge, Bale and Sidamo (see Fig. 27.3), comprises 10 *awrajas* with a total population of about 1.4 million, most of whom are Somali-speaking nomads. It lies on a plateau bordered to the north and west by the Ethiopian highlands and to the south and east by Somalia, and by a small corner of Kenya in the extreme south-west. At its widest the desert extends 800 kilometres from east to west and 400 kilometres from north to south; it covers an area of about 200 000 square kilometres (Fig. 27.7). From the autumn of 1976 onwards the increasing guerrilla activities in the Ogaden made it more and more difficult for both WHO and Ethiopian programme staff to carry out surveillance; smallpox programme activities conducted by Ethiopian staff were finally halted in July 1977, when the Somali army invaded the area, but were resumed in March 1978, when the Ethiopian army regained possession.

Arrangements for surveillance. To cope with this situation, Arita went to Addis Abeba in mid-1977 to discuss with local WHO and Ethiopian national programme staff how best to maintain active surveillance in the Ogaden. This was of the utmost importance, because the Western Somalia Liberation Front had overrun the area, so that it was inaccessible to the Ethiopian smallpox eradication programme staff. Moreover, at that time smallpox was still endemic in southern Somalia. There was therefore a real risk that endemic smallpox might be re-established in Ethiopia, and it was essential that this should be prevented.

Two major actions were therefore taken, one in Ethiopia and one in Somalia. First, in Ethiopia a "belt" area was established between the highland areas adjacent to the

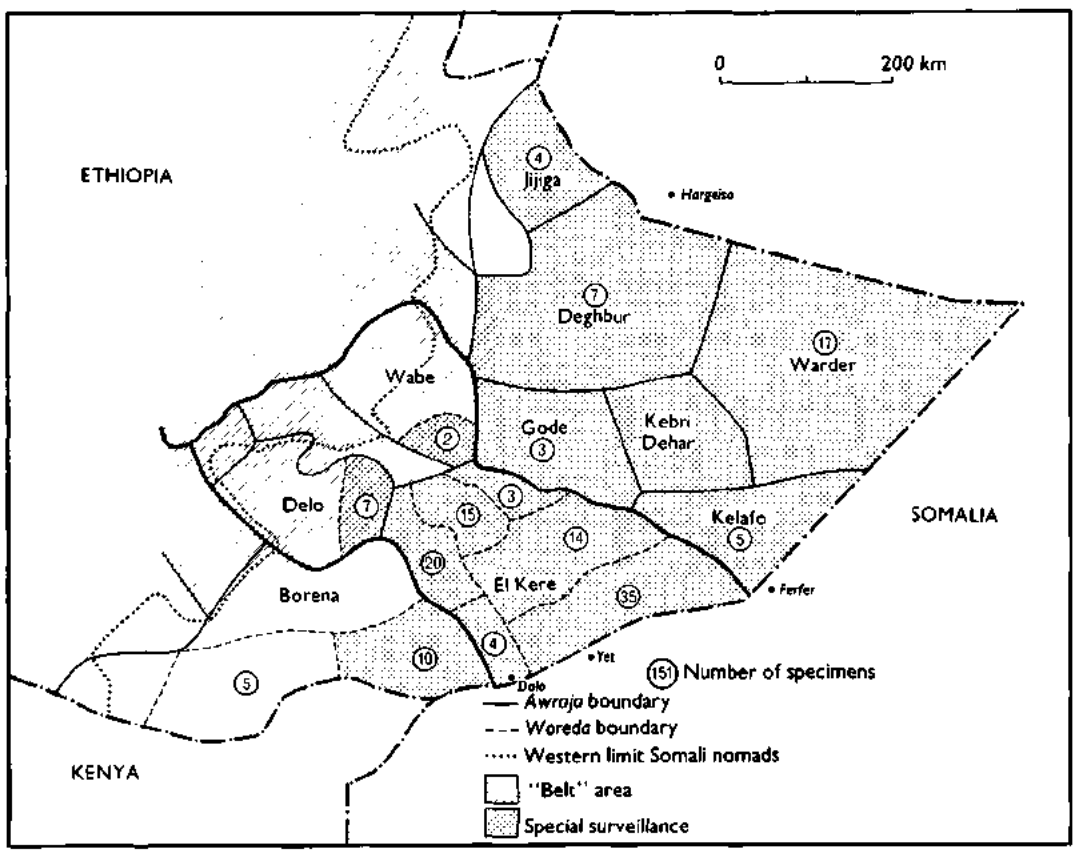

Fig. 27.7. Ethiopia: Areas of the Ogaden desert under special surveillance, showing *awrajas* in Hararge, Bale and Sidamo Regions, the western limits of the seasonal migrations of the Somali nomads, and the "belt" area where a special vaccination campaign was conducted in September-December 1977. The numbers of specimens collected for laboratory examination between July 1977 and April 1978 are shown by *awraja* and *woreda*.

Surveillance Activities and the War in the Ogaden Desert

Early in 1977, the Ethiopian national smallpox eradication programme tried to strengthen surveillance by the assignment of 4 WHO epidemiologists (Dr do Amaral, Dr Arbani, Dr El Naggar and Dr Gromyko) and national coordinators. However, because of increasing unrest in the Ogaden, their activities were limited in scope outside the capital towns of the *awrajas* of Kebri Dehar, Deghbur, Warder, Kelafo, Gode and El Kere in the Ogaden desert (Fig. 27.7).

In April, Mr William Waugh, one of the helicopter pilots working for the Ethiopian smallpox eradication programme, was kidnapped at gunpoint and held for ransom near Gode. In May, Dr do Amaral was held for 2 days in Somalia when he came too close to the border while checking a rumour in Warder *awraja*. Again in June, he was kidnapped by guerrillas in Warder *awraja* but a week later turned up in Hargeisa in northern Somalia.

In June, immediately after this incident, WHO received a cable from the United Nations Economic Commission for Africa (ECA), Addis Abeba, stating that WHO epidemiologists were taking unacceptable risks. Arita flew to Addis Abeba to attend a meeting with ECA security officials to discuss the matter. It was agreed that the withdrawal of WHO epidemiologists would in fact mean the discontinuation of precertification activities, which would be a set-back not only for the eradication campaign in the Horn of Africa, but also for the global programme as a whole. The participants agreed that minimal activities should be continued by WHO and national staff in the Ogaden, but formulated a plan for emergency evacuation, should this prove necessary.

During the last 2 weeks of July, however, the Somali army invaded and overran the entire area, forcing the withdrawal of all the WHO staff. Thus, the surveillance of smallpox by the Ethiopian smallpox eradication programme ceased in these areas until March 1978, when the Ethiopian army resumed control.

Ogaden, which were under Ethiopian control, and the Ogaden desert, stretching from Djibouti to the border with Kenya (Fig. 27.7). An intensive surveillance and vaccination programme was carried out here between September and December 1977. On average, 55% of all farmers' associations were visited each month and by the end of the 4-month campaign, virtually all had been visited by a worker from the Ethiopian smallpox eradication programme. Altogether 348 suspected cases were investigated and 272 specimens collected, but no evidence of smallpox was found.

Secondly, an attempt was made to conduct an active search from the Somali side. Efforts to achieve this by collaboration with the International Committee of the Red Cross, which was doing relief work for wounded soldiers in the Somali-occupied areas of the Ogaden, were unsuccessful, but other arrangements succeeded.

Early in September 1977, Arita organized a private meeting in Mogadishu of senior WHO and Somali staff who had extensive experience of surveillance and knew the geography of the Ogaden. It was decided to seek the agreement of the Western Somalia Liberation Front to enter the Ogaden and to employ 5 WHO epidemiologists, Dr Mohamed El Naggar, Dr Bert van Ramshorst, Dr Jean-Paul Ryst, Dr Jay S. Weisfeld and Mr Carl Hasselblad, to carry out across-the-border searches. Operational border posts were established in Hargeisa, Ferfer, Yet and Dolo (see Fig. 27.7). Many of the workers who had been employed in this area under the aegis of the Ethiopian smallpox eradication programme were recruited, because most had remained in the area after it had been occupied and were happy to return to duty. As the WHO epidemiologists could not cross the border into the area, which was under the control of the Somali army and the Western Somalia Liberation Front, experienced local workers supervised the searchers and verified rumours.

During these surveillance activities, 143 searchers visited 599 villages and 383 watering-places; 219 rumours were investigated. Posters giving information on the reward offered were displayed in each of the villages and at Koranic schools and watering-

places. The number of rumoured cases of smallpox was almost certainly exaggerated, as former Ethiopian staff had not been paid since the cessation of their programme in the area; by providing reports of possible cases of smallpox they assured their continued employment. In spite of the many suspected cases reported, experienced national epidemiologists found no evidence of continuing transmission.

In November 1977, Arita was informed by messenger that the Western Somalia Liberation Front had agreed that WHO staff could work in the Ogaden. Dr El Naggar, accompanied by a Somali counterpart, entered the Ogaden from Somalia to supervise surveillance personally and to check rumours. Because he was known to the local population, they cooperated closely with him. Borena and El Kere *awrajas* were chosen for the initial searches because they shared long borders with areas of southern Somalia in which smallpox had persisted until October 1977; furthermore, 11 of the 12 rumours of smallpox which had not been investigated by a WHO epidemiologist had originated in this area. Dr El Naggar supervised 20 searchers, who visited 33 000 houses and 300 Koranic schools. Independent assessment revealed that 94.6% of the houses had been visited by the searchers and that 51% of households knew of the reward of 200 Somali shillings (US$32). No smallpox was found.

In January 1978, Dr Rabie A. L. Khattab succeeded Dr El Naggar as the WHO epidemiologist responsible for surveillance in the Ogaden. He continued the programmes in Borena and El Kere *awrajas* and extended his activities to the adjacent *awrajas* of Delo and Wabe. With the aid of 79 searchers, 20 000 houses and 700 Koranic schools were visited, but no evidence of smallpox was found. Surveillance from the Somali side was terminated early in March 1978, when Ethiopian forces reoccupied the Ogaden, but was then resumed under Ethiopian auspices.

Laboratory investigations. During special surveillance activities in the Ogaden between July 1977 and March 1978, 151 specimens were collected from cases of chickenpox or fever with rash and tested by WHO collaborating centres. The geographical distribution of the cases from which these specimens were collected is shown in Fig. 27.7. All the important areas in which smallpox importation or transmission was suspected were covered. Half the specimens were collected in El Kere *awraja*, the area in which the last known smallpox case in Ethiopia had occurred. Four of the 151 specimens were reported to contain small numbers of pox virions, as revealed by electron microscopy. Vaccinia virus was cultured from 2 of them, while the other 2 were negative. It was found that surveillance workers were using bifurcated needles that had been used for vaccination, to dislodge scabs, so that the positive results were presumably due to contamination with vaccinia virus. The source of 1 of the 2 specimens which was negative on culture was investigated by a WHO epidemiologist, who reported that, on clinical and epidemiological grounds, the case was definitely not smallpox. It was not possible to reinvestigate the patient from whom the fourth specimen had been taken. It was collected in July 1977 in El Kere *awraja*, but intensive and continuous search between August 1977 and March 1978 failed to find any smallpox in this area.

ologists, and about 1600 other personnel, using 65 vehicles, were engaged in surveillance and containment measures for the smallpox eradication campaign. Dr Abdullahi Deria, director of the national campaign, and Ježek, WHO coordinator, assisted by Mr Rodney J. Hatfield, WHO administrator, directed the campaign. This impressive force continued active search operations during 1978 and 1979, as required for certification, although the number of WHO epidemiologists was reduced to 10 by the end of 1977 as activities became better organized. The eradication campaign and subsequent precertification activities have been described in detail by Ježek et al. (1981).

Development of reporting systems

Apart from one person who was infected in southern Somalia in July 1977, but moved to a military camp in the north during the incubation period, all cases in the Somali epidemic had occurred in southern Somalia. The surveillance and containment programme had therefore been focused on that part of the country. With the conversion of the programme into post-eradication active search operations, routine reporting systems were developed throughout the country. To achieve this, a smallpox office was established in each of the 16 regions and 83 districts (Fig. 27.8).

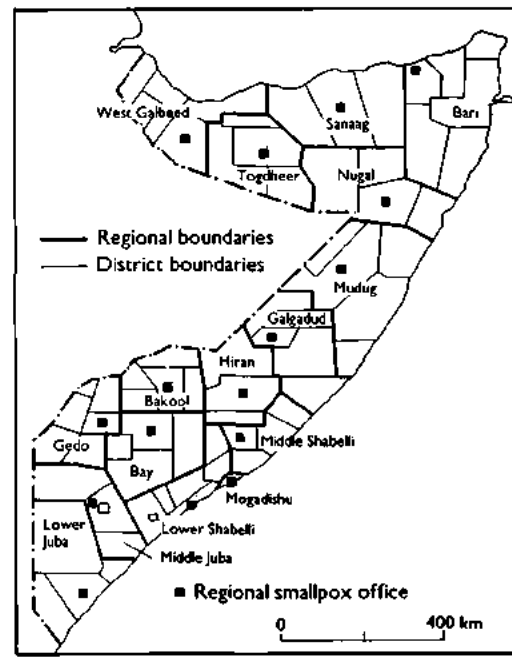

Fig. 27.8. Regions (named) and districts in Somalia. A smallpox office was established in each region and district during the period 1978 – 1979.

The regional smallpox offices were staffed by WHO or national epidemiologists and the district offices by local staff. They served to intensify the routine reporting of suspected cases of smallpox and other cases of fever with rash. A cable reporting findings was sent

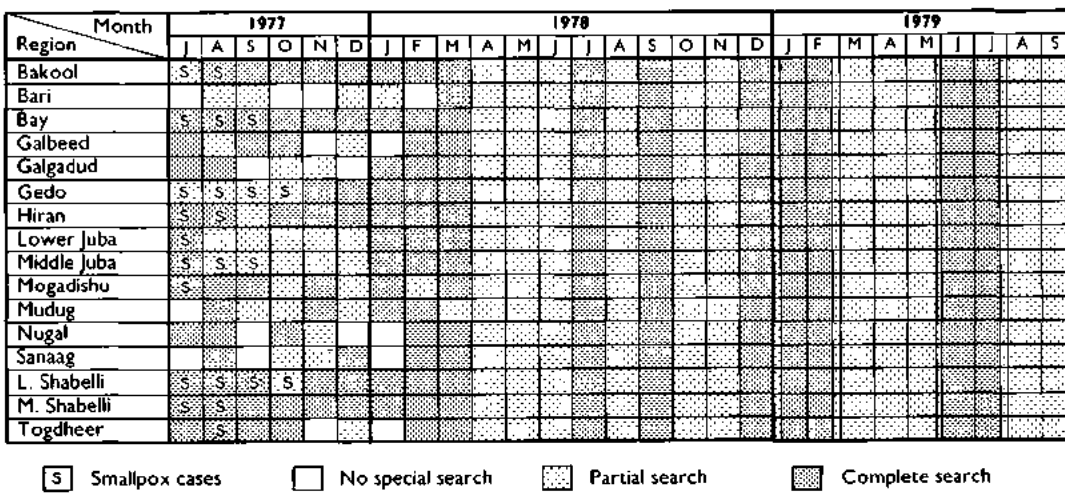

Fig. 27.9. Somalia: Frequency of search operations for cases of fever with rash, by region. Partial searches were carried out by regional surveillance teams at hospitals and markets, and in high-risk areas. Most parts of the country were searched 6 times in 1978 and twice in 1979. In 1978 the full search procedure usually lasted a month but in 1979 less frequent searches allowed greater attention to detail and more thorough independent assessment of performance.

Table 27.2. Somalia: assessment of public awareness of smallpox activities among settled and nomadic populations, July 1978–June 1979

Year	Quarter	Population type	Total number of households interviewed	Percentage who had seen:		Percentage aware of:	
				Searcher	Recognition card	Reward	Where to report
1978	Third	Settled	36 529	78	79	77	72
		Nomadic	12 776[a]	73	73	70	64
	Fourth	Settled	26 967	80	80	79	74
		Nomadic	8 810	76	69	78	68
1979	First	Settled	15 000[b]	79	79	81	74
		Nomadic	7 000[b]	67	68	68	60
	Second	Settled	17 516	78	86	81	78
		Nomadic	7 699	74	80	75	71

every week from each district to its respective region, and from there to Mogadishu. In addition to these reports, supplementary documentation was sent to Mogadishu describing the investigation of all suspected smallpox cases or deaths associated with fever with rash.

Although new to Somalia, this reporting system proved to be most effective, almost complete returns being received from all the smallpox offices. Regional and district offices gathered comprehensive demographic data including maps showing localities, households, population, etc., which were also used for other health programmes. These had to be updated frequently as the nomadic population moved from one part of the country to another.

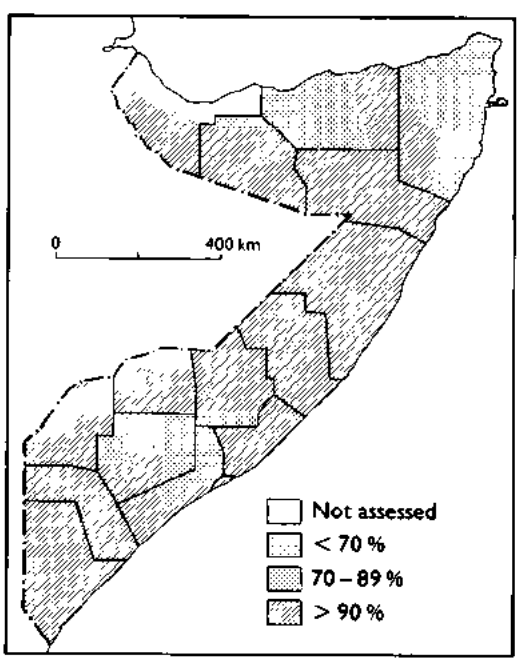

Fig. 27.10. Somalia national assessment of March 1979: percentages of localities found to have been searched in each district.

Search for cases of fever with rash

The search for cases of fever with rash which had been developed during the smallpox epidemic in 1977 (see Chapter 22) was continued throughout 1978 and 1979. Six country-wide searches were conducted in 1978 and 3 in 1979. Except in the searches carried out during the first 3 months of 1978, all districts were covered (Fig. 27.9).

Following the pattern that had been developed in India, every search was assessed by national assessment teams, which found coverage to be very good (Fig. 27.10); over 70% of the general public reported that they had seen searchers with recognition cards and knew about the reward and where to report a case of suspected smallpox if they found one (Table 27.2). The high level of awareness among the nomadic population was impressive, since these people were rarely in contact with the established health services.

Table 27.3. Somalia: results of laboratory examinations of specimens submitted to WHO collaborating centres, 1977–1979

Year	Total number of specimens	Results			
		Variola virus	Herpesvirus	Vaccinia virus	Molluscum contagiosum virus
1977	879	265	203	1	0
1978	1 646	0	463	0	1
1979	1 074	0	214	1	0
Total	3 599	265	880	2	1

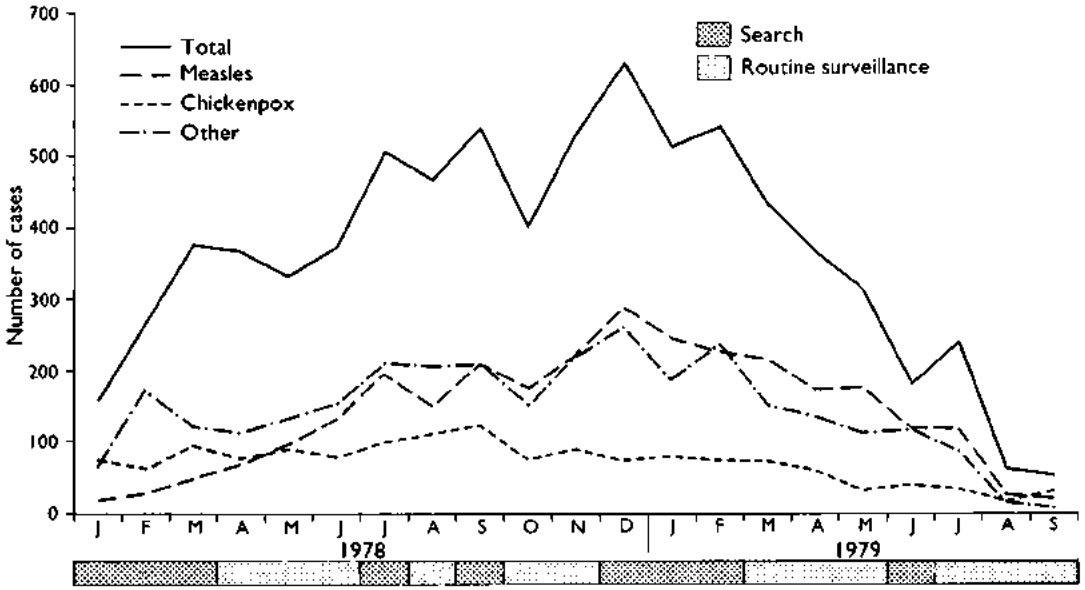

Fig. 27.11. Somalia: Number of cases of fever with rash reported monthly between January 1978 and September 1979.

In all, 19 623 cases of fever with rash were investigated in 1978 and 11 576 cases during the first 9 months of 1979 (Fig. 27.11). The diseases seen included chickenpox, measles and various other diseases associated with a rash; none proved to be smallpox.

Laboratory investigations

Laboratory specimens were collected from patients with clinically suspected smallpox and chickenpox, especially from those who had not been vaccinated, as well as from individuals affected in outbreaks of fever with rash in which a death had occurred.

Altogether 1646 specimens were collected in 1978 and 1074 in 1979, all of which were negative for variola virus (Table 27.3). Specimens were collected from all over Somalia, especially from the south (Fig. 27.12). The absence of variola virus in any of the specimens gave staff confidence that variola minor had not been misdiagnosed as chickenpox.

Precertification Activities in Kenya

Despite strenuous efforts, Kenyan and WHO epidemiologists had not been able to identify the geographical source of the outbreak of smallpox in Mandera District, northern Kenya, which occurred between December 1976 and February 1977, but it was thought to have been the result of importation from Somalia (see Chapter 19). During 1978 and 1979, searches in Kenya were conducted by staff recruited within the districts to be searched, and supervised by local health workers and senior health officers from the Division of Disease Control of the Ministry of Health, Nairobi. Dr W. Koinange, a Kenyan member of the Global Commission, Dr Ziaul Islam and Mr Vincent Radke contributed to the development of the Kenyan certification work. The Ministry of Health offered a reward of 200 Kenya shillings (US$25) for any confirmed smallpox case, and the radio and press publicized the search operations and the need to report promptly any cases of fever with rash to the staff of the nearest health unit or to other government officials.

Special searches

High-risk areas were designated, essentially those bordering on Ethiopia and Somalia (Fig. 27.13), and special searches conducted in them. Searches were supervised at three levels: (1) by the public health technician (daily supervision); (2) by senior supervisors from the district headquarters; and (3) by independent assessment teams consisting of both national staff and their WHO counterparts working in the Division of Disease Control.

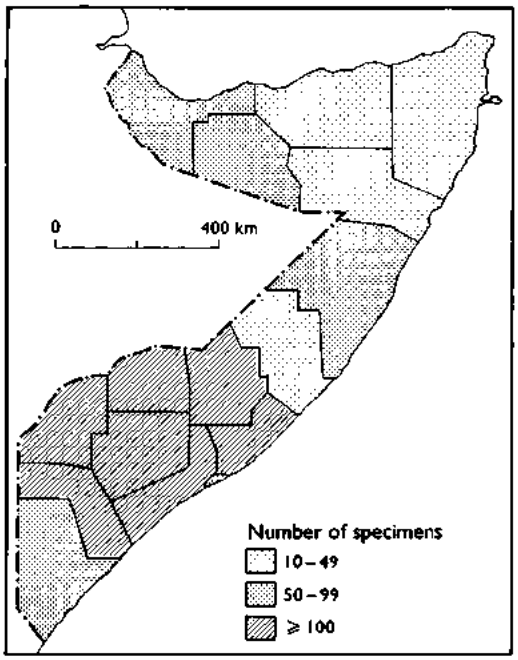

Fig. 27.12. Somalia: Number of specimens collected for laboratory examination from cases of fever with rash during 1978, by region.

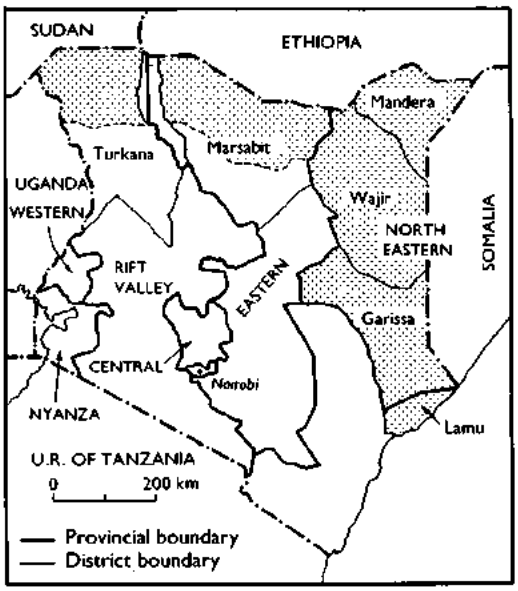

Fig. 27.13. Kenya: Areas of high priority for active search operations in 6 northern districts.

The searches in the high-risk districts of Mandera, Wajir, Garissa and Marsabit were conducted between September 1977 and March 1978, 189 searchers and 43 supervisors, with 16 vehicles, being employed (Table 27.4). They covered over 440 000 persons in an area of 200 000 square kilometres.

In Mandera District, 6 searches were conducted, although occasionally some areas were not accessible to the local searchers and supervisory staff because of bad weather or for security reasons. Out of 134 rumours received only 2 could not be checked immediately because of security problems, but were checked later when the areas were visited.

In Wajir District, areas bordering on Ethiopia and Somalia were given priority in surveillance and vaccination activities. At the time, a large number of people had crossed from Ethiopia into northern Kenya to escape the conflict in the Ogaden and in search of water and grazing land. As rumours of smallpox from the Ethiopian side of the

Plate 27.4. Pilgrims' tents near Mecca in Saudi Arabia. The annual influx of people from the Muslim world provided an explosive potential for the spread of smallpox.

border came to the attention of Kenyan teams, they crossed the border to investigate whenever the security situation permitted. Five searches were conducted in the district and 35 rumours of possible cases were recorded. Only 3 rumours, all from the Ethiopian side of the border, could not be investigated because of security problems. However, cross-notifications were made to the Ethiopian health authorities through WHO in Geneva. Although Garissa District was not as important epidemiologically as Mandera and Wajir Districts, 4 searches were conducted there and 1 search in the northern area of Marsabit District.

A cluster sampling technique was used in assessing the search operations, 118 out of 120 localities sampled being assessed (98.3%) and 905 people interviewed. Of the latter, 72% reported that they had seen the searchers, and 75% had a smallpox vaccination scar.

Laboratory investigations

In 1978 and 1979, 1599 specimens were collected in high-risk areas and tested by WHO collaborating centres, with negative results.

Precertification Activities in Djibouti

Whenever famine or political unrest occurred in the Ogaden desert, many refugees fled to Djibouti. Between June and December 1977, when Somali troops invaded the Ethiopian Ogaden, some 10 000–20 000 refugees crossed into Djibouti, camping mainly in Djibouti City, Dikhil and Tadjoura.

On his return from the second Nairobi coordination meeting in September 1977, the representative of Djibouti, Dr A. A. Warsama, began work aimed at strengthening the local vaccination programme as well as surveillance for the detection of imported cases of smallpox. In November–December 1977, Dr Nicole Grasset visited Djibouti to work with the programme in conducting a special search for smallpox among the refugees. Dr Jean-Paul Ryst assisted the programme from September 1978 to October 1979 and Dr Arnaud Trébucq between May and December 1979.

The 1977 vaccination campaign reached 94 289 persons in Djibouti City, out of an estimated total population of 150 000. In December 1977, a vaccination scar survey of

1517 persons found 90% or more with scars in each age group.

Active search operations

Active search operations were planned in November 1977. The smallpox eradication programme activities were widely publicized, in particular the reward of 5000 Djibouti francs (US$28) which would be given to anyone reporting a case of smallpox. An appeal from the President of the Republic to the population to collaborate actively with the programme and announcing the reward was published in the local press and read over the radio in Afar, Somali, Arabic and French. Any cases of fever with rash found during the search were to be reported to the supervisor or the Chief of the Department of Hygiene and Epidemiology on the same day. Refugees were vaccinated if they did not have a vaccination scar.

Full coverage of this small country was achieved in the course of 2 search operations, the first between December 1977 and January 1978 and the second between February and April 1978. In the second search, 20 chickenpox cases were found but no case of smallpox. Altogether 142 specimens were collected during 1978 and 1979 and tested by WHO collaborating centres; none contained variola virus.

Smallpox Surveillance among Muslim Pilgrims from the Horn of Africa

The pilgrimage season, during which over a million Muslims from about 40 countries visit the holy towns of Mecca and Medina, occurs in November–December. Even before the season starts, the number of international travellers to Saudi Arabia increases.

In 1977, the Saudi Arabian health authorities set up smallpox surveillance centres in Jeddah, Medina, Mecca, Mona and Arafat. A circular was sent to all medical groups concerned with the health problems of the pilgrims, indicating that any suspected case of smallpox should be promptly reported and investigated.

The Saudi Arabian health service checked all pilgrims on their arrival at ports of entry to ascertain whether they had an appropriate certificate of smallpox vaccination. Pilgrims from Djibouti, Ethiopia, Kenya and Somalia were examined to see whether they had vaccination scars. Pilgrims from Ethiopia and Somalia also had to submit particulars of their itinerary, intended address, the name of their guide, the name of the regions from which they came and whether they knew of any smallpox cases in their villages during the previous 3 months. Somali pilgrims were all vaccinated on arrival, regardless of their vaccination history, and the Somali govern-

ment sent smallpox surveillance teams to accompany the Somali pilgrims during their trip, to deal promptly with an outbreak should it occur. Foreign medical missions collaborated fully in these surveillance activities, making regular inquiries about cases of fever with rash. Saudi Arabian medical officers at Jeddah, Mecca and Medina visited Ethiopian and Somali camps at least twice a week. No case of smallpox was found. A total of 22 specimens collected from patients suffering from fever with rash were all negative. These activities were supervised by Dr Ehsan Shafa from the Smallpox Eradication unit, who worked in Saudi Arabia between 3 November and 9 December 1977.

CERTIFICATION OF SMALLPOX ERADICATION IN THE HORN OF AFRICA

Since endemic smallpox had persisted in the Horn of Africa for many months after it had been eradicated from all other parts of the world, the certification of smallpox eradication in the countries concerned had important implications in terms of vaccination requirements throughout the world. The Smallpox Eradication unit therefore went to considerable trouble to organize certification activities and, believing that the last endemic countries could be certified by the commissions, prepared to publicize the event. Arrangements were made for all 4 countries to be visited simultaneously in October 1979 by separate international commissions, which would then meet in Nairobi to discuss their respective findings and announce the certification of smallpox eradication for the Horn of Africa as a whole on 26 October 1979, exactly 2 years after the recognition in Somalia of the world's last case of endemic smallpox. Arrangements were made in advance with representatives of the world media in order to ensure public recognition of the global eradication of smallpox.

By September 1979 each of the 4 countries concerned had prepared a comprehensive report on its national eradication programme and precertification activities. These reports were submitted in advance to the members of the respective international commissions before their visits. In order to coordinate arrangements, the chairmen of the 4 international commissions met at WHO Headquarters in Geneva and discussed the strategy of their activities in each country and at the combined meeting in Nairobi. Prior to this, however, preliminary visits were made to Ethiopia.

Preliminary Visits to Ethiopia

Two preliminary visits to Ethiopia by some Commission members were arranged, from 31 May to 15 June 1978 and from 3 to 18 April 1979, because Ethiopian certification involved some areas that were not fully under government control, and many high-priority areas were situated in regions in which travel was extremely difficult. The first visit, by Dr Keith Dumbell and Dr P. N. Shrestha, led to a joint decision by the Ethiopian government and WHO to carry out a single thorough search, instead of a multiplicity of searches, which were always incomplete and in fact beyond the capacity of the programme staff available.

In the second visit in April 1979, 7 commission members, of whom only Dr Jan Kostrzewski (chairman) and Dr Dumbell (rapporteur) also served on the final Ethiopian International Commission in October (see Chapter 24, Annex 24.1), went to Ethiopia. The group visited all the regions and 70 of the 102 *awrajas*, mainly in the highland areas, so that in October 1979 the final visit by

the International Commission would be able to concentrate on critical areas in the Ogaden (Fig. 27.14).

Visits by the International Commissions

Separate international commissions visited the individual countries of the Horn of Africa during the first 3 weeks of October 1979, as follows:

	Date	*Commission chairman*
Djibouti	9–18 October 1979	Dr R. Netter
Ethiopia	1–17 October 1979	Dr J. Kostrzewski
Kenya	1–19 October 1979	Dr R. N. Basu
Somalia	1–21 October 1979	Dr H. Lundbeck

The 20 members of the 4 international commissions travelled extensively in their respective countries. In Ethiopia, because of the difficult terrain, a fixed-wing aircraft and helicopters were placed at the disposal of commission members, who used them to travel extensively throughout the country and to visit areas not accessible by overland travel. Since variola minor had been prevalent in these areas, the commissions paid special attention to the laboratory investigation of 6671 specimens collected from cases of fever with rash in the 4 countries during 1978 and 1979; all proved to be negative for smallpox (Table 27.5).

In each country, the commission members were satisfied with the data presented on past surveillance activities and certified that the country concerned had been free of smallpox for at least the previous 2 years.

Joint Meeting in Nairobi

After the certification of the individual countries had been completed, all members of the 4 international commissions and a number of others involved in the smallpox eradication programme, including 12 members of the Global Commission, some of whom had not been members of the international commissions, met in Nairobi, where the chairmen of the 4 commissions presented their respective reports. Having agreed that endemic smallpox no longer occurred in the Horn of Africa, and taking into consideration the recommendations presented in the reports of the 4 commissions, the joint meeting made the following recommendations:

(1) Smallpox vaccination should be terminated throughout Djibouti, Ethiopia, Kenya and Somalia.

(2) Vaccination certificates for smallpox should no longer be required of any travellers coming to, or leaving, the 4 countries.

(3) Experience from previously certified countries indicated that smallpox rumours would continue to occur even after certification. All such rumours were to be reported promptly to national authorities and thoroughly investigated by competent personnel, and the findings transmitted to WHO, so as to minimize unnecessary national and international concern. Specimens should be collected if necessary and sent through WHO, Geneva, to the WHO collaborating centres.

On 26 October 1979 a conference organized by the Smallpox Eradication unit was held in the Kenyatta Hall, Nairobi, in the presence of the Director-General of WHO, Dr Halfdan Mahler, the Regional Director for Africa, Dr Comlan A. A. Quenum, and the Regional Director for the Eastern Mediterranean, Dr Abdul H. Taba. Dr Kostrzewski, as the chairman of the joint meeting of the individual commissions, reported to Dr Mahler the commissions' conclusion that smallpox had been eradicated in the Horn of Africa. Immediately after this meeting, Dr Mahler sent the following message by cable or telex to all Member States and to international organizations:

"The Director-General of the World Health Organization presents his compliments and has the honour to ... inform you that International Commission today certified smallpox eradication in Horn of Africa which was last stronghold of disease Stop I personally believe smallpox has now been eradicated throughout world and am confident that Global Commission for Certification of Smallpox Eradication will confirm this in December 1979 Stop I shall then present final report to World Health Assembly in May 1980 Stop World Health Organization has accomplished this mission with support and participation of all Member States"

On the same date, 26 October 1979, in the *Weekly epidemiological record*, health officials throughout the world were informed of the successful certification of smallpox eradication in the Horn of Africa (Plate 27.8).

The certification of the Horn of Africa meant that all countries in Africa had been certified. However, neither the Global Commission nor WHO was yet able to make a definitive statement on global eradication, since smallpox eradication in China had not yet been certified.

Table 27.5. Horn of Africa: numbers of specimens tested by WHO collaborating centres during 1978 and 1979[a]

Country	Population, 1979[b] (millions)	Year	
		1978	1979
Djibouti	0.3	67	75
Ethiopia	31.4	1 168	1 042
Kenya	16.1	126	1 473
Somalia	4.3	1 646	1 074
Total	48.9	3 007	3 664

[a] All were negative for variola virus.

CERTIFICATION OF SMALLPOX ERADICATION IN CHINA

After the Second World War, civil war broke out in the Republic of China. In October 1949, after the defeat of the Kuomintang government, the government of the People's Republic of China was established and controlled the whole of mainland China. However, the Kuomintang government, which controlled only Taiwan, was until 1971 recognized by the United Nations as having the right to represent the entire country. Obviously, the Kuomintang government was unable to provide WHO with data about smallpox on the mainland. WHO was therefore not in a position to receive information on mainland China until 1972, when it followed the policy of the United Nations and recognized the government of the People's Republic of China as the only government having the right to represent China.

Lack of Information on Smallpox Eradication

Although mainland China was in theory accessible to WHO representatives from 1972 onwards, for several years it was very difficult to obtain information on health matters. From the outset of the global eradication programme, the Organization was understandably concerned about the smallpox situation in the most populous country in the world. Discussions in Geneva with Dr Chang

2
YEARS / ANS

SANS VARIOLE
26 octobre 1977
au
26 octobre 1979

Exactly two years to the day have elapsed since this man fell ill with smallpox in the town of Merca in southern Somalia. He is the world's last known case of endemic smallpox.

The basic criterion for confirming the eradication of smallpox is that two years must have elapsed without a case of smallpox being detected by a system of surveillance sufficiently sensitive to have detected a case had it occurred.[1] This criterion has now been met. The evidence will be subjected to critical review by a panel of experts, the Global Commission for the Certification of Smallpox Eradication. Their report will be the basis of a presentation to the World Health Assembly in May 1980. The endorsement of eradication will signify formal recognition that routine smallpox vaccination and vaccination certificates are unnecessary. The risk of complications from vaccination is obviously greater than the risk of getting smallpox which is now zero.

[1] Wld Hlth Org. Techn. Rep. Ser., 1972, No. 493.

Deux années exactement se sont écoulées depuis que cet homme a contracté la variole dans la ville de Merca en Somalie du Sud. Il s'agissait du dernier cas connu au monde de variole endémique.

Le critère fondamental de confirmation d'éradication de la variole est que deux années se soient écoulées sans qu'un cas de variole ait été décelé par un système de surveillance suffisamment sensible pour avoir pu détecter tout cas qui se serait produit.[1] Cette condition se trouve maintenant remplie. Les pièces du dossier feront l'objet d'un bilan critique de la part d'un groupe d'experts, à savoir la Commission mondiale pour la Certification de l'Eradication de la Variole. Le rapport de cette Commission servira de base à un exposé qui sera présenté à l'Assemblée mondiale de la Santé en mai 1980. L'entérinement de l'état d'éradication apportera la confirmation officielle que la vaccination antivariolique systématique et l'exigence de la production de certificats de vaccination n'ont plus de raison d'être. Le risque de complications vaccinales est de toute évidence plus grand que le risque de contracter la variole, qui est devenu nul.

Plate 27.8. Cover of the *Weekly Epidemiological Record* for 26 October 1979, the day on which certification of the Horn of Africa was completed in Nairobi. The illustration shows Ali Maow Maalin, who was diagnosed as having variola minor on 26 October 1977 and was the last case in the world of endemic smallpox.

Wei-hsun, an Assistant Director-General of WHO, who was a paediatrician from Beijing, elicited the information that he had not seen a case of smallpox since 1957 and was unaware of cases anywhere in China after about 1960.

In the absence of better ways of obtaining information, two other approaches were adopted. Whenever possible, Henderson and Arita met individuals or delegations planning to visit China and told them that the Smallpox Eradication unit wished to obtain more definite information about smallpox in China. They were asked to look for facial pockmarks wherever they went and to estimate the age of any person with such pockmarks. About 15 reports were received on facial pockmarks seen in China, but without exception the persons concerned were adults—no pockmarked children were seen.

Another approach was to examine refugees from China after they had crossed the border into Hong Kong and Nepal. Arita visited Hong Kong in 1970 to request the local authorities to conduct a pockmark survey. However, although the Hong Kong health authorities originally agreed to do so, they subsequently declined, feeling that it was a politically sensitive matter. In 1975, Dr P. N. Shrestha, director of the national smallpox eradication programme in Nepal, conducted pockmark surveys among Tibetan refugees in that country, and found that 43 out of 2350 of them (1.8%) had facial pockmarks. Although they could not remember exactly when they had had smallpox, none of these people recollected that it had been contracted later than 1961 and none was less than 14 years old in 1975. The results suggested that smallpox had been eradicated in Tibet early in the 1960s.

The Consultation on the Worldwide Certification of Smallpox Eradication, held in October 1977, devoted some time to discussing the smallpox situation in China. It considered that, although according to the information available it seemed unlikely that smallpox was still endemic there, China's vast size and population—one-quarter of the world's total—justified a more detailed study. For this purpose, the Commission recommended that during 1978 China should be visited by an international commission, WHO consultants or WHO staff, to verify and document its history of smallpox eradication. This was eventually achieved in July 1979.

The problem was one of effective communications. Chinese officials, on the one hand, felt that additional documentation and a visit by Commission members were unnecessary, as transmission had been interrupted many years earlier; the Commission, on the other hand, believed that the available documentation from China was not sufficient to convince the world community of the reality of this achievement.

Because of the difficulty of obtaining the requisite information, China was (with Democratic Kampuchea, see Chapter 26) the last country to be certified by the Global Commission as being free of endemic smallpox, on 9 December 1979.

Development of Effective Contacts with China

Initial efforts, 1973–1976

At the Twenty-sixth World Health Assembly, in May 1973, the delegate from China reported that smallpox eradication had been achieved in practice by 1959 through a country-wide vaccination campaign initiated following Liberation (World Health Organization, 1973b). Extensive use had been made of part-time vaccinators and health auxiliaries in order to cover remote areas adequately. Once vaccination of the population had been completed, smallpox control had been integrated into the general health services and everyone was routinely vaccinated and revaccinated every 6 years. This had been reinforced by the recent growth of health cooperatives and the "barefoot doctor" system. No other details were given. Information on the health system in China began to emerge with the WHO study visits in 1973 and 1974, but none of these provided any specific details about smallpox, nor was there any assurance that importations from endemic neighbours to the south (Bhutan, India and Nepal) would be quickly detected and contained.

1977: Increasing urgency of better contacts

In January 1977 WHO was still no better informed about the eradication of smallpox in China and was beginning to consider seriously how to approach the problem of certification. A representative of China was invited to serve on the International Commission for the

Certification of Smallpox Eradication in Bangladesh and Burma in November–December 1977, in the expectation that the Chinese authorities might be interested in determining whether China's southern neighbours were free of smallpox. However, an invitation sent in May 1977 was declined on the grounds of "busy working arrangements". A separate invitation to participate in the October 1977 Consultation on Worldwide Certification was also refused, despite the personal attention of Dr Ch'en Wen-chieh, the Chinese Assistant Director-General of WHO who had succeeded Dr Chang Wei-hsun.

Following a request from the Smallpox Eradication unit, the WHO Regional Office for the Western Pacific cabled Beijing on 26 September 1977 and requested a brief summary statement covering the date of the last case, ongoing surveillance activities, vaccination policy and information on laboratory stocks of variola virus. The reply sent on 24 October 1977 was, if anything, briefer than the statement made by the Chinese delegation at the World Health Assembly in 1973, except that the information was given that variola virus was being held by specific institutions designated by the government. The reaction of the Chinese seemed to be one of indifference to the opinion of the rest of the world. They seemed to feel that no one need doubt their word that smallpox had been eliminated from China many years earlier.

Predictably, the Consultation in October 1977 recommended that WHO should obtain more information from China and that a visit should be arranged for a group which would include members of the Global Commission.

1978: Further informal contacts

On 4 January 1978, a letter was sent from the Regional Office for the Western Pacific proposing that 3 international experts and 3 WHO medical officers should visit China for 3 weeks during July–August 1978, and pointing out that "smallpox eradication in China appears to have been uniquely successful in terms of the vast geographical areas and methods employed. Detailed information on these activities would be of considerable value when worldwide eradication is reported to all Member States of WHO at the World Health Assembly". In order to make the proposal more readily acceptable a list of 6 experts and 5 WHO epidemiologists was attached to the letter, to enable the Chinese government to make a choice.

On 28 February 1978, following the adoption by the Executive Board of a resolution requesting the Director-General to establish the Global Commission for the Certification of Smallpox Eradication, the Chinese government was invited to nominate a member of the Commission. In their reply of 29 April, the Chinese authorities again declined to become involved in the certification process. At the same time a brief reply was received to the letter of 4 January from the Regional Office for the Western Pacific reiterating what had been stated previously concerning smallpox and adding:

> "It is based on the principle of responsibility for the health of the Chinese people and the people of the world and on the conscientious and careful conclusion reached after long years of thorough investigation and scientific surveillance that the Chinese Government has declared smallpox eradicated. As to the proposed visit to China by a group including members of the Global Commission with a purpose to 'certify' whether or not China has really achieved smallpox eradication ... I regret such a visit could not be arranged."

It was obvious that more effective communications were required between China and WHO on the philosophy of the certification programme. During the Thirty-first World Health Assembly, in May 1978, informal discussions were held between Dr Hsueh Kung-cho and other members of the Chinese delegation and WHO officials, including Arita, Chief of the Smallpox Eradication unit, at which it was agreed that the proposed visit should be postponed and that China would prepare a country report for the Global Commission before any further steps were taken. There followed a prolonged series of informal contacts aimed at convincing the Chinese authorities that the requests by WHO for more information and the invitations to participate in the certification commissions did not imply that WHO doubted their word that smallpox eradication had been achieved, but rather that it was a matter of compiling formal documentation which would convince health authorities all over the world so that it would be possible to discontinue smallpox vaccination everywhere.

Informal approaches were made during the visits to China by Dr William Foege, Director of the Center for Disease Control, Atlanta, USA, in June 1978 and by Mr Paul Lawton,

Record of the Exchange of Views at an Informal Meeting in May 1978 (I. Arita)

"Dr Hsueh Kung-cho first explained the smallpox situation in China. In 1950, special regulations to deal with the smallpox problem were set up and an eradication programme started. In 1959 the last case was recorded and to date there have been no further smallpox cases detected. Notably during the last ten years, national health programmes have been further strengthened, establishing close communication at province, country and town levels.

"I [Arita] explained the following points: Although I personally believed that smallpox had been eradicated in China, data to support this achievement were not sufficient. In the context of certification activities for global smallpox eradication, there are still a considerable number of health personnel as well as the press community who express uncertainty regarding smallpox in China. It is most desirable therefore for China to show their achievement to the world.

"In reply to this, Dr Hsueh Kung-cho indicated that a country report on surveillance activities for smallpox eradication would be prepared by China and submitted to WHO and all other necessary action required would be further reviewed when this report was prepared. In the circumstances, it was agreed that the initial proposal from WHO for Global Commission members to visit China during July–August 1978 should be postponed.

"The timing of the certification activities was discussed. The first Global Commission meeting would take place in December 1978 and the final meeting was expected to take place in October or November 1979, so that preparation of the report had to be started as soon as possible. It was agreed that the Smallpox Eradication unit would submit items to be included for special documentation during the next few days."

Division of Coordination, WHO, in October 1978. No concrete results were obtained, but the impression was gained that the Chinese authorities were becoming more open and responsive.

On 27 November 1978 WHO received a 2-page document entitled *A General Introduction on the Eradication of Smallpox in the People's Republic of China*, from Dr Chiang Yi-chen, Minister of Public Health. The only new information was that the last case had occurred in March 1960 in Yunnan Province and that variola virus was held by the National Institute for the Control of Drugs and Biological Products in Beijing.

During the meeting of the Global Commission in December 1978, Arita organized a special subcommittee to discuss this report and future plans for the certification of China, the participants being Fenner, Chairman of the Global Commission; Dr Foege, who had recently visited China; Henderson, former Chief of the Smallpox Eradication unit; Dr Kostrzewski, who had been Chairman of the International Commission for the Certification of Smallpox Eradication in India; and Dr Shrestha, who had organized the pockmark survey of Tibetan refugees in Nepal. The unanimous opinion of the subcommittee was that it was highly likely that smallpox had been eradicated in China, in view of the structure of the health and social services in the country, but that evidence was lacking; that high-level negotiations between China and WHO or influential WHO Member States on behalf of WHO would be required to obtain data; and that technically the minimum data requirement would include the results of surveys for facial pockmarks and vaccinations scars on a province-by-province basis. Dr Kostrzewski stressed the desirability of oral negotiations at the stage that had been reached; continued written requests might be perceived as intimidating. The subcommittee drafted a statement which was approved by the plenary meeting of the Global Commission and included in the Commission's report for 1978:

"Considering the extensive health service network in China and its capability for effective surveillance, the Commission expressed confidence that smallpox transmission had been interrupted. However, it was believed that more

substantial documentation would be of considerable importance to provide persuasive evidence of this fact to the world community. A more complete country report should be sought with information presented, if possible, on a province-by-province basis. Useful information would include documentation of the last cases, an account of past smallpox activities in individual provinces and current epidemiological surveillance activities indicating how suspected cases would be detected. Certification of freedom from smallpox was deferred pending receipt of additional information."

During 1978, the Global Commission certified a number of countries, including Namibia, Southern Rhodesia (Zimbabwe), and Thailand, but deferred certification of China, Democratic Kampuchea, Iraq, Madagascar and South Africa because of insufficient evidence.

1979: A visit by a WHO team is arranged

The next initiative in what had become rather delicate negotiations was undertaken, at WHO's request, by Sir Gustav Nossal, Chairman of the WHO Western Pacific Advisory Committee for Medical Research, who visited China in April 1979. He engaged in informal discussions to find out under what conditions the Chinese would accept a visit by Fenner (a fellow Australian who was Chairman of the Global Commission), accompanied by a WHO staff member. The response was encouraging. He detected a positive and flexible attitude on the part of the Chinese, who showed far less sensitivity to the issue than he had expected. The proposed visit appeared to be welcome. During the Thirty-second World Health Assembly, in May 1979, information was provided informally to the effect that the Chinese would agree to a visit by Fenner in July.

Visit of the WHO team to China

The result of these protracted negotiations was that a WHO team consisting of Fenner and Dr Joel Breman, of the Smallpox Eradication unit, visited China from 14 to 30 July 1979. They found that a country report had already been prepared by Professor Jiang Yutu, Professor Li Heming and Dr Zhao Kai, three scientists who had participated in a meeting of officials from laboratories retaining variola virus and the national control authorities concerned, which had been held

BY COURTESY OF J. BREMAN

Plate 27.9. The WHO team of J. Breman and F. Fenner, in Kunming, Yunnan Province, China, with Fu Guichen, Jiang Yutu, Jiang Weizhang and Zuo Kejia. Jiang Yutu accompanied the WHO team; the other Chinese were health officials of Yunnan Province.

The Improvement of Health Services in China

Immediately after the Liberation, one of the first acts of Mao Zedong's government was to eliminate smallpox from China by mass vaccination campaigns. This was achieved by enlisting community support and using all available health personnel for intensive vaccination campaigns (see Chapter 8). Later, routine vaccination was incorporated into primary health care. Although there had been undeniable improvements since 1949, in the early 1960s health services were still not being provided to many of the 85% of the population living in the rural areas. Mao Zedong's directive of 26 June 1965 prescribed that, in health and medical work, the stress should be put on the rural areas. The changes made were: (1) the establishment of mobile medical teams formed out of existing health manpower to work in the rural areas; (2) the discontinuation of formal medical education pending its complete reform; (3) the genuine unification of traditional and western medicine; and (4) the massive training of "barefoot doctors" and health auxiliaries for the delivery of health services to the rural population.

The Ministry of Health was reorganized and responsibility for the delivery of health services delegated to the provincial, regional or municipal level. At the same time, five-sixths of the state bureaucracy in Peking was disbanded. As a consequence of this radical decentralization, emphasis was given to the rural areas and by 1974 satisfactory coverage of the entire population had been achieved. This, however, also had the result that there was little or no epidemiological information on a country-wide basis at national level. On the other hand, comprehensive information was available at provincial and commune level.

Awareness of the need to report communicable diseases was highly developed and coverage in terms of surveillance very extensive, as even in production teams—the basic units of community organization—one person was made responsible for disease notification.

in Geneva from 23 to 24 April 1979. As others had predicted, once discussions had been established on a person-to-person basis, matters went very smoothly. The WHO team reviewed the report with the authorities as well as a special detailed report on the last outbreaks in Yunnan Province. This report also included the results of a vaccination scar and pockmark survey of 73 820 persons in the border areas of Yunnan carried out in March–May 1979. Their only real concern at the time was that, while there was comprehensive information concerning the last cases reported from Yunnan in 1960, cases had also been reported in Xizang Autonomous Region (Tibet) in 1960, about which there were no details. It was impracticable for the WHO team to visit Xizang, but the Chinese authorities promised to carry out investigations comparable to those described for Yunnan.

The WHO team, accompanied by Dr Jiang Yutu, examined the communicable disease surveillance system in three areas: Beijing municipality, Shanghai municipality and Yunnan Province, from which the last endemic case in China has been reported in 1961 (Fig. 27.15). In all areas, visits were made to provincial, municipal and district epidemic prevention sections, commune hospitals, health centres, and village primary schools. The team was impressed by the detailed records available at provincial and municipal level about smallpox outbreaks and vaccination campaigns which had been conducted well over 20 years previously. Fenner and Dr Breman felt confident that the system for the surveillance of communicable diseases operating in the country would have detected outbreaks of smallpox if they had occurred after 1960.

It was also agreed that 2 representatives from China would participate in the December meeting of the Global Commission in 1979, one of whom would be a member of the Global Commission and the other an epidemiologist familiar with the details of the eradication of smallpox in China.

The WHO team's visit as well as communications between China and WHO resulted in several documents becoming available on smallpox eradication in China, containing a great deal of data completely unknown to WHO and to the world scientific community before 1978 (WHO/SE/79.142 Rev. 1;

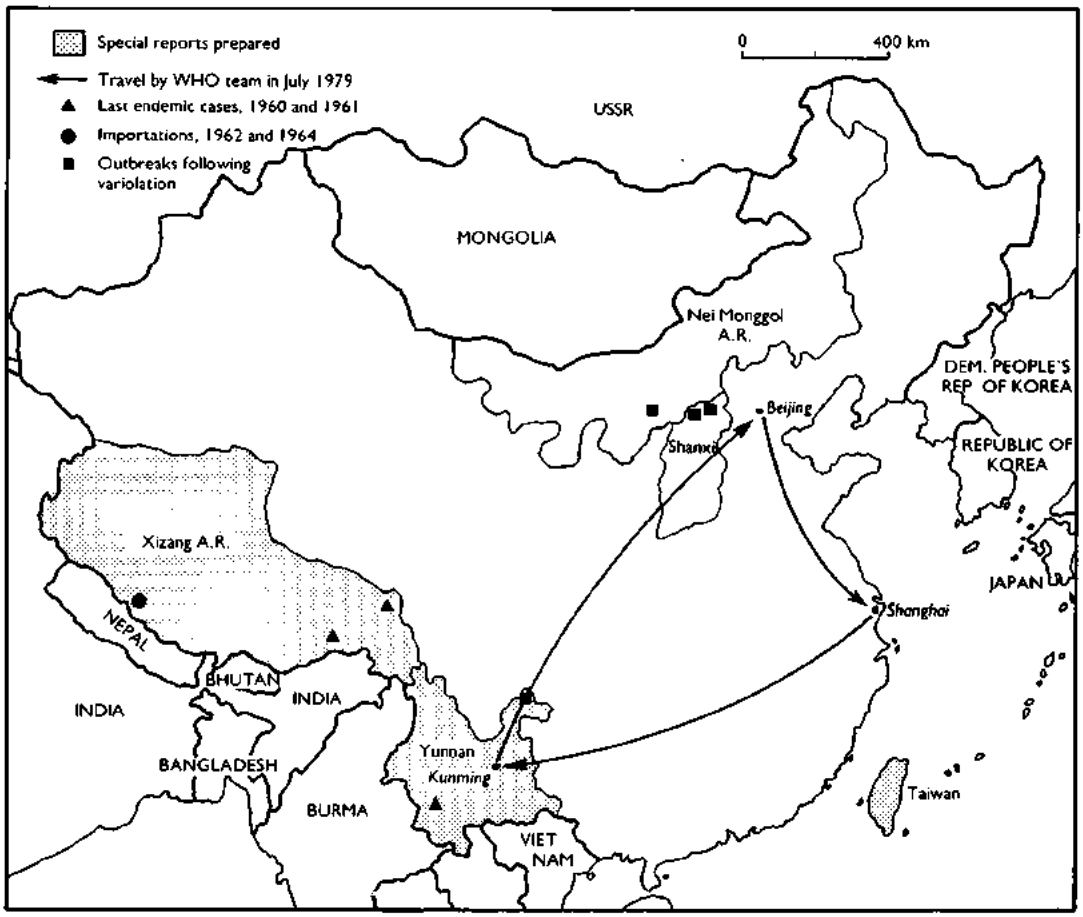

Fig. 27.15. China and neighbouring countries, in relation to certification activities, showing travel by the WHO team in July 1979 and the areas for which special reports were prepared (Provinces of Yunnan and Taiwan; Xizang Autonomous Region [Tibet]). Places where the last cases of endemic smallpox were reported in Xizang in 1960 and in Yunnan in 1961, the site of imported cases in Xizang in 1962 and 1964, and the locations of outbreaks following variolation in northern Yunnan in 1958 and in Nei Monggol Autonomous Region and Shanxi Province in 1962–1965 are also shown.

Table 27.6. China: numbers of reported cases of smallpox between 1957 and 1965, by province and autonomous region[a]

Province or autonomous region	1957	1958	1959	1960	1961	1962	1963	1964	1965
Provinces:

Total	315	671	476	23	28	2	283	35	4

[a] Data for all provinces, autonomous regions and municipalities over the period 1950–1965 are shown in Chapter 8, Table 8.13. No cases were reported after 1956 in the administrative units not listed. No cases were reported anywhere in China after 1965.

[b] Associated with variolation.

[c] Importations from Nepal.

WHO/SE/79.151; SME/79.10; SME/79.11, Fenner & Breman). Subsequently, Xu & Jiang (1981) described the elimination of smallpox from Shanghai, and Jiang Yutu published an account of smallpox in China in a Chinese medical encyclopaedia (Jiang, 1985). The description of the eradication of smallpox in China given in Chapter 8 is based on the relevant information in these reports. Three matters of particular importance for the certification programme are described below: smallpox in Yunnan Province and in Xizang Autonomous Region (Tibet), and the location of laboratory stocks of variola virus. Also included in the present chapter is an account of outbreaks of smallpox in northern China in 1962–1965, which did not come to the attention of WHO until the 1980s. The data are shown in Table 27.6.

Smallpox in Yunnan Province

Yunnan, with a population of about 30 million, is situated in south-western China and borders on Burma, the Lao People's Democratic Republic and Viet Nam (Fig. 27.16). Although the reported incidence of smallpox had been reduced to zero throughout most of China by the late 1950s (see Chapter 8, Table 8.13), cases continued to occur in Yunnan until 1961 (Table 27.7). Scattered cases were reported from counties in many parts of Yunnan up to 1959, but after that year 5 out of the 6 outbreaks reported occurred in counties adjacent to Burma (Fig. 27.16). The villages in these counties were inhabited by ethnic minorities having strong ties with Burma and there was frequent communication with villages across the border. At the time, communications between these areas and Kunming, the provincial capital, were very poor, and elements of the Kuomintang, by preventing adequate vaccination coverage, had increased the difficulty of eliminating smallpox. Up to 1960, smallpox outbreaks repeatedly occurred on the Burmese side of the border and the disease then passed over into China as the inhabitants carried it across. For example, in 73 of the 461

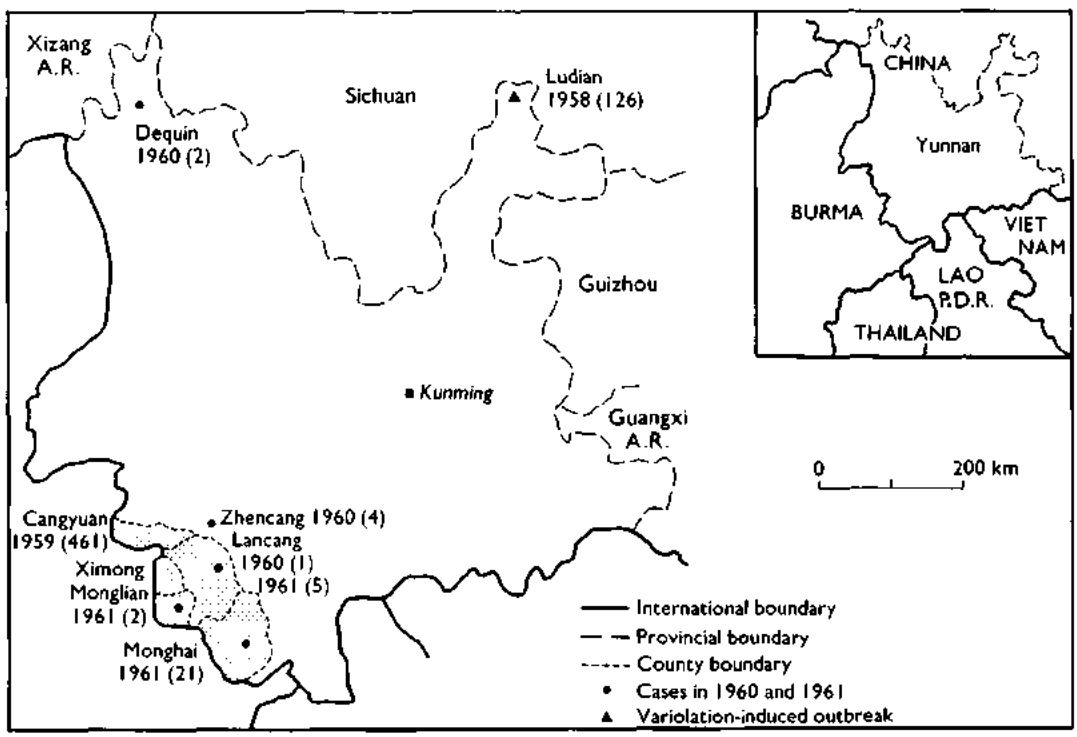

Fig. 27.16. Yunnan Province, showing sites of smallpox outbreaks in 1960–1961 and counties near the Burmese border where vaccination scar and facial pockmark surveys were conducted in 1979. An outbreak of 461 cases occurred in Cangyuan county in 1959 and a variolation-induced outbreak of 126 cases occurred in Ludian county in northern Yunnan in 1958. Numbers next to locations indicate the year in which the number of cases (in parentheses) occurred.

cases (16%) reported in 1959 from Cangyuan county, the disease had been contracted in Burma. It was estimated that at this time between 30% and 60% of the villagers on the Chinese side of the border were vaccinated. After a delayed but intensive vaccination campaign in Cangyuan and neighbouring counties in 1959, which was said to have reached 98.8% of the population, the outbreaks subsided. Seven cases were reported from 3 counties in 1960 and 28 cases in 1961, 5 from Lancang county, 21 from Monghai county, and finally 2 from Monglian county—the last endemic cases in China.

In the border districts in which the last smallpox outbreaks had occurred, vaccination scar and pockmark surveys were conducted in March–May 1979, in preparation for the visit to Kunming by the WHO team. The overall vaccination rate among 44 771 persons examined in the rural districts was 90.4%, compared with 94.0% for Kunming municipality (Table 27.8). In both areas, the rate was also satisfactory for the age group 0–4 years. The overall frequency of pockmarks in persons in these districts was 6.0%, compared with 0.3% in Kunming municipality (Table 27.9), but the age distribution (Table 27.10) revealed that in Monglian county, in which, as has already been mentioned, the last reported cases occurred in 1961, no person under 22 years of age had facial pockmarks, nor were any pockmarked persons under 20 found elsewhere in Yunnan.

The evidence provided to the Global Commission showed that endemic smallpox had persisted in these remote border areas of Yunnan for several years after it had been eliminated from the rest of China (except Xizang Autonomous Region; see below). However, the pockmark and vaccination scar surveys conducted in 1979 in the counties in which smallpox was last endemic provided reassurance that transmission had been interrupted in the early 1960s and that no further outbreaks had occurred.

Smallpox in Xizang Autonomous Region (Tibet)

Xizang Autonomous Region (Fig. 27.17) is separated from the neighbouring countries of Bhutan, India and Nepal by the Himalayan mountain chain. Its 1.8 million inhabitants are spread over 1.2 million square kilometres, giving a population density of only 1.5 per square kilometre. Xizang therefore appears to have been a rather unfavourable place for maintaining smallpox transmission, although

Table 27.8. Yunnan Province: results of vaccination scar survey among rural and urban populations, March–May 1979, by age group

[a] None of whom had had smallpox after 1960; ..=data not recorded.

it was periodically subject to epidemics of great severity. In all, 23 cases were reported in 1955 and 4 in 1956, followed by 16 in 1960. This led to a request from the WHO team for a special report, which was forwarded to WHO in November 1979. No further details of the cases in 1960 were available except that 5 of them occurred in Changdu subregion and 11 in Lhasa subregion.

The special report provided details of subsequent vaccination coverage, information on suspected cases of smallpox, and the results of vaccination scar and facial pockmark surveys conducted in August 1979. Between 1960 and 1979, 39 cases of suspected smallpox were investigated in the 3 years 1963, 1965 and 1970. All turned out to be cases of chickenpox. At the time of the Global Commission meeting, the Chinese authorities reported rumours of 4 importations from Nepal into Xizang in the early 1960s, with 1 secondary case. Subsequently Dr Jiang Yutu (personal communications, 1984, 1985) confirmed that, following importations from Nepal, 1 case had occurred in Nielamu county (Rikeze subregion) in 1962 and 5 cases in 1964.

In addition to routine vaccination, for which freeze-dried vaccine was used from 1965 onwards, mass vaccination campaigns were carried out in 1964 and 1975 to increase the immunity level of the population in areas bordering on India and Nepal. Limited data showed that the take rate in persons undergoing primary vaccination varied between 86% and 95%.

The vaccination scar and facial pockmark surveys in August 1979 covered 15 661 persons in Shannan and Rikeze subregions and Lhasa City (Table 27.11). Vaccination rates were high (91%) among those over 4 years of age but only 57.5% in those below that age. No persons with facial pockmarks were found in Shannan subregion but about 1% of over 12 000 persons examined in Lhasa City and Rikeze subregion, all of them over the age of 20 years, were pockmarked. This evidence reinforced the data from the pockmark survey on Tibetan refugees provided to WHO earlier.

Province of Taiwan

In 1972, WHO decided to follow the United Nations in recognizing the Beijing government as representing China, considering Taiwan as one of its provinces and referring to the island as "China (Province of Taiwan)".

Unlike mainland China, Taiwan had been an active member of WHO from 1948, when the Organization was established, until 1972, when it was excluded following the above-mentioned decision. In 1978, Taiwan had a population of 17.9 million (7.5 million in 1950) and a comprehensive health services infrastructure. The last big epidemic of smallpox had occurred in 1946–1947: 6754 cases with 2040 deaths. Mass vaccination campaigns with the annual primary vaccination of infants and vaccination of the entire population eliminated endemic smallpox in 1954, after which no cases had been found. The country report, endorsed by the Director-General of Health Services, together with a signed "Declaration of Smallpox-free Status", was judged to be satisfactory by the Global Commission on 8 December 1978, but for purposes of formal certification Taiwan could, of course, only be considered together with China as a whole.

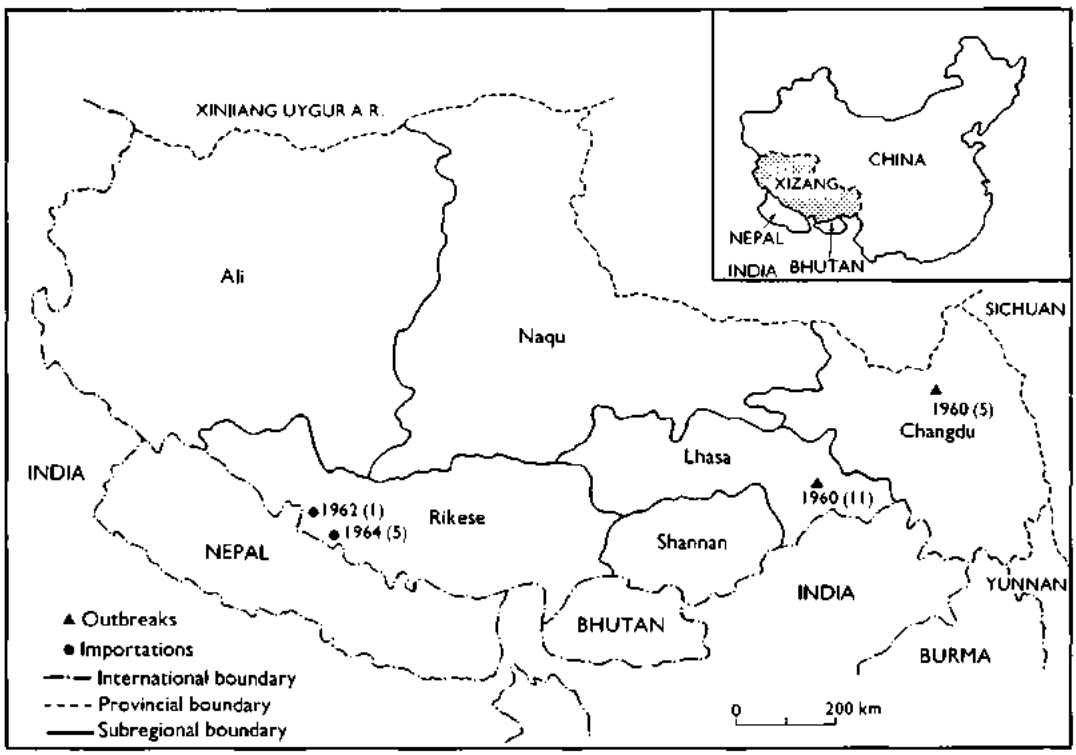

Fig. 27.17. Xizang Autonomous Region (Tibet), showing subregional, provincial and international boundaries, and the sites where the last endemic cases occurred in 1960: 5 cases in Changdu county (Changdu subregion) and 11 cases in Linzki county (Lhasa subregion). There was 1 case in 1962 and 5 cases in 1964 in Nielamu county (Rikese subregion), associated with importations from Nepal. Numbers next to locations indicate the year in which the number of cases (in parentheses) occurred.

Variolation in China after 1950

Variolation, initially by insufflation and later by scarification, had been practised in China since about the 10th century (see Chapter 6), and was practised almost as widely as vaccination during the early years of the 20th century. It continued to be used for over a decade after the Liberation in remote rural areas that were at the time served almost exclusively by practitioners of traditional medicine. The Global Commission was told of an outbreak of 126 cases in 1958 in Ludian county in the north-east corner of Yunnan Province (see Fig. 27.16) which followed variolation by nasal insufflation, 5 years after the last case of endemic smallpox in that county but only a year after the last outbreaks in other counties in northern Yunnan.

Some years after the last meeting of the Global Commission, information was provided by Dr Jiang Yutu (1985; and personal communications, 1984, 1987) about other variolation-induced outbreaks in northern China in the mid-1960s (Fig. 27.18), in Nei Monggol Autonomous Region (1 case in

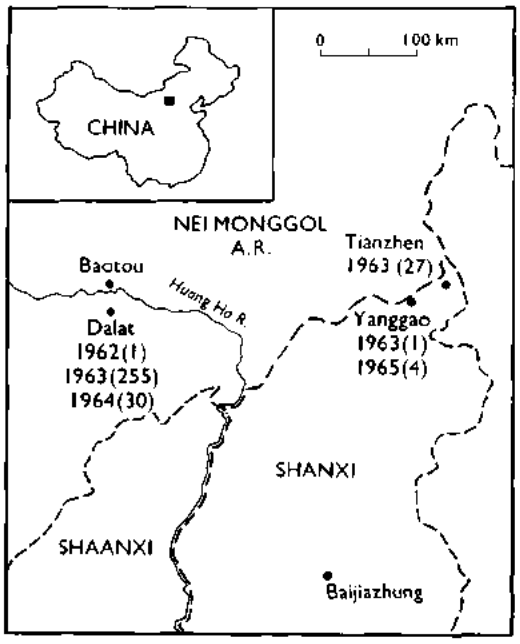

Fig. 27.18. Sites of the outbreaks in northern China, 1962–1965, following variolation. Figures beneath place names indicate the year of the outbreak and the number of cases (in parentheses). (From Jiang Yutu, 1985; and personal communications, 1984, 1987.)

1962, 255 cases in 1963 and 30 cases in 1964) and 2 nearby counties of Shanxi Province (28 cases in 1963 and 4 in 1965).

These incidents have been explained by Dr Jiang Yutu (personal communications, 1984, 1987) as follows. Throughout the whole of continental China between 1959 and 1962, almost everything, including smallpox vaccine, was in short supply. In 1963, just after the country had recovered from this situation, people demanded that their children should be vaccinated but supplies of potent vaccine were not sufficient to ensure the coverage of all areas, especially the mountainous and remote ones. In Nei Monggol and Shanxi, as a result, the inhabitants turned to their local traditional doctors, some of whom had been variolators, maintaining virus in sealed jars containing honey. After smallpox had disappeared from their region in the 1950s (see Chapter 8, Table 8.13), they had continued to maintain the viability of the virus by the annual inoculation of their own children. Thus, when supplies of vaccine failed in the early 1960s, these variolators still had active variola virus, and with the cessation of vaccination many more children became susceptible and many more were inoculated with the virus. The outbreaks which then occurred were investigated by Dr Zhao Kai, of the National Vaccine and Serum Institute, Beijing, who recovered variola virus both from cases and from the variolation material. Stringent measures were taken to eliminate the practice and supplies of potent freeze-dried vaccine were provided to remove any need for recourse to variolation. As has been pointed out earlier, a massive reorganization of the health services in China in 1965 greatly improved the quality of health care in the rural areas. No cases of smallpox occurred after 1965, either in these areas or elsewhere in China.

Variola Virus Stocks

Inquiries made by the Chinese Ministry of Health in 1961–1962, 1966 and again in 1978 established that the only variola virus stocks held in laboratories were located in the National Institute for the Control of Biological Products in Beijing. The virus had last been used in 1967, as a positive control during laboratory investigations of material from a suspected case of smallpox. The WHO team noted:

"The laboratory does not conform to WHO standards for facilities storing variola virus. As a depository only, the physical and administrative arrangements seem adequate for the particular situation, but the building housing the virus stocks, and the cabinet itself, would not offer maximum security against a determined saboteur."

In January 1981 these stocks were destroyed by the Chinese government.

Review by the Global Commission

WHO's efforts to collect additional information on smallpox in China had eventually resulted in a visit of a team of experts to the country in July 1979 and the accumulation of substantial data that lent support to the view that smallpox had been eradicated. However, there was little time left for review and assessment of these data by the Global Commission, since the target date for global certification was the end of 1979. On 21 August 1979, Arita wrote to members of the Global Commission and submitted to them all the data then available: the country report by the Ministry of Health (WHO/SE/79.142

Rev. 1); a provincial report by the Health Department of Yunnan Province, in which the last endemic case had occurred (SME/79.10); a report on the visit to China by Fenner and Breman (SME/79.11); and a report on smallpox eradication in Taiwan Province. Information on Xizang (Tibet) and vaccine production arrangements did not become available to WHO until November 1979. In the letter, Arita noted that the WHO team believed, from the evidence that it had been able to collect on its visit, that smallpox had been eliminated from China, and specifically requested an answer to the following 3 questions:

(1) Do you think that the Global Commission should now approve certification of smallpox eradication in China?; or

(2) Do you as an individual member of the Global Commission approve certification of smallpox eradication in China, but feel that its final eradication should not be declared until all the Commission members meet again from 6 to 9 December 1979?; or

(3) Do you have any other comments or recommendations which do not fall into the above two categories?

The response of the members of the Global Commission was equivocal; 8 advocated immediate certification, 5 wished to discuss it at the December meeting, and 6 did not reply. Dr Holger Lundbeck, a Commission member from Sweden, expressed a widely held view by saying that, while he had no doubt that smallpox transmission had been interrupted long ago in China, in order to convince the world community, more information should be sought about Xizang for "there will always be people who doubt that eradication has been achieved, in particular in countries as big as China".

Consideration of the certification of smallpox eradication in China was therefore deferred until the meeting of the Global Commission in Geneva in December 1979, which was attended by Dr Zhang Yi-hao from China as a member and Dr Jiang Yutu as an adviser. In addition to the reports previously circulated, 2 further reports were then available: (1) *Supplementary Report about the Eradication of Smallpox in China*, sent to WHO on 17 November 1979 by the Minister of Public Health, Dr Qian Xinzhong, which provided information on the production of smallpox vaccine, the health service structure, and the quarantine services; and (2) a report (WHO/SE/79/151) which included details of vaccination campaigns and coverage in Xizang, the last outbreaks there, and the results of a pockmark survey carried out in August 1979, which has already been described. Having considered all the data and heard reports from Dr Zhang Yi-hao and Dr Jiang Yutu, the Commission certified China to be free of smallpox on 9 December 1979.

CONCLUSIONS

In every health programme, success depends not only on the scientific technology but also on the managerial arrangements and political negotiations which pave the way for its implementation. The certification activities in the Horn of Africa and China illustrate how scientific technology and managerial and political arrangements were developed in parallel in order to accomplish a single task.

With the certification of the Horn of Africa and China, the chapter on the certification of the global eradication of smallpox, which had commenced in 1971 when Brazil recorded the last case on the South American continent, was closed. Activities had been greatly intensified since 1976 when it became apparent that global eradication was imminent. Four years of effort, from 1976 to 1979, had been successful in confirming that the world had become free of smallpox. This was the first time in history that human efforts had succeeded in eliminating a disease—and one which had been feared for thousands of years. Neither the vigorous operational campaign for the eradication of the disease nor the diligent certification programme was free from technical and human errors. Nevertheless, both were eventually successful.

The Global Commission met in Geneva from 6 to 9 December 1979. It had before it a draft final report which had already been reviewed and revised by 12 members of the Commission in Nairobi in October. The meeting concentrated its attention on the conclusions and recommendations (World Health Organization, 1980). After 4 days of intensive discussions, it accepted the following conclusions:

(1) Smallpox eradication had been achieved throughout the world.

(2) There was no evidence that smallpox would return as an endemic disease.

L. BANCO

Plate 27.10. Members of the Global Commission for the Certification of Smallpox Eradication, 9 December 1979. *From left to right, front row:* S.S. Marennikova (USSR), J. Azurin (Philippines), P.N. Burgasov (USSR), F. Fenner (Australia; Chairman), J. Kostrzewski (Poland; Vice-Chairman), D.A. Henderson (USA), W. Koinange (Kenya), Zhang Yihao (China); *back row:* P.F. Wehrle (USA; Rapporteur), R.N. Basu (India), J.M. Aashi (Saudi Arabia), H.B Lundbeck (Sweden), B.A. Rodrigues (Brazil), K.R. Dumbell (United Kingdom), R. Netter (France), I. Tagaya (Japan), J.S. Moeti (Botswana), Kalisa Ruti (Zaire), P.N. Shrestha (Nepal), A. Deria (Somalia).

The 19 recommendations covered all aspects of operations relevant to orthopoxviruses and the diseases that they cause in a world from which smallpox had been eradicated. The meeting closed on 9 December 1979 with a ceremony in which the members of the Global Commission signed a parchment declaring that the world was free of smallpox (see frontispiece).

The final report of the Global Commission, *The Global Eradication of Smallpox* (World Health Organization, 1980), was published in the 6 official languages of the World Health Organization and its conclusions and recommendations were accepted without change by the Thirty-third World Health Assembly on 8 May 1980.

INTRODUCTION

In order to convince the world community that smallpox had indeed been eradicated globally, WHO developed a comprehensive and sophisticated system for the certification of smallpox eradication, culminating in the final meeting in December 1979 of the Global Commission for the Certification of Smallpox Eradication (see Chapter 24). The Global Commission foresaw that the certification of eradication was not enough in itself—steps would have to be taken over the ensuing years to maintain public confidence in the reality of eradication and to ensure that advantage was rapidly taken of the benefits of the achievement, such as the ending of vaccination against smallpox. With this aim in view, the Commission's final report (World Health Organization, 1980) listed 19 recommendations indicating the activities to be undertaken during the years following the declaration by the Thirty-third World Health Assembly on 8 May 1980 that smallpox had been eradicated throughout the world.

The 19 recommendations made by the Global Commission were unanimously endorsed by the World Health Assembly on the same date (resolution WHA33.4). They dealt with post-eradication policies under 8 headings: (1) smallpox vaccination policy; (2) reserve stocks of vaccine; (3) investigation of suspected cases of smallpox; (4) laboratories retaining variola virus stocks; (5) human monkeypox; (6) laboratory investigations; (7) documentation of the smallpox eradication programme; and (8) WHO Headquarters staff.

Concurrently with the declaration of the global eradication of smallpox the Global Commission was dissolved, and in 1981 a new 6-member committee—the Committee on Orthopoxvirus Infections—was established by the Director-General of WHO. Its membership was drawn from the Global Commission, whose chairman, Fenner, also became chairman of the Committee. Except in 1985, this Committee met annually in Geneva from 1981 to 1986, critically reviewed the progress made in the post-smallpox-eradication programme and advised WHO on the implementation of the Global Commission's recommendations. The Committee was serviced and the implementation of post-eradication activities supervised by the Smallpox Eradication unit, which continued to exist, though with a reduced staff (consisting of 3, later 2, medical officers, an operations officer and support staff), all of whom had had extensive experience in the eradication programme. In the regional offices, all activities related to the post-eradication programme were transferred to the general programme of disease control and prevention or to the Expanded Programme on Immunization.

In this chapter, the post-eradication programme activities carried out between 1980 and 1986 are described, each of the 8 groups of recommendations being considered in turn. Each section is preceded by the relevant statement from the final report of the Global Commission (World Health Organization, 1980) together with the corresponding recommendations.

VACCINATION POLICY

"*Smallpox vaccination of the general public.* As smallpox has been eradicated, smallpox vaccination is no longer justified. Because vaccination may result in serious complications, which are occasionally fatal, no one except investigators at special risk should be vaccinated in any country including those where monkeypox cases have occurred.

"*Recommendation (1).* Smallpox vaccination should be discontinued in every country except for investigators at special risk.

"*Smallpox vaccination certificates for international travellers.* With the certification of global eradication of smallpox, no country should now require vaccination certificates from international travellers.

"*Recommendation (2).* International certificates of vaccination against smallpox should no longer be required of any travellers."

Routine Vaccination Programmes

In North America and in many countries of Europe and the Western Pacific Region, routine vaccination programmes had ceased before recommendation (1) was made (Table 28.1).

The health administrations of countries in other regions, however, weighed the risks and benefits of smallpox vaccination in the light of the progress made with the global smallpox eradication programme. In previously endemic countries, international commissions for the certification of smallpox eradication had recommended that vaccination programmes

Table 28.1. Number of countries carrying out vaccination against smallpox, by WHO region, 1976–1985[a]

WHO region	Number of countries[b]	Year

[a] The figures are those for the end of each of the years in question.
[b] Based on the membership of WHO of the countries in the different WHO regions as at January 1984.

should be maintained until global eradication had been certified. When this occurred, in May 1980, these programmes were soon curtailed or discontinued, particularly in countries that depended on WHO for their supplies of vaccine. Of the 156 Member States of WHO at that time, 52 were still conducting routine smallpox vaccination programmes at the end of 1980, but by the end of 1983 this number had been reduced to 2—namely, Albania, in which both primary vaccination and revaccination continued to be performed, and France, in which only revaccination was recommended. Both these countries stopped all routine vaccination in 1984.

The official discontinuation of routine vaccination programmes, however, did not always mean that vaccination had ceased altogether. In many countries, both developed and developing, appropriate instructions were not always effectively promulgated by the central health administration, and local vaccination programmes sometimes continued to be conducted. The distribution of vaccine could be readily controlled in countries in which production was carried out in national laboratories, but such control was more difficult in those in which private companies produced vaccine and sold it on request. In the USA, a few cases of severe complications (e.g., eczema vaccinatum and progressive vaccinia) occurred when vaccinia virus was used for the treatment of herpes simplex, a form of therapy with a long history but one whose effectiveness was open to question. Eventually, agreement was reached in the USA in 1984 that, apart from making provision for the armed services, the producer would restrict the supply of smallpox vaccine to the Centers for Disease Control, for use by laboratory workers where indicated. By means of announcements in the *Weekly epidemiological record* and communications with governments, WHO intervened several times to advise that vaccination programmes should be stopped, stressing the risk of complications. In addition, in 1983, the Smallpox Eradication unit contacted all vaccine producers to urge that no vaccine should be made available for civilian use.

Although routine vaccination of the general public was speedily abandoned in most countries, military personnel continued to be vaccinated. As a result, incidents occurred in several countries in which a newly vaccinated recruit infected a close contact, often in the home (Laboratory Centre for Disease Control, 1981; *Morbidity and mortality weekly report*, 1984; *Journal of the American Medical Association*, 1985). Although on scientific grounds the vaccination of military personnel could have been discontinued at the same time as that of the civilian population, decisions whether or not to do so were based on political considerations, and WHO could do little to influence them. However, as time went on, an increasing number of countries discontinued the vaccination of military personnel. In order to prevent accidental vaccinial infections of civilians, the WHO Committee on Orthopoxvirus Infections recommended in 1984 that "military personnel who have been vaccinated be confined to their bases and prevented from contacting unvaccinated persons for a period of two weeks following vaccination" (WHO/SE/84.162). This recommendation was made known to all Member States. Reviewing the situation in March 1986, the Committee on Orthopoxvirus Infections rec-

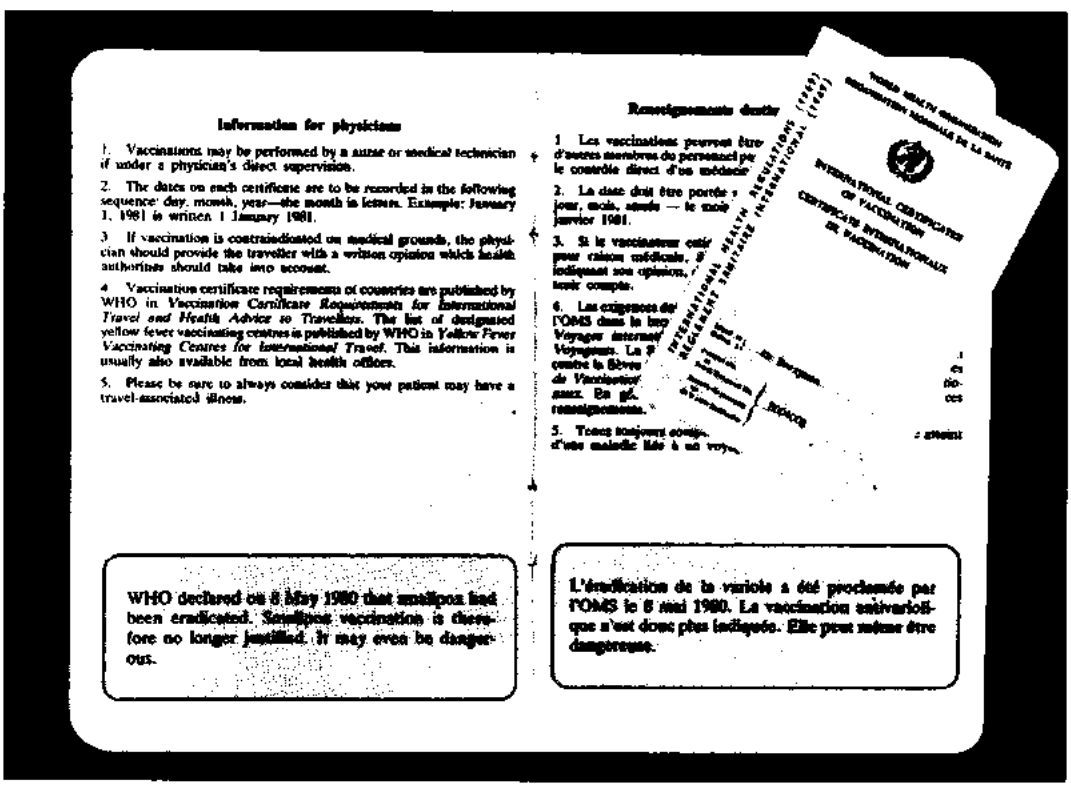
ommended that "smallpox vaccination to protect military personnel against the disease be terminated" (*Wkly epidem. Rec.*, 1986b).

Recommendation (1) exempts only "investigators at special risk" from the recomendation that vaccination should be discontinued. This group includes the following 3 categories: (1) Investigators who handle variola or monkeypox virus in a laboratory—a very small group. Everyone who enters such laboratories should undergo regular annual or triennial vaccination. (2) Investigators who work with other orthopoxviruses that are infectious for man (vaccinia and cowpox viruses). Triennial vaccination of those who handle such viruses is recommended. (3) Special surveillance teams investigating cases of human monkeypox in Zaire. At the present time, vaccination of the general population in areas in which human monkeypox virus is present is not recommended, on the grounds that the risk of monkeypox infection does not warrant either the cost of vaccination or its risks. In all, the number of persons for whom smallpox vaccination is still recommended is very small, amounting to only a few hundred persons throughout the world.

Vaccination Certificates for International Travel

At the beginning of 1980, 23 of the 155 countries for which information was available still required international travellers to hold an international certificate of vaccination against smallpox. In May 1981 the Thirty-fourth World Health Assembly formally struck smallpox from the International Health Regulations and in 1983 the new edition of the International Certificates of Vaccination no longer contained any pages for smallpox vaccination (Plate 28.1).

After the declaration of the global eradication of the disease, the number of countries officially requiring international travellers to hold a certificate of vaccination against smallpox quickly decreased to only 2 (Chad and Democratic Kampuchea) in 1981 and to none in 1982. These figures are based on the reports



Information for physicians
1. Vaccinations may be performed by a nurse or medical technician if under a physician's direct supervision.
2. The dates on each certificate are to be recorded in the following sequence: day, month, year—the month in letters. Example: January 1, 1981 is written 1 January 1981.
3. If vaccination is contraindicated on medical grounds, the physician should provide the traveller with a written opinion which health authorities should take into account.
4. Vaccination certificate requirements of countries are published by WHO in *Vaccination Certificate Requirements for International Travel and Health Advice to Travellers*. The list of designated yellow fever vaccinating centres is published by WHO in *Yellow Fever Vaccinating Centres for International Travel*. This information is usually also available from local health offices.
5. Please be sure to always consider that your patient may have a travel-associated illness.
WHO declared on 8 May 1980 that smallpox had been eradicated. Smallpox vaccination is therefore no longer justified. It may even be dangerous.
INTERNATIONAL CERTIFICATE OF VACCINATION
CERTIFICAT INTERNATIONAL DE VACCINATION
L'éradication de la variole a été proclamée par l'OMS le 8 mai 1980. La vaccination antivariolique n'est donc plus indiquée. Elle peut même être dangereuse.
WHO

Plate 28.1. The 1983 version of the International Certificate of Vaccination. It no longer contains any pages for smallpox vaccination but includes a statement that it is no longer justified.

to WHO of national health administrations, but in fact during the first few years of the 1980s international travellers were sometimes asked for certificates of smallpox vaccination by health officers at ports or airports or by consulates when they applied for visas, or were informed that they would need certificates by those through whom they arranged their travel. This occurred in developed as well as developing countries, both because of poor communications between the ministries of health and other national authorities, such as ministries of foreign affairs and their representatives abroad, and because of the difficulty of ensuring that travel agencies were properly informed and gave correct advice to their clients. Following repeated interventions by WHO, the number of such incidents gradually diminished and by 1984 only a few occurred.

RESERVE STOCKS OF VACCINE

"Although human-to-human transmission of smallpox has been interrupted everywhere and the Global Commission believes that the likelihood of reintroduction of smallpox from laboratories or natural or animal reservoirs is negligible, it is prudent for WHO and national health authorities to be prepared for unforeseen circumstances. One measure that should be taken is to ensure that adequate reserves of potent freeze-dried vaccine are available. This vaccine should be stored at −20 °C and its potency periodically checked. Seed lots of vaccinia virus for the future preparation of vaccine should be maintained, and stocks of bifurcated needles should be available.

"*Recommendation* (*3*). Sufficient freeze-dried smallpox vaccine to vaccinate 200 million people should be maintained by WHO in refrigerated depots in two countries, together with stocks of bifurcated needles.

"*Recommendation* (*4*). The stored vaccine should be periodically tested for potency.

"*Recommendation* (*5*). Seed lots of vaccinia virus suitable for the preparation of smallpox vaccine should be maintained in designated WHO collaborating centres.

"*Recommendation* (*6*). National health authorities that have vaccine stocks should be asked to inform WHO of the amount of vaccine maintained."

WHO Reserve Stocks of Vaccine

In December 1980, the Smallpox Eradication unit drew up detailed procedures for implementing recommendations (3) and (4); these were set out in a document entitled *Management of reserve stocks of vaccine in the post-smallpox eradication era* (WHO/SE/80.158 Rev.1), which was approved by the WHO Committee on Orthopoxvirus Infections in March 1981. The recommended storage temperature of −20 °C or lower was based on previous experience in the potency testing of batches of vaccine produced in the Connaught Laboratories, Canada; the Lister Institute, United Kingdom; the National Institute of Public Health, Netherlands; the Swiss Serum Institute, Switzerland; and Wyeth Laboratories, USA (Table 28.2). These batches had been stored at temperatures ranging from +4 °C to −20 °C over a period of 8–13 years. The potency of the great majority had remained at an adequate level, and it was

Table 28.2. Smallpox vaccine titres[a] after long-term storage: typical results from laboratories in 4 countries

Country and batch number	Year of manufacture	Original titre[b]	Storage temperature	Storage period (years)	Titre on retesting
Canada:					
1517-12	1971	..	4 °C	8	8.1
Switzerland:					
L4695	1966	8.0	−20 °C	10	8.0
United Kingdom:					
701	1963	8.0	−15 °C	13	7.9
USA:					
177501	1963	..	5 °C for 7 years; −20 °C for 4 years	11	8.2

[a] Expressed as $\log_{10}$ pock-forming units per ml of reconstituted vaccine.
[b] .. = data not available.

assumed that storage at a temperature of −20 °C would suffice to maintain a satisfactory titre for many years.

At the end of 1980, 68 million doses of vaccine were stored in Geneva and 6 million doses in New Delhi. These stocks had been donated by 9 countries—Belgium, Canada, the German Democratic Republic, India, the Islamic Republic of Iran, the Netherlands, Sweden, the USSR and the USA—India and the USSR being the major donors. Between 1981 and 1985, further donations were made by Belgium, India and the USSR, but some stocks were destroyed (see below), so that the total reserve stocks at the end of 1985 amounted to 5 034 178 vials, in 459 batches. If bifurcated needles were to be used, this amount of vaccine would be sufficient to vaccinate some 300 million persons. About 3.7 million bifurcated needles are also stored in Geneva.

These stocks can be made available for any country needing to undertake emergency containment measures, but only if a presumptive diagnosis of smallpox has been confirmed by expert clinical and laboratory investigations (see below).

Testing

Batches of vaccine will continue to be sampled periodically for as long as the WHO reserve is maintained, in accordance with the procedure laid down in document WHO/SE/80.158 Rev. 1; in this way the potency of all batches can be regularly monitored so that any decline in potency can be detected without delay.

Testing is carried out by the National Institute of Public Health, Bilthoven, Netherlands, which remains the WHO International Collaborating Centre for Smallpox Vaccine. In order to ensure that the data are comparable with those obtained in previous years, the Institute has decided to continue potency testing by pock counting on the chorioallantoic membrane, rather than by the newer and somewhat more accurate technique of plaque assay.

Problems encountered

The problems encountered during the implementation of the recommendations regarding reserve stocks are described below.

Location. In accordance with recommendation (3), two depots were established in 1981, one at the Société des Gares Frigorifiques et Ports Francs de Genève, Switzerland, and the other in the WHO Regional Office for South-East Asia, New Delhi, India. In the Geneva depot the requisite temperatures were satisfactorily maintained, but in the New Delhi depot the temperatures fluctuated from −10 °C to +10 °C. In 1982, the Smallpox Eradication unit arranged for a refrigeration consultant to visit the Regional Office depot in New Delhi, but it still proved impossible to keep the temperature at the proper level. In addition, the depot was flooded during heavy rains, and all the ampoules of diluent, which were stored separately from the vaccine, were submerged and had to be destroyed. In February 1984 the entire stock of vaccine in the New Delhi depot was transferred to Geneva. It was expected that, because of the high heat stability of freeze-dried smallpox vaccine, the stock would not have been affected by the temperature fluctuations, and, indeed, satisfactory results were obtained when all the batches were tested before their transfer.

The Global Commission's recommendation that vaccine depots should be located in two countries could thus not be implemented. After the difficulties in New Delhi, attempts were made to find a second depot in Japan or the USA, but these failed because the veterinary health authorities of these countries objected to the introduction of calf skin vaccine, which might contain foot-and-mouth disease virus. The Committee on Orthopoxvirus Infections therefore agreed to divide the vaccine stocks equally between the cities of Geneva and Lausanne, which are about 60 kilometres apart and connected by a motorway. Geneva has good communications with the rest of the world, and experience during the smallpox eradication programme showed that, in the event of an emergency, vaccine could be dispatched to any country in the world within 24 hours.

Potency. Although there was good evidence that vaccine could be stored indefinitely at −20 °C, tests carried out in Bilthoven between 1981 and 1983 revealed that the potency of 6 batches of vaccine, from the Islamic Republic of Iran (200 000 doses of vaccine for multiple puncture), and the USA (1.9 million doses of jet injector vaccine), had declined. No attempt was made to determine the causes of this decline; the most probable explanation was that the ampoules were not

WHO / M. VANAPPELGHEM, 1984

Plate 28.2. The reserve of smallpox vaccine in Geneva being checked by J.F. Wickett. At −20 °C it may be expected to retain its potency for many years. Nevertheless, samples are periodically tested, in accordance with a statistically designed procedure.

properly sealed or that the vaccine had too high a moisture content. These batches were removed from the stock and destroyed. Otherwise all samples tested have been found to be of satisfactory potency (Table 28.3).

In 1984, the Committee on Orthopoxvirus Infections discussed the need to keep about 7 million doses of jet injector vaccine donated by Canada, Sweden and the USA. In the Committee's view, bifurcated needles, because of their simplicity, were much to be preferred to jet injectors for the administration of smallpox vaccine should any emergency arise, so that the cost of keeping the jet injector vaccine was not justified. The donor countries were asked whether they would like the batches to be returned to them, but since none was willing to take them, they were destroyed.

Long-term maintenance

During the period 1981–1985 the existence of the WHO vaccine reserve made it much easier for Member States to decide to discontinue both smallpox vaccination and vaccine production. The annual cost of maintaining the vaccine depots amounted to US$21 000 and that of testing to US$3000. Reviewing the situation in March 1986, the Committee on Orthopoxvirus Infections concluded that

smallpox vaccine reserves were no longer required and recommended that the maintenance of a global reserve by WHO was no longer indicated. However, it suggested that a decision to offer to return vaccine to donor countries should not be implemented until the situation had been considered by an *ad hoc* committee to be convened by WHO (*Wkly epidem. rec.*, 1986b).

National Stocks of Vaccine

In addition to the WHO reserves, 22 countries reported in 1985 that they had their own national vaccine reserves, which amounted to over 100 million doses, though only about 84 million were properly maintained (Table 28.4). The national health administrations of the countries concerned are responsible for monitoring the potency of these stocks.

Seed Lots of Vaccinia Virus

Seed lots of vaccinia virus produced and kept by the National Institute of Public Health, Bilthoven (see Chapter 11), have been distributed to 3 WHO collaborating centres—namely, the Centers for Disease Control, Atlanta, the National Health Laboratory, Paris, and the National Institute of Health, Tokyo. In addition, in 1985 13 laboratories in countries in which vaccine production had ceased held seed lot material (see Table 28.5), so that, if necessary, production could be rapidly resumed. If there were ever a national emergency, or if the WHO reserve were short of potent vaccine, the seed lots stored in the WHO collaborating centres could be made available to any country that needed to produce vaccine.

Vaccine Production Laboratories

In 1975, towards the end of the Intensified Smallpox Eradication Programme, 84 laboratories were producing freeze-dried or liquid vaccine, the latter being used for routine vaccination programmes in some countries with temperate or cold climates. A few countries discontinued production during the next few years, and, after the declaration of smallpox eradication in 1980, many more did so, often when the national health administrations discontinued routine smallpox vaccination programmes (Table 28.5).

In 1985, only 14 laboratories in 11 countries were still producing vaccine, mainly for the use of national defence forces or to stock national emergency reserves.

INVESTIGATION OF SUSPECTED SMALLPOX CASES

"Experience in many countries indicates that reports of suspected cases of smallpox can be expected to be received from many sources for several years after the certification of global eradication. The importance of thorough investigation of these reports, if necessary with laboratory testing, is illustrated by the fact that one such report led to the recognition of human monkeypox. It is also important that public confidence in the fact of eradication should be maintained by thorough and prompt investigation of all reports and disclosure of the results to health officials throughout the world.

Table 28.4. Known national stocks of smallpox vaccine, by WHO region, 1985[a]

[a] Excluding those still producing vaccine.

"Suspected smallpox cases should therefore be investigated by experienced personnel. WHO should provide an effective system to promote, coordinate, and participate in the investigation of suspected smallpox cases. The international smallpox rumour register that was established by WHO in Geneva in January 1978 should be maintained.

"The reward of US$1000 established by the Director-General in 1978 in accordance with resolution WHA31.54 should be discontinued, since global eradication has now been certified.

"*Recommendation (7).* In order to maintain public confidence in the fact of global eradication, it is important that rumours of suspected smallpox, which can be expected to occur in many countries, should be thoroughly investigated. Information should be provided to WHO, if requested, so that it can be made available to the world community.

"*Recommendation (8).* WHO should maintain an effective system to coordinate and participate in the investigation of suspected smallpox cases throughout the world. The international smallpox rumour register should be maintained."

Guidelines for the Management of Suspected Cases of Smallpox

Early in 1981, WHO distributed to all national health administrations a document entitled *Management of suspected cases of smallpox in the post-eradication period* (WHO/SE/80.157 Rev. 1), which provides a practical guide on how to act if a report of a suspected case of smallpox is received. One of the most important pieces of advice given is that vaccination should not be carried out unless a presumptive diagnosis of smallpox has been established, based on an examination by a physician with extensive experience in the clinical diagnosis of the disease and on a laboratory report that poxvirus particles have been demonstrated by electron microscopy. This advice was included because, when the document was being prepared, certain health officials who were not convinced that eradication had been achieved had recommended that vaccination programmes should be undertaken if a suspected case of smallpox were to be reported.

The International Rumour Register

In accordance with recommendations (7) and (8), post-smallpox-eradication surveillance was initiated by the Smallpox Eradication unit in 1980 and is being continued; 131 rumours reported to WHO between January 1980 and December 1986 were investigated with the results shown in Table 28.6. In fact, only a minority of rumours come to the attention of WHO Headquarters, the majority being dealt with at country level without being referred to WHO. In India, for example, about 2000 rumours were investigated and 79 specimens examined virologically between 1980 and 1984.

The main sources of rumours reaching WHO Headquarters have been the general public, tourists, physicians and the mass media. On receiving information of a rumour, WHO Headquarters usually contacts the WHO regional office concerned and requests that an investigation should be undertaken. If the situation is considered to be urgent, WHO Headquarters contacts the informant direct, asking for more details; at the same time it requests the government health services, as well as WHO epidemiologists in the country

or at the regional office concerned, to investigate the rumour. The results of investigations of rumours deemed to be important because of the wide publicity they have received, or for other reasons, are published promptly in the *Weekly epidemiological record*, so that Member States are kept informed.

All these rumours have turned out to be false alarms, thus confirming that there has been no evidence of smallpox anywhere in the world since the declaration by WHO of smallpox eradication in 1980.

In checking rumours reported to WHO, use is made of the diagnostic services provided by the WHO collaborating centres at the Centers for Disease Control, Atlanta, USA, and the Moscow Research Institute for Viral Preparations, Moscow, USSR. All investigations, both by the WHO collaborating centres and by national laboratories, have failed to reveal variola virus in any sample tested.

Nature and sources of rumours reported

As was mentioned above, 131 rumours were reported to WHO Headquarters between January 1980 and December 1986 (Table 28.6). About half the total number of these reports were received between 1980 and 1982; by 1985–1986, only 10 were being reported annually. Experience in India, where most rumours were investigated locally without being referred to WHO, was comparable, the yearly totals of specimens investigated by the smallpox reference laboratory of the National Institute of Communicable Diseases being 30, 16, 8, 10 and 15, respectively, over the period 1980–1984.

Of the 131 rumours reported to Headquarters, about 70% were investigated and the results made known to WHO within 2 months, but delays of up to 6–9 months occurred in some cases. The principal diseases misdiagnosed as smallpox were chickenpox and measles, which had also been the main causes of misdiagnosis before smallpox was eradicated (see Chapter 1). A significant proportion of the rumours arose from inaccurate reporting or recording. Even cholera was sometimes reported as smallpox in the mass media. Human monkeypox was occasionally misdiagnosed as smallpox and reported as such, but these cases have been excluded from the register since they occurred in Zaire, in which the disease has been under special surveillance since 1982 (see below).

Examples of the kinds of rumours reported

Rumours arose from various sources and a wide variety of actions were taken to investigate them. A few examples are given below; others have been described by Khodakevich & Arita (1985).

Rumours circulated by the mass media. The national and international news media were a common source of rumours and occasionally reported outbreaks of smallpox in areas in which epidemics of an infectious disease had occurred and caused several deaths. Expecting to find an increased incidence of infectious diseases in refugee camps and regions affected by famine, reporters sometimes alleged the occurrence of smallpox despite the lack of any supporting evidence. For example, *Newsweek*, on 26 November 1984, carried an article describing the famine situation in Ethiopia, in which it stated: "... Starvation brought other ailments with it, including influenza, measles, tuberculosis, diarrhea, smallpox, ty-

Table 28.6. International rumour register: suspected cases of smallpox reported to WHO Headquarters, Geneva, by WHO region, 1980–1986

WHO region	Number of reports								Results of investigation			
	1980	1981	1982	1983	1984	1985	1986	Total	Chicken-pox	Measles	Skin disease	Erroneous reports by news media
Africa	9	11	5	5	6	5	6	47	18	7	8	14
Americas	3	6	0	4	5	0	1	19	11	1	3	4
South-East Asia	12	4	3	8	8	5	2	42	17	7	2	16
Europe	1	2	0	0	0	0	0	3	3	0	0	0
Eastern Mediterranean	4	3	2	1	2	0	0	12	2	1	2	7
Western Pacific	2	4	0	1	0	0	1	8	3	3	1	1
Total	31	30	10	19	21	10	10	131	54	19	16	42

phus and kwashiorkor . . .". When WHO drew the attention of the editor of the magazine and of health staff in Ethiopia to the erroneous nature of this report, it transpired that there had been cases of measles, but not of smallpox.

Rumours related to variolation. On 18 November 1983, WHO was informed by the Kenyan health services that a suspected case of smallpox had occurred in Kenya in an adult male from Nandi Hill Estate in the Rift Valley Province. The patient was hospitalized on 8 November and died on 15 November, 3 days after developing a papular rash, mainly on the face and limbs. Scab specimens were taken and sent immediately from Nairobi to the WHO collaborating centre at the Centers for Disease Control, Atlanta.

It was noted that the patient, whose vaccination status was not known, had been a traditional healer, perhaps a former variolator who might have inoculated himself with old material still in his possession, but that his 5-year-old son had had chickenpox shortly before the onset of the illness. On 21 December, the collaborating centre in Atlanta informed WHO that herpesvirus particles had been seen in the specimens by electron microscopy, and this information was immediately relayed to the Kenyan health authorities. Virus cultivation on the chorioallantoic membrane gave negative results for smallpox. The prompt reporting and collection of specimens by the Kenyan health services, and the equally prompt laboratory investigation by the WHO collaborating centre, led to the correct diagnosis of this case within a few days of its occurrence.

Scabs on old corpses. Early in 1985 some student archaeologists were engaged in excavating the vaults of a church near Spitalfields, London. One coffin was found to contain the well-preserved remains of a person who had died of smallpox in about 1840. As a precaution, the United Kingdom Health and Safety Executive closed the site and vaccinated the 3 student archaeologists concerned, and "scab" material from the corpse was sent to the WHO collaborating centre in Atlanta. Exhaustive electron microscopic examination there revealed one object that might have been a poxvirus particle but all attempts at cultivation were unsuccessful. Later, Fornaciari & Marchetti (1986) published photographs of objects that they considered to be poxvirus particles on the basis of electron microscopy of material taken from a vesiculopustular eruption on the mummy of a 2-year-old boy who died in Naples in the 16th century. Exhaustive testing in the WHO collaborating centres failed to reveal any infectious virus in samples of this material. Bodies buried in Artic permafrost, referred to in Chapter 30, might pose a greater risk, although very few smallpox victims would have been interred in such places.

Efficacy of the international rumour register

The international rumour register constituted the ultimate level of reference in a system operating primarily at the country or WHO regional office level for the investigation of rumours of smallpox, although it often received rumours direct from a source rather than through the network. This continuing surveillance failed to find any evidence of the recurrence of smallpox anywhere in the world. Had there not been such surveillance by WHO, backed up by special investigations at the WHO collaborating centres, it is highly likely that some rumours would have had significant repercussions, resulting in damage to public confidence in the WHO declaration, and even the initiation of a mass vaccination programme against smallpox. In the event, vaccination was never needed nor was it ever recommended, since no case occurred which satisfied the requirements laid down by the guide to the management of suspected cases of smallpox. The confidence thus built up undoubtedly assisted in ensuring the universal discontinuation of routine smallpox vaccination.

LABORATORIES RETAINING VARIOLA VIRUS STOCKS

"A committee of experts meeting in February 1979 advised the Global Commission that it was necessary for scientific reasons to preserve stocks of variola virus in a few laboratories, but that the position should be reviewed in 1982. In view of the potential danger of reintroduction of smallpox from variola virus stocks held in laboratories, no more than four WHO collaborating centres should be approved as suitable for the storage of and work with variola virus in accordance with WHO safety standards. These WHO collaborating centres should report annually to WHO and their containment facilities should be periodically inspected to ensure that storage is secure and that safe operating conditions are maintained. All other laboratories

should be asked to destroy any stocks of variola virus that they hold, or to transfer them to an approved WHO collaborating centre.

"*Recommendation (9).* No more than four WHO collaborating centres should be approved as suitable to hold and handle stocks of variola virus. A collaborating centre would be approved only if it had adequate containment facilities. Each such centre should report relevant information on its safety measures annually to WHO and be inspected periodically by WHO.

"*Recommendation (10).* Other laboratories should be asked to destroy any stocks of variola virus that they hold, or transfer them to an approved WHO collaborating centre."

Reduction in Number

As early as 1976 the Smallpox Eradication unit began trying to reduce the number of laboratories holding stocks of variola virus (see Chapter 30). This was successful in that the number of such laboratories fell from 75 in 1975 to 7 at the time of the final meeting of the Global Commission in December 1979 (see Chapter 30, Tables 30.6 and 30.7).

A laboratory-associated outbreak of smallpox in Birmingham, England, in 1978 and the declaration of smallpox eradication by the Thirty-third World Health Assembly in 1980 provided a strong incentive for laboratories not actively working with variola virus to destroy their stocks or transfer them to one of the WHO collaborating centres that was equipped with a high-security containment laboratory. By the end of 1981, only 4 laboratories still retained variola virus stocks: one each in South Africa, the United Kingdom, the USSR and the USA. Except for the South African laboratory, all were WHO collaborating centres for the diagnosis of, or research on, orthopoxvirus infections.

Between 1979 and 1982 Dr Keith Dumbell, a member of the Committee on Orthopoxvirus Infections, was engaged in research on variola virus, including the cloning of its DNA, in the biocontainment laboratory at the Centre for Applied Microbiology and Research, Porton Down, England. With the completion of this work in September 1982, all the variola virus stocks held at Porton Down were transferred to the Centers for Disease Control, Atlanta.

BY COURTESY OF J. SPAANDER

JANUARIE 1984 SALUS 3

Smallpox virus destroyed

VARIOLA, that is smallpox isolates contained in 177 vials were destroyed at the P4 high security laboratory at the South African National Institute for Virology in Johannesburg on 9 December 1983.

Previously the deadly virus had been stored in three centres, i.e. the Centre for Disease Control in Atlanta, USA, the Russian Institute for Virus Production in the USSR, and the SA National Institute for Virology. The South African laboratory had been approved and regularly inspected by the World Health Organisation, the last inspection having been in February 1983.

Because research regarding the genotype mapping of the smallpox virus had been completed and it was no longer required for the preparation of vaccine or other research, there was no reason for keeping the virus here any longer.

Normally the virus had been stored at 20°C and in order to destroy all the isolates the vials were placed in an autoclave and submitted to 130°C and 240 kpa for 20 minutes. Copies of all the isolates are, however, still available at the Centre for Disease Control in Atlanta.

The last known natural case of smallpox occurred in October 1977 in Somalia, and in 1980 the WHO declared the world free of the dreaded disease.

Dr The Honourable C V van der Merwe, Minister of Health and Welfare officiated and pressed the button to set the destruction process in motion. It was also done in the presence of Prof Keith Dumbell, an observer and former member of the World Health Organisation Committee on the Global Eradication of Smallpox.

Prof Keith Dumbell, (left) former member of the World Health Organisation Committee on the Global Eradication of Smallpox was present to witness the destruction of all the virus. With him is Dr Bob Swanepoel, Senior Virologist in charge of the P4 Laboratory.

SALUS, JANUARY 1984

Plate 28.4. Destruction of variola virus stocks at the National Institute for Virology, Sandringham, South Africa, on 9 December 1983. The operation was carried out by the Minister of Health and Welfare of South Africa and witnessed by Dr K.R. Dumbell (left), a member of the Committee on Orthopoxvirus Infections and Dr Bob Swanepoel (right), Senior Virologist in charge of the P4 Laboratory.

In South Africa, the National Institute for Virology in Sandringham retained locally isolated strains of variola virus in a high-security biocontainment laboratory, although they had not been used for many years. Because of South Africa's political isolation, the health authorities were afraid that, if the virus were destroyed, they would have difficulties in diagnosing variola virus should any unexpected circumstances occur. However, when cloned preparations of fragments of variola virus DNA (which cannot replicate and are completely safe to work with) were made available to the National Institute for Virology by Dr Dumbell, their anxieties were relieved and the South African government destroyed all virus stocks in December 1983, in the presence of Dr Dumbell (Plate 28.4).

Since the beginning of 1984, stocks of variola virus have been retained only in the WHO collaborating centres in the Centers for Disease Control, Atlanta, USA, and the Moscow Research Institute for Viral Preparations, USSR, each of which possesses a high-security biocontainment laboratory. During 1983, the remodelling of these laboratories was completed, and both were approved by WHO inspection teams for work with variola virus. The retention of these facilities and their associated personnel has been costly, but the governments of the USSR and the USA have continued to provide the necessary support because of their value in examining material from cases of human monkeypox and from suspected cases of smallpox referred to them through the international rumour register.

The stocks held at the Centers for Disease Control include those transferred from the National Institute of Health, Japan; the National Institute of Public Health, Netherlands; the Centre for Applied Microbiology and Research, United Kingdom; the American Type Culture Collection, New York; and the United States Army Medical Research Institute for Infectious Diseases, Frederick, Maryland, USA. In addition to variola virus stocks, the Moscow laboratory holds "white-pox" viruses isolated from animal specimens and from monkeypox virus stocks (see Chapter 30). These virus stocks are regarded as just as dangerous as variola virus and are kept in the containment laboratory under the same security conditions as that virus. The variola virus stocks in Atlanta and Moscow contain strains of variola major and variola minor viruses from most areas in which smallpox has occurred since 1967.

In March 1986 the Committee on Orthopoxvirus Infections reviewed its policy on the retention of stocks of variola virus in the light of the existence of DNA from 5 strains of variola virus cloned in *Escherichia coli* and the current situation in relation to the use of the virus in research and diagnosis. The meeting was attended by senior public health officials from the two countries in which variola virus stocks are currently held—namely, the USSR and the USA. The Committee advised WHO that the cloned DNA would be satisfactory both for assisting diagnosis in any situation in which that might prove necessary and for archival purposes. Since the Committee considered that research work requiring the use of viable variola virus was no longer justified, it recommended that remaining stocks of the virus should be destroyed, and that this recommendation should be widely publicized but not implemented until approval had been

given by an *ad hoc* committee of experts, which it suggested should be convened by WHO (*Wkly epidem. rec.*, 1986b).

Inspection

Since 1978, WHO inspection teams consisting of epidemiologists, virologists and biosafety experts have periodically visited all the laboratories retaining variola virus, in order to determine whether each of them satisfied the relevant WHO requirements. Inspections have been made annually or every second or third year (Table 28.7), a special check-list being used to cover all safety aspects. These inspections have revealed that problems sometimes occur in the efficient operation of biocontainment laboratories, even though the personnel concerned are highly trained.

HUMAN MONKEYPOX

"Human monkeypox is a rare zoonosis that was not recognized until smallpox was eliminated from the area where it occurs. Clinically it resembles smallpox. Human cases can be expected to appear where the ecological conditions are appropriate and perhaps to show some increase as smallpox vaccination ceases and immunity wanes. Because it is caused by a poxvirus distinct from variola virus and has a limited capacity to spread between humans, monkeypox virus does not constitute a threat to the permanence of smallpox eradication. However, it is important that close surveillance of human cases should continue and that further investigation should be made into the natural history of the disease.

"*Recommendation (11).* In collaboration with country health services, WHO should organize and assist a special surveillance programme on human monkeypox, its epidemiology, and its ecology in areas where it is known to have occurred. The programme should continue until 1985, when a further assessment of the situation should be made".

The demonstration that monkeypox virus caused sporadic infections in man was an important scientific discovery directly attributable to the smallpox eradication programme. Consideration of the ecology of the disease indicated that it was not a new, but a newly discovered, one. The implementation of recommendation (11) of the Global Commission constituted the greater part of the post-smallpox-eradication programme. The organization of surveillance is described below and the results of these studies are reported in Chapter 29. Activities relating to human monkeypox were planned by Arita and Ježek, and implemented by the joint efforts of WHO, national staff in western Africa and Zaire, and the WHO collaborating centres.

Epidemiological Surveillance in Zaire

Work in Zaire from 1980 onwards built on the surveillance system established there in the late 1970s (see Chapter 29).

Seminar in Brazzaville, May 1980

A seminar on the surveillance of monkeypox and viral haemorrhagic fevers was held in the WHO Regional Office for Africa, Brazzaville, Congo, in May 1980. Its objective was to devise ways of further strengthening the surveillance of monkeypox and viral haemorrhagic fevers in areas of central and western Africa in which these zoonoses occurred. WHO staff from Geneva and the regional office and delegates from 10 countries in central and western Africa and 2 countries in eastern and southern Africa participated in the seminar, which recommended that the health services of each country should develop special surveillance of these diseases. A document entitled *Procedures for the surveillance and management of monkeypox and viral haemorrhagic fevers* (CDS/80.1) was promptly prepared by WHO and widely distributed, but only 3 cases of monkeypox were reported in 1980 and 8 in 1981.

Health-institution-based surveillance in Zaire

In the summer of 1980, Arita visited Kinshasa, Zaire, to discuss with the health authorities and the staff of the monkeypox programme how to strengthen surveillance activities. A review of the previous 3 years of surveillance in Zaire revealed 2 important findings: (1) most of the cases reported were patients who had visited hospitals or dispensaries seeking medical treatment; and (2) an earlier recommendation that mobile surveillance teams should visit all health stations every 3 months had never been implemented because of limited resources. Furthermore,

African Viral Haemorrhagic Fevers

In addition to smallpox and yellow fever, which were for centuries the commonest viral diseases with haemorrhagic manifestations, several other viral haemorrhagic fevers have been recognized in recent decades (McCormick & Johnson, 1984). All are presumed to be contracted by man from an animal source. Three of them, Ebola virus disease, Lassa fever and Crimean-Congo haemorrhagic fever, occur in central and western Africa. The natural history of Ebola virus, which caused a major outbreak in a hospital in Zaire in 1976, is unknown, and there are many gaps in our knowledge of the ecology of the other two diseases. In the studies planned in Zaire, surveillance for haemorrhagic fever was added to monkeypox surveillance, since the geographical areas in which these diseases have been identified overlap and the methods of investigation are similar. In this way the best use could be made of the sparse resources available in central and western Africa.

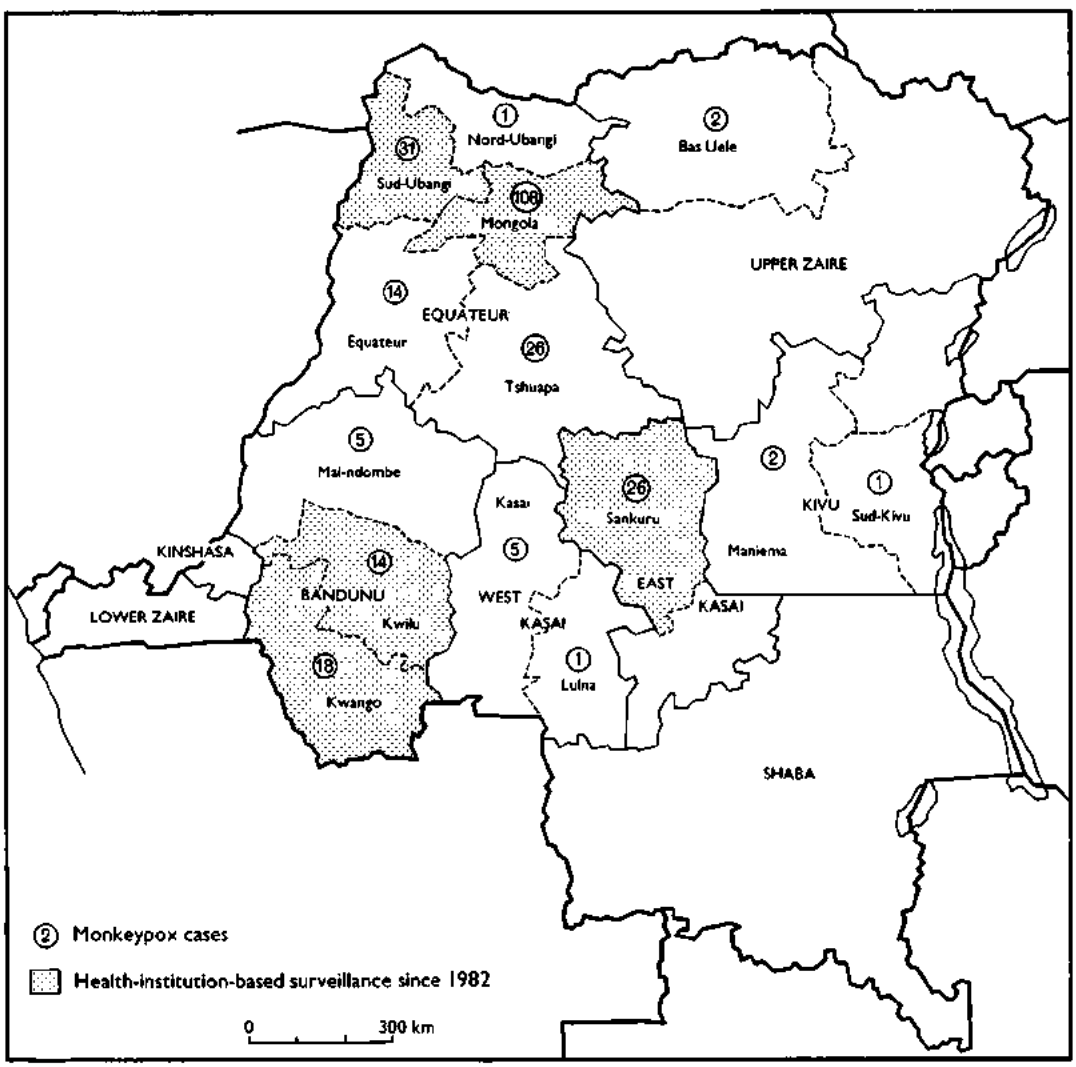

Fig. 28.1. Zaire: subregions where intensive health-institution-based surveillance has been carried out since 1982, and numbers of cases of human monkeypox by subregion, 1970 – 1984.

Health-Institution-Based Surveillance

The idea of using health-institution-based surveillance for human monkeypox in Zaire stemmed from experience in western Africa with Lassa fever. This is a haemorrhagic fever caused by an arenavirus, which was first recognized in a hospital outbreak in Lassa, Nigeria, in January 1969. Outbreaks subsequently occurred in hospitals in several other parts of western Africa, and in the early 1970s it was thought to be a rare zoonosis, which was associated with a case-fatality rate of about 50% when outbreaks did occur. In 1977 a study was commenced in the Kenema District, Sierra Leone, under the direction of Dr Joseph B. McCormick, of the United States Center for Disease Control, to assess the prevalence and importance of Lassa fever. A surveillance system based on the hospital reporting of febrile disease was established, together with a small diagnostic laboratory. Local personnel were trained to take specimens from patients and to investigate any suspected cases of Lassa fever. The system was successful and showed that the disease was a common cause of hospital admission for both adults and children, with several hundred cases occurring annually in the area. The severity of cases varied greatly, with a case-fatality rate of less than 5% among subjects sick enough to report to hospital. The overall case-fatality rate was even lower, since other studies revealed that 6% of a population surveyed in Kenema District had complement-fixing antibodies against Lassa virus while only 0.2% had recognized disease (Fraser et al., 1974).

This experience suggested that health-institution-based surveillance might be a practical method for monitoring the prevalence of a disease in areas in which the infrastructure for public health and preventive medicine was rudimentary.

the mobile teams were frequently used in the control of cholera outbreaks. In the circumstances, health-institution-based surveillance, which was based on the collaboration of hospital and dispensary staff, appeared to be the most promising method of obtaining more information about human monkeypox. The system was concentrated in 4 subregions of 3 regions in northern Zaire, which had extensive areas of tropical rain forest and in which a relatively high incidence of the disease had been observed in 1978 and 1979.

Between December 1980 and November 1981, 4 seminars on monkeypox and viral haemorrhagic fever surveillance were organized by Ježek, in collaboration with Dr Kalisa Ruti, of the Ministry of Health of Zaire, in which medical staff from 154 health institutions participated. The seminars, which brought together all senior staff of health units working within a radius of 250–500 kilometres, were held in Lisala for Mongola subregion (December 1980), in Gemena for Sud-Ubangi subregion (February 1981), in Lodja for Sankuru subregion (June 1981) and in Kikwit for Kwango and Kwilu subregions (November 1981) (see Fig. 28.1). It was the first time in central and western Africa that seminars had been devoted specifically to these newly discovered diseases, with the participation of senior government officials and technical experts. Monkeypox recognition cards, sample collection kits and the document *Instructions for health-institution-based surveillance of monkeypox and viral haemorrhagic fevers* (CDS/80.2) were distributed to participants. It was announced that a reward of 500 zaires (US$90) was to be offered to any person, including health staff, who reported a case of human monkeypox.

Following each seminar, health-institution-based surveillance for human monkeypox and viral haemorrhagic fevers, supported by WHO funds, was developed in each subregion (Fig. 28.1), and by the end of 1981 was functioning effectively in all of them. The selected areas together represented about 15% of the land area of Zaire and contained about 5 million inhabitants—18% of the country's population—among whom 89% of the human monkeypox cases recorded in Zaire up to that time had been detected. Sporadic cases of Ebola haemorrhagic fever were also known to occur in some of the

selected areas. A total of 154 health establishments participated in surveillance activities, including 55 government and missionary hospitals, 62 dispensaries and 37 other health units (health centres and maternal and child health clinics). They were responsible for the discovery, identification and notification of suspected cases of monkeypox or viral haemorrhagic fever as well as the proper collection and dispatch of specimens for laboratory investigation. Their activities were supported by 4 mobile surveillance teams, which provided technical advice and material support. This well-designed and well-supervised surveillance system based on peripheral health units and mobile surveillance teams was supplemented by posting special surveillance officers in 4 areas of epidemiological priority to carry out village-based surveillance and assist in ecological surveys.

The striking increase in the number of monkeypox cases reported in Zaire in 1982 (39 cases) and 1983 (84 cases), as compared with previous years (see Chapter 29, Table 29.3), was due principally to the strengthened health-institution-based surveillance and intensified field activities, since 90% of the cases reported in Zaire in 1982–1983 were detected in areas of strengthened surveillance; and health-institution-based surveillance itself accounted for about 60% of the reported cases. The description of the clinical features and epidemiology of human monkeypox given in Chapter 29 is based on the results obtained by this intensive surveillance in Zaire, supported by laboratory studies in the WHO collaborating centres in Atlanta and Moscow.

Serological survey of unvaccinated subjects

In order to estimate the prevalence of human monkeypox in central and western Africa, serological surveys were conducted on unvaccinated subjects living in tropical rain forest areas of the Congo, Côte d'Ivoire, Sierra Leone and Zaire (see Chapter 29, Table 29.10). These surveys revealed that at least 0.7% of the persons concerned, who lived in areas in which monkeypox could be expected to occur, had specific antibody to it. Follow-up examinations of persons with positive serological findings indicated that over half of them had no history of a vesiculopustular disease or any facial pockmarks. It was concluded that at least some of them had suffered from a subclinical infection with monkeypox virus (see Chapter 29).

Studies on the ecology of monkeypox virus

In 1984–1986, Dr Lev Khodakevich and his collaborators carried out surveys in the Central African Republic and Zaire in order to try to determine the reservoir host of monkeypox virus. These were successful in incriminating squirrels as a significant wild animal host of monkeypox virus in some areas (see Chapter 29).

Review of Monkeypox, March 1986

In its review of the situation in March 1986, the Committee on Orthopoxvirus Infections noted that excellent progress had been made in understanding the epidemiology of human monkeypox and the ecology of monkeypox virus since its third meeting, in 1984. The results of these studies, described in detail in Chapter 29, indicated that human monkeypox was a rare zoonosis in which human-to-human infection sometimes occurred. The Committee concluded that it was now clear that the disease was not a serious public health problem and recommended that WHO involvement in monkeypox surveillance and research should be phased out (*Wkly epidem. rec.*, 1986b).

LABORATORY INVESTIGATIONS

"There are still some important unsolved virological problems that are relevant to smallpox eradication, especially in relation to the "whitepox" viruses. The solution of these problems and preparedness for unexpected problems that might arise in relation to smallpox or other poxvirus diseases of man call for the maintenance of suitable virological expertise.

"Besides encouraging scientists in various nations to continue research on orthopoxviruses, WHO has responsibility for the regular testing of the potency of the WHO vaccine reserves and for the provision of laboratory diagnostic facilities for suspected smallpox cases. It can best discharge this responsibility by continuing the system of WHO collaborating centres. If competent research workers from laboratories not approved by WHO for work with variola and whitepox viruses wish to conduct experiments with these viruses, facilities should, if possible, be provided by a suitable WHO

collaborating centre. These experiments must be approved by the appropriate WHO committee.

"*Recommendation* (*12*). WHO should continue to encourage and coordinate research on orthopoxviruses.

"*Recommendation* (*13*). WHO should maintain the system of WHO collaborating centres for carrying out diagnostic work and research on orthopoxviruses.

"*Recommendation* (*14*). Research workers who do not work in a WHO collaborating centre and who wish to carry out experiments with variola or whitepox virus that are approved by the appropriate WHO committee should be offered the use of the special facilities in a WHO collaborating centre.

"*Recommendation* (*15*). Research on poxviruses other than variola or whitepox viruses should not be performed under circumstances where there is any possibility of cross-contamination with these two agents."

Laboratory Diagnosis of Suspected Smallpox and Monkeypox

Since 1980 the two WHO collaborating centres in Atlanta (Dr James Nakano, director) and Moscow (Dr Svetlana Marennikova, director) have continued the diagnostic testing of specimens collected from suspected cases of smallpox throughout the world, employing for this purpose laboratory workers with extensive experience obtained during the Intensified Smallpox Eradication Programme. In addition to examining material from some of the cases reported to the international rumour register, the centres examined specimens collected from suspected cases of human monkeypox and from other poxvirus infections (tanapox and molluscum contagiosum) in western and central Africa. Between 1980 and 1984, 16 650 specimens were tested (Table 28.8), the majority having been collected during serological surveys for human monkeypox. Requests for viral isolation came mainly from countries in which human monkeypox cases had occurred or were suspected, mostly as part of the special surveillance for human monkeypox described earlier in this chapter and in greater detail in Chapter 29. In addition, 193 requests were received from 28 other countries in connection with suspected cases of smallpox. In no case was variola virus found.

[a] Countries in which monkeypox has been found (Cameroon, Central African Republic, Côte d'Ivoire, Nigeria, Sierra Leone, Zaire).
[b] Includes 8867 specimens of serum from Côte d'Ivoire, Sierra Leone and Zaire collected in serological surveys (see Chapter 29, Table 29.10).
[c] Other countries (i.e., those not mentioned in footnote[a]).
[d] Includes 1433 specimens of serum from the Congo collected in serological surveys (see Chapter 29, Table 29.10).

Continuing Research on Orthopoxviruses

Research problems of importance to WHO in the post-smallpox-eradication era fell into 3 categories: (1) analysis of the DNA of variola virus and other orthopoxviruses; (2) development of sensitive tests to detect antibody specific to monkeypox virus in human and animal sera; and (3) ecological and epidemiological research on the natural history of monkeypox.

Analysis of orthopoxvirus DNA

In June 1979, in view of the fact that the certification of global eradication was imminent, WHO organized a meeting on orthopoxvirus research, which was co-sponsored by the Centers for Disease Control and held in Atlanta (SME/79.9). The objective was to define fields of research relevant to the post-smallpox-eradication era. At that time there was still considerable controversy as to the significance of the "whitepox" viruses that had been isolated in laboratories in the Netherlands (Bilthoven), and the USSR (Moscow). Following discussions at the meeting, collaborative work with personnel from the Bilthoven and Moscow laboratories was carried out by Dr Dumbell at the Centre for Applied Microbiology and Research, Porton Down, and by Dr Joseph Esposito at the Centers for Disease Control. These studies showed that all strains of "whitepox" virus were identical with variola virus and probably originated as laboratory contaminants (see Chapter 30).

Dr Dumbell, Dr Esposito and their colleagues continued to carry out studies on the DNA of various strains of variola and monkeypox viruses, thereby considerably increasing our understanding of these viruses; the results of these studies are summarized in Chapters 2, 29 and 30. Dr Esposito also produced, for the first time, restriction endonuclease maps of the DNA of camelpox, taterapox and raccoonpox viruses, all of which are species of *Orthopoxvirus* (Esposito & Knight, 1985).

Both Dr Dumbell and Dr Esposito cloned variola virus DNA in *Escherichia coli*, rendering it safe to handle in any laboratory. By March 1986, libraries of cloned fragments of the DNA of 2 strains of variola major virus (Harvey and a strain from Bangladesh) and of 3 strains of variola minor virus (2 strains of alastrim virus and a strain from Somalia) were available. At that time, the Committee on Orthopoxvirus Infections suggested that a western African strain should also be cloned, so as to provide a reasonable range of strains of variola virus DNA for archival purposes and for scientific research. It was because this material was or would be available that the Committee recommended the destruction of the remaining stocks of viable variola virus (see below).

Development of tests for antibody specific to monkeypox virus

The genus *Orthopoxvirus* includes 9 known species, of which 3 (vaccinia, monkeypox and taterapox viruses) or possibly 4 (with Uasin Gishu disease virus, an orthopoxvirus that affects horses in Kenya) occur in western and central Africa. All species of *Orthopoxvirus* show extensive serological cross-reactivity. Methods existed for making presumptive species-specific diagnoses of infections with monkeypox, variola and vaccinia viruses by tests on sera absorbed with viral suspensions, but their use with sera from healthy animals or man taken during ecological or epidemiological surveys gave uncertain results. It was therefore difficult to evaluate the significance of the large number of orthopoxvirus-positive sera obtained in ecological surveys in Zaire in 1979 and earlier (see Chapter 29). Consequently, there was an urgent need for a sensitive test for monkeypox-specific antibodies which could be used with sera collected during ecological and epidemiological surveys to support surveillance and field studies of human monkeypox. Such a test would also help to determine the extent of subclinical and person-to-person infection with monkeypox virus.

Several steps were taken to try to solve this problem. In 1981 Dr W. K. Joklik, of Duke University Medical Center, Durham, North Carolina, USA, attempted to develop a radioimmunoprecipitation test for the identification of monkeypox-specific antibody, but without success. Monoclonal antibodies that reacted with monkeypox virus but not with certain other orthopoxviruses were developed by Dr Y. Ichihashi in Dr Joklik's laboratory, and at the WHO collaborating centre in Atlanta, in 1983. Subsequently Dr Ichihashi continued work on monoclonal antibodies at Niigata University, Japan, with financial assistance from WHO; he developed a number of monkeypox-specific and vaccinia-

specific monoclonal antibodies and an antigen-binding inhibition test that could be used with certain sera to detect monkeypox-specific antibodies. However, at the time of writing this test requires further development.

Fortunately, in 1985 Dr Nakano developed modifications of the radioimmunoassay adsorption test which made it possible to evaluate the significance of some of the orthopoxvirus antibody-positive animal sera collected in Zaire in 1979 (see Chapter 29).

Other Studies of Variola and "Whitepox" Viruses

Recommendation (14) envisaged the possibility that workers in laboratories other than the two WHO collaborating centres might wish to work with variola or "whitepox" viruses, but no such requests have been made.

Recommendation (15), designed to minimize the possibility of laboratory contamination with variola virus, has been rigorously observed in both WHO collaborating centres.

DOCUMENTATION OF THE SMALLPOX ERADICATION PROGRAMME

"The eradication of smallpox is a unique event in human history and a signal achievement of WHO. It should be fully documented by the publication of a comprehensive book. Further, it is essential for future historians that all relevant documents covering matters of scientific, operational, or administrative interest should be catalogued and preserved in suitable archives. The feasibility of distributing copies of this archival material to several centres, perhaps as microfiche, should be explored.

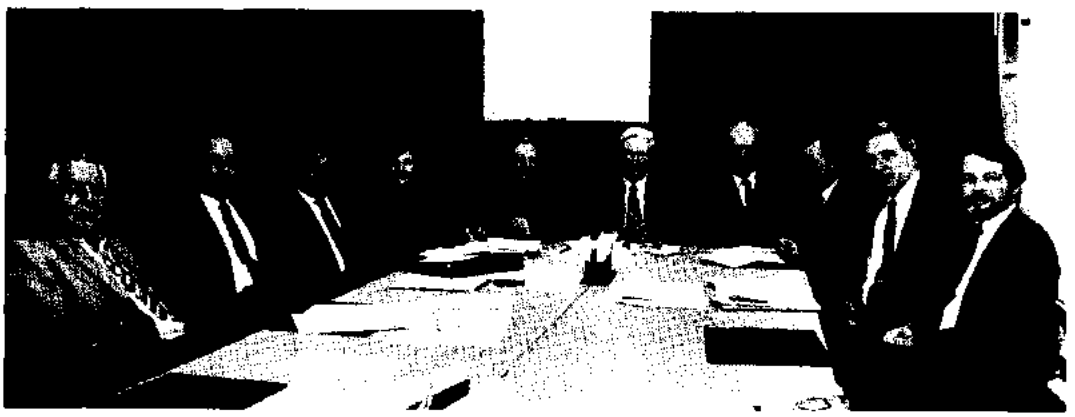
"It is important that the experiences of the smallpox eradication programme that are applicable to other health programmes should be defined and elaborated, in order to help public health officials develop strategies and tactics for the conduct of other programmes, especially those for the control of infectious diseases. However, the problem is complex since the lessons learnt from the smallpox eradication programme need to be evaluated in each instance by the health programme to which they may be applied.

"*Recommendation (16)*. WHO should ensure that appropriate publications are produced describing smallpox and its eradication and the principles and methods that are applicable to other programmes.

"*Recommendation (17)*. All relevant scientific, operational and administrative data should be catalogued and retained for archival purposes in WHO headquarters and perhaps also in several centres interested in the history of medicine."

Publications

Planning for a comprehensive publication on all aspects of smallpox and recording its eradication had in fact begun in 1979 before recommendation (16) was made, and work on the present book started early in 1980. In addition, the WHO Regional Office for



WHO / T FARKAS

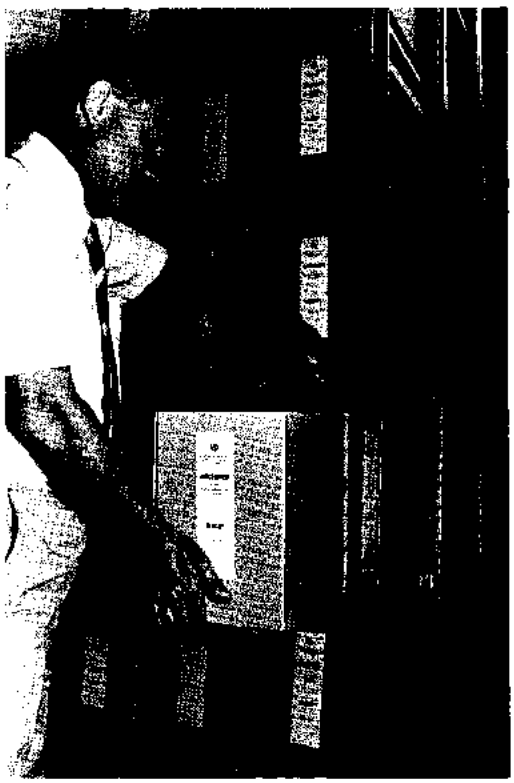
Plate 28.5. Participants in the seventh meeting of the Editorial Board for *Smallpox and its Eradication*, 26 March 1986. *Left to right:* **A.D. Loveday (WHO)**, K. Wynn (WHO), **I. Arita (Japan)**, N. Henderson (USA), S.M. Deck (WHO), **F. Fenner (Australia), I.D. Ladnyi (USSR), Z. Ježek (WHO), D.A. Henderson (USA)**, J.F. Wickett (WHO). The names of the Board members are in bold type.

South-East Asia published books dealing with the eradication programmes in India (Basu et al., 1979) and Bangladesh (Joarder et al., 1980); the government of Somalia and WHO jointly published the account of the programme in Somalia (Ježek et al., 1981); and the government of Ethiopia and the WHO Regional Office for the Eastern Mediterranean did likewise for the programme in Ethiopia (Tekeste et al., 1984). WHO also assisted in the preparation of a book dealing with the management aspects of the programme in India (Brilliant, 1985).

Recommendation (16) has also been implemented by the publication in WHO periodicals and elsewhere of numerous articles on smallpox and its eradication written by WHO staff and by other persons who were concerned with the eradication campaign. Reference to these is made throughout this book.

The Smallpox Eradication Programme Archives

The smallpox eradication programme records were put in order by a professional archivist specifically employed for the purpose in 1981–1982. All WHO records prior to 1981 are now catalogued and indexed; they occupy 400 large boxes, which are stored in the Organization's archives at WHO Headquarters. Additional material, much of it voluminous and not available elswhere, has accumulated since 1981. The Committee on Orthopoxvirus Infections suggested that it be added to the permanent archives.



WHO / M. VAN APPELGHEM

Plate 28.6. Archives of the smallpox eradication programme in WHO Headquarters, Geneva, being consulted by Ježek.

WHO HEADQUARTERS STAFF

"The foregoing recommendations cannot be carried out successfully without central coordination, which should be provided at WHO headquarters. Since it is expected that the Global Commission for the Certification of Smallpox Eradication will be dissolved after the World Health Assembly in 1980, another mechanism is needed to enable the headquarters staff to obtain advice and assistance from scientists. This could be achieved by setting up a committee on orthopoxvirus infections.

"*Recommendation (18).* An interregional team consisting of not less than two epidemiologists with past experience in the smallpox eradication campaign, plus supporting staff, should be maintained at WHO headquarters until at least the end of 1985. At least one additional field officer should be assigned to cover areas where human monkeypox is under investigation.

"*Recommendation (19).* WHO should set up a committee on orthopoxvirus infections."

Staff Arrangements at WHO Headquarters

The Smallpox Eradication unit, headed by Arita until March 1985 and then by Ježek, remained in being up to the end of 1987 with the requisite number of staff, including at various times Ježek (1980–1987), Dr A. Gromyko (1980–1983) and Dr L. Khodakevich (1983–1986) as medical officers, Mr J. Wickett (1980–1987) as consultant and Mrs S. Woolnough (1980–June 1985) as secretary. This unit, with its name unchanged, supervised the implementation of all the foregoing recommendations of the Global Commission, maintained the international rumour register, participated in the monkeypox studies in Zaire and in the preparation of publications, and organized meetings of the Committee on Orthopoxvirus Infections.

L. KHODAKEVICH, 1979

Plate 28.7. Alexander Gromyko (b. 1937), a physician from the USSR, worked for the Intensified Smallpox Eradication Programme as a WHO consultant in India in 1975 and then became a medical officer in the Smallpox Eradication unit (1977–1983). He participated in the monkeypox surveys in western Africa and in the investigation of rumours of smallpox reported to WHO.

Committee on Orthopoxvirus Infections

A group of experts, all former members of the Global Commission, met in Geneva from 3 to 5 February 1981 to discuss the implementation of the post-smallpox-eradication policy. Subsequently the Director-General of WHO appointed this group as the WHO Committee on Orthopoxvirus Infections, with Fenner as chairman. In 1984, all 6 members were appointed for a second term of 2 years.

The Committee met annually and reviewed the situation in relation to all aspects of post-eradication activities (Global Commission recommendations 1–19). In 1984 the Committee undertook a comprehensive review of the human monkeypox programme, published a report on current knowledge of the disease (*Bulletin of the World Health Organization*, 1984), and made recommendations for future activities (WHO/SE/84.162). In 1986 it reviewed the operation of the post-smallpox-eradication programme and made recommendations on all its aspects. The Committee's report was published (*Wkly epidem. rec.*, 1986b) and widely circulated; its recommendations have been discussed in the relevant sections of this chapter.

USE OF VACCINIA VIRUS AS A VECTOR FOR FOREIGN GENES

The 19 recommendations made by the Global Commission in December 1979 effectively covered all aspects of orthopoxvirus infections then known to be important in the post-smallpox-eradication era. However, within 6 months, one of the members of the Global Commission, Dr K. R. Dumbell (Sam & Dumbell, 1981) discovered—and this was independently confirmed in the USA (Nakano et al., 1982)—that cells could be "transfected" with fragments of DNA from one orthopoxvirus, and that these fragments could be rescued by recombination when the cell was infected with another orthopoxvirus. It was only a short step from this to the insertion of genes coding for antigens inducing an immune response against one or more of a variety of pathogens into plasmids in such a way that they recombined with vaccinia virus. The hybrid viruses thus produced were found to express antigens whose genes had been inserted in this way, and animal experiments showed that vaccination with them conferred protection against the infections concerned. This opened up the possibility that genetically engineered vaccinia virus might be used for immunization against a wide variety of protozoal, bacterial and viral diseases (Brown et al., 1986). WHO established a Scientific Advisory Group of Experts in 1984 to guide the work of a new Programme on Vaccine Development in which developments in the use of vaccinia virus are being monitored, together with the application of genetic engineering in the production of new vaccines.

INTRODUCTION

Human monkeypox was first recognized in 1970; it is a severe systemic disease with a generalized pustular rash, clinically indistinguishable from smallpox. In addition to variola and monkeypox viruses, 7 other species of poxvirus, of 4 genera, can cause lesions in man (Table 29.1). Although infection with each of these viruses produces at the most mild symptoms and usually only a localized skin lesion, the diseases in question presented a potential diagnostic problem during the global eradication of smallpox, since virus particles found in lesions by electron microscopic examination could be confused with those of variola virus. Because of its importance, monkeypox is the main subject of this chapter, but a brief description is given of each of the other poxvirus infections of man.

Table 29.1. Poxvirus infections of man

Genus and infection	Skin lesions in man	Severity of systemic symptoms	Host range in laboratory animals	Known reservoir hosts in nature
Orthopoxvirus				
Variola	Generalized	+++	Narrow	Man
Monkeypox	Generalized	+++	Broad	Squirrels, monkeys
Cowpox	Localized	+	Broad	Rodents
Vaccinia	Localized (very rarely, generalized)	+	Broad	Buffaloes[a]
Parapoxvirus				
Pseudocowpox	Localized	–	Narrow	Cattle
Bovine papular stomatitis	Localized	–	Narrow	Cattle
Contagious pustular dermatitis	Localized	–	Narrow	Sheep
Unclassified				
Molluscum contagiosum	Generalized	–	Narrow	Man
Tanapox	Localized	+	Narrow	Monkeys

[a] In 1984–1986, several years after the cessation of vaccination, epizootics of buffalopox were reported in several parts of India, and humans were infected. The virus involved was shown to be vaccinia virus (K. R. Dumbell, personal communication, 1986).

MONKEYPOX IN CAPTIVE PRIMATES

Monkeypox virus was discovered in 1958, when it was isolated from the lesions of a generalized vesiculo-pustular disease among captive monkeys at the State Serum Institute, Copenhagen (Magnus et al., 1959). It was apparent that if an animal reservoir of variola virus existed the eradication of smallpox would be impossible (see Chapter 10). The close resemblance between smallpox and monkeypox in captive primates focused attention on monkeypox virus as a potential threat to smallpox eradication (Arita & Henderson, 1968). WHO therefore contacted laboratories in Europe and North America which used monkeys (27 in 1968 and 51 in 1970; Arita et al., 1972), inquiring about the occurrence of monkeypox and asking specifically whether any infections had occurred among laboratory workers or animal handlers. The ensuing investigations revealed 4 other reported outbreaks and 4 hitherto unreported outbreaks in primates (Table 29.2), but there were no reports of infection in humans. Monkeypox virus was recovered in 6 of these episodes. All except episode 3 occurred in Asian monkeys, although in some outbreaks African primates (and, in episode 2, New World monkeys) were also infected.

The circumstances of these outbreaks have been summarized by Arita et al. (1972). One episode described in their paper, but omitted from Table 29.2, calls for special comment—namely, the observation made by Gispen & Kapsenberg (1966) of the National Institute of Public Health in Bilthoven, Netherlands, that monkeypox virus had been recovered from normal cynomolgus kidney cell cultures. Subsequent examination of the laboratory records led Dr J. G. Kapsenberg (personal communications, 1980, 1983) to decide that this isolation was probably due to inadvertent laboratory contamination of the culture with monkeypox virus, which had been isolated in the same laboratory at about this time from animals infected in the Blijdorp Zoo outbreak (episode 2).

Seven of the 9 outbreaks of monkeypox in captive monkey colonies between 1958 and 1968 occurred in monkeys shipped from Asia, leading to the suspicion that the reservoir of monkeypox virus was probably located in that continent. However, collaborative serological surveys organized by WHO failed to detect orthopoxvirus antibodies in over 1000 monkey sera collected in India, Indonesia, Japan and Malaysia (Arita et al., 1972). After the discovery of human monkeypox in Africa in 1970 (see later in this chapter), sera were collected from monkeys and other animals in Zaire and several countries of western Africa. Monkeypox-virus-specific antibodies were demonstrated in sera from 8 species of monkey and 2 species of squirrel, and monkeypox virus was recovered from the organs of a squirrel (see below).

Although primates from Asia, Africa and South America (and an anteater from the last-mentioned area) experienced infections with monkeypox virus in captivity, there is no evidence that the virus occurs naturally anywhere except in Africa. During the period 1958–1968 large numbers of primates were being imported into Europe and North

Table 29.2. Outbreaks of monkeypox in captive primates[a]

Country	Episode and reference	Virus isolation[b]	Date	Species affected	Origin	Interval after arrival
Denmark	1(a). Magnus et al. (1959)	+	30 June 1958	Cynomolgus	From Singapore by air	62 days

[b] .. = data not recorded.

America from Asia, and smaller numbers from western Africa, mainly for the manufacture and safety testing of poliomyelitis vaccines. At that time the conditions under which monkeys were moved from their place of capture in Asia or Africa to the recipient laboratory in Europe or North America presented many opportunities for them to be infected with agents carried by other wild animals or by man while in transit (Kalter & Heberling, 1971). The cessation of outbreaks after 1968 can be ascribed to improved conditions in the shipment of primates at about that time and the much more extensive use by laboratories of monkeys bred in captivity in Europe and North America.

The clinical features of naturally occurring cases in cynomolgus monkeys have been described by Magnus et al. (1959) and Sauer et al. (1960). No signs are detected until the rash appears, usually as a single crop of discrete papules over the trunk and tail and on the face and limbs, being particularly abundant on the palms of the hands and the soles of the feet (Plate 29.1). The papules become vesicular and then pustular and are often umbilicated. Scabs develop and fall off 7–10 days after the onset of rash, leaving small scars. Circular discrete ulcers about 2 mm in diameter often occur in the oropharynx.

The severity of symptoms varied among the several different primate species infected in the outbreak of the Blijdorp Zoo in Rotterdam (episode 2, Table 29.2). All the species suffered from a generalized disease characterized by pocks on the skin, lips and mucous membranes. Orang-utans were particularly susceptible, several dying in the acute viraemic stage, before the skin lesions were fully developed.

Plate 29.1. Generalized lesions of monkeypox in a cynomolgus monkey. **A:** Acute stage; pustules on the leg and sole of the foot. **B:** Convalescent stage; healing pustules and scars. (From Magnus et al., 1959.)

THE PROPERTIES OF MONKEYPOX VIRUS

In Chapter 2 the biological characteristics of monkeypox virus have been enumerated together with those of other orthopoxviruses (Table 2.3), and the restriction endonuclease map of monkeypox virus DNA has been compared with the corresponding maps of DNAs of other species of *Orthopoxvirus* (Fig. 2.6, 2.7 and 2.9).

Pathogenicity for Laboratory Animals

Monkeypox virus has a broad host range and infects most of the common laboratory animals, producing moderate-sized haemorrhagic pocks on the chorioallantoic membrane and a large indurated swelling with a haemorrhagic centre after intradermal inoculation into rabbits (see Chapter 2, Plates 2.5 and 2.6). It produces lytic plaques in most kinds of cultured cells, but unlike variola virus, it does not grow in pig embryo kidney cells when first cultured in them, although adaptation occurs quickly.

Comparison of DNA Maps of Strains of Monkeypox Virus

Esposito & Knight (1985) analysed the DNA of 12 strains of monkeypox virus, 4 recovered from outbreaks in laboratory primates in Europe and North America and 8 from human cases in 4 countries in central and western Africa. The physical map locations of the sites of cleavage by the restriction endonuclease *Hin*dIII for the DNA of these strains of monkeypox virus, and the DNA of 2 strains each of variola and vaccinia viruses, are compared in Fig. 29.1.

As has been shown in the other comparisons described in Chapter 2, the DNAs of all strains of monkeypox virus are clearly different from those of both variola and vaccinia viruses. However, the monkeypox virus

The Nomenclature of Poxvirus Diseases

For centuries it has been traditional to name poxvirus diseases after the animals in which they were first observed—for example, cowpox, horsepox, sheep-pox and fowlpox. The practice has continued in more recent times with the use of the terms monkeypox, rabbitpox, buffalopox, elephantpox virus to designate the viral agents recovered from infections of the animals concerned. Some of these designations are misleading. Thus it now appears that "cowpox" virus is primarily a disease of rodents, which has a wide host range and occasionally infects cows, cats, zoo animals and man. Rabbitpox and buffalopox are caused by strains of vaccinia virus, propagated in series in rabbits and buffaloes respectively. And although African monkeys are infected in nature with monkeypox virus, and may indeed be an important source of infection of humans, they are probably sentinel animals, only occasionally infected with this virus, rather than its principal reservoir host.

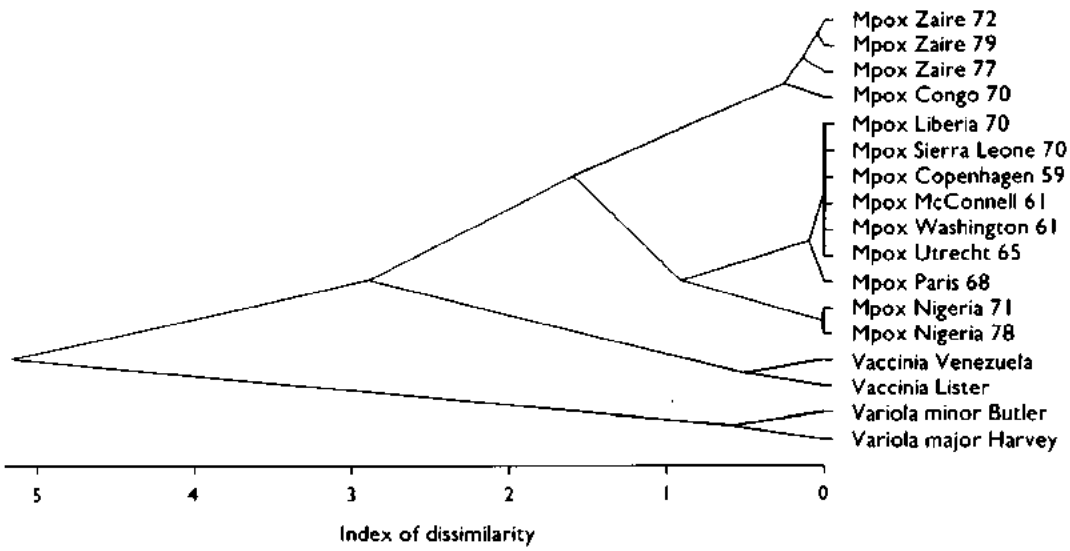

Fig. 29.1. Dendrogram illustrating the similarities and differences between the *Hin*dIII cleavage sites of the DNAs of 12 strains of monkeypox (Mpox) virus (McConnell and Washington are different passages of the same strain), 2 strains of vaccinia virus and 2 strains of variola virus. Presence, absence or impossibility of cleavage sites were analysed as described by Gibbs & Fenner (1984) using the squared Euclidean metric (number of attributes = 36). (Data from Esposito & Knight, 1985.)

DNAs cluster into 2 groups, according to the geographical origins of the specimens, rather than the animal of origin (man or monkey) or the year of isolation. The upper group of 4 in Fig. 29.1 are strains from human cases occurring in Zaire. The lower group consist of human isolates from 3 countries in western Africa—Nigeria, Liberia and Sierra Leone—and isolates from outbreaks in captive monkeys between 1959 and 1969. It is probable that all the outbreaks in captive monkeys (see Table 29.2) originated from western Africa rather than Zaire, since exports of monkeys from Africa in the late 1950s and during the 1960s were from western African countries.

Genetic Studies

Like other orthopoxviruses that produce haemorrhagic pocks on the chorioallantoic membrane, monkeypox virus produces white pock mutants. These were first observed by Bedson (1964) and first reported by Gispen &

Brand-Saathof (1972). They were shown closely to resemble the parental monkeypox virus in tests for species-specific antigen (Gispen et al., 1976) and intracellular polypeptide patterns (Harper et al., 1979).

Subsequently it was reported that variants called "whitepox" viruses, which resembled variola virus by all biological tests, could be recovered from certain laboratory stocks of monkeypox virus, either by passage in hamsters (Marennikova & Shelukhina, 1978) or by inoculation on the chorioallantoic membrane (Marennikova et al. 1979). This initially raised important questions about a possible animal reservoir of variola virus, but these were subsequently discounted. By about 1982 accumulating evidence had convinced most laboratory workers that the "whitepox" viruses were in fact strains of variola virus inadvertently introduced as laboratory contaminants (see Chapter 30).

Species Diagnosis

The biological characteristics used to identify monkeypox virus and, in material derived from human cases, to distinguish it from variola virus, are the haemorrhagic pock and high ceiling temperature on the chorioallantoic membrane, the production of a large haemorrhagic lesion after intradermal inoculation in rabbits, its wide host range and its failure to grow in pig embryo kidney cells when first inoculated into these cells. The DNA map is characteristic of the species, but can be used to distinguish western African from Zairian strains.

Serological Diagnosis of Past Monkeypox Infection

An understanding of the ecology of monkeypox virus depends either on the isolation of virus from animals captured in the field or on serological surveys for monkeypox-virus-specific antibodies. The isolation of virus from animals captured in the field is likely to be a rare event in orthopoxvirus infections, in which persistent infection does not occur, and in fact only one such isolation has been made (see below).

During the 1970s methods had been developed that enabled species-specific diagnoses of recent infection with monkeypox, vaccinia and variola viruses to be made with hyperimmune or other highly potent sera, by adsorption with appropriate viral suspensions and tests for residual antibody by gel precipitation (Gispen & Brand-Saathof, 1974), immunofluorescence (Gispen et al., 1976), radioimmunoassay (Hutchinson et al., 1977), and enzyme-linked immunosorbent assay (ELISA) (Marennikova et al., 1981) (see Chapter 3). For these tests, rather large quantities of high-titre serum were required, and for the radioimmunoassay adsorption test employed by the WHO collaborating centre in the Centers for Disease Control in Atlanta, GA, USA, antibodies to the gammaglobulin of the relevant species were thought to be necessary, which were available for monkeys but not for other species of wild animals.

However, as a result of experience with sera from persons known to have human monkeypox, some of whom had been vaccinated years earlier, Dr J. H. Nakano (personal communication, 1984) developed criteria that allowed a positive or presumptive diagnosis of monkeypox to be made in most suspected cases involving human sera. In mid-1985, Dr Nakano and Mrs Donna Miller (personal communication, 1986) developed a method of carrying out radioimmunoassay adsorption tests with sera from squirrels and some other species of wild animals, using staphylococcus A protein instead of a species-specific anti-gammaglobulin. This made it possible to test many animal sera from the field and has helped to elucidate the ecology of monkeypox virus.

HUMAN MONKEYPOX

Discovery of Human Infections

The first case of human monkeypox was found in the Basankusu Hospital, Equateur Province, Zaire (Ladnyj et al., 1972). The Basankusu Zone covers an area of about 20 000 square kilometres and in 1970 had an estimated population of 62 000, mostly primitive farmers and hunter-gatherers living in small villages in dense tropical rain forest. The last known outbreak of smallpox in Basankusu Zone occurred in 1968 and comprised 70 cases with 18 deaths. Several suspected cases of smallpox were treated at the hospital in 1969, but none was confirmed. Two suspected cases were reported in 1970; one of these turned out to be chickenpox, and the other was the first case of human monkeypox to be detected. The patient, a 9-month-

old boy, became ill with fever on 22 August 1970 and a rash developed 2 days later. He was admitted to hospital on 1 September, the 9th day of the rash, which had the characteristic centrifugal distribution of smallpox. Crusts were collected for laboratory examination and sent through WHO in Geneva to the WHO collaborating centre in the Moscow Research Institute for Viral Preparations, USSR. The patient recovered and was about to be discharged, but on 23 October he developed measles (acquired while in hospital) and died 6 days later.

During 1970 the WHO collaborating centre in Moscow had received a number of specimens from various provinces of Zaire (but not from Equateur Province) from which variola virus had been recovered. The virus from Basankusu Hospital produced pocks on the chorioallantoic membrane that were quite different from those of variola virus. More detailed studies of this isolate, including inoculation in rabbit skin, showed that it was monkeypox virus (Marennikova et al., 1972a). Investigations of the epidemiological circumstances of the patient by Ladnyi and Dr P. Ziegler in 1971 revealed that the child was the only unvaccinated member of his family, and that there had been no other cases of fever with rash recently in the village concerned or in neighbouring villages. Such an isolated case was most unlikely to be smallpox.

The discovery of human monkeypox in central Africa in September 1970 was followed by the demonstration that 4 cases of suspected smallpox in Liberia and 1 case in Sierra Leone in 1970, and 1 each in Nigeria and Côte d'Ivoire in 1971 (Foster et al., 1972) were cases of human monkeypox (Lourie et al., 1972). A series of coordinated laboratory and field studies was organized to determine the incidence of the disease, to study its clinical features and epidemiology and to search for the animal reservoir or reservoirs of the virus.

Organization of Laboratory Research

In order to obtain guidance on what further research might be undertaken on the

Recognition of Human Monkeypox in Central and Western Africa

Virologists interested in the poxviruses had known since 1959 that monkeypox virus could cause a generalized disease resembling smallpox in cynomolgus monkeys, and in the 1960s similar cases were recognized among other species of monkeys and in anthropoid apes. Although animal handlers had been exposed to risk during the several outbreaks among laboratory and zoo primates during the 1960s, there was at this time no indication that monkeypox virus would infect humans.

At the first meeting of the WHO Informal Group on Monkeypox and Related Viruses, in Moscow in March 1969, the experts agreed that the first indication that virus recovered from a skin lesion might be monkeypox virus would be the haemorrhagic appearance of the pocks produced on the chorioallantoic membrane after 3 days' incubation at 35 °C.

On 23 September 1970 Dr S. S. Marennikova, Dr E. M. Shelukhina and Dr N. N. Maltseva, of the WHO collaborating centre in Moscow, recovered a virus on the chorioallantoic membrane from material sent from a patient in Zaire. When examined after incubation for 2 days, the pocks were "perfectly typical" of variola virus. However, after another day's incubation at 35 °C, there was some haemorrhage around the pocks, a feature never seen with variola virus and characteristic of monkeypox virus. Further tests showed that, like monkeypox virus and unlike variola virus, the Zaire isolate produced large lesions in the rabbit skin.

Meanwhile, a diagnosis of variola virus had been made in the WHO collaborating centre in Atlanta with material obtained from 2 cases of smallpox-like disease discovered in different parts of Liberia in mid-September. This diagnosis caused great concern, since Liberia was thought to have been free of smallpox since 1969. Having learned of the occurrence of human monkeypox in Zaire, Henderson suggested to the WHO collaborating centre in Atlanta that the Liberian isolates should be carefully examined by appropriate tests to see whether they might be monkeypox virus. The Liberian isolates, and subsequent isolates from Sierra Leone and Nigeria, were then found to have the characteristics of monkeypox virus (Lourie et al., 1972).

Arrangements were made for further examination of both the Zaire and the Liberian isolates by Dr Keith Dumbell in London and Dr Rijk Gispen in Bilthoven, as well as in the WHO collaborating centres in Atlanta and Moscow. Work on these isolates formed the main topic of discussion at the second meeting of the Informal Group on Monkeypox and Related Viruses in February 1971. The experts attending that meeting agreed that these isolates were indeed monkeypox virus. This conclusion was a source of considerable relief, since it excluded the possibility that smallpox had been recurring in the most unlikely epidemiological situations; yet it also caused some concern, in that a new generalized orthopoxvirus disease of man had been discovered, the public health importance of which was unknown.

problem of monkeypox and to find out whether there was any evidence of an animal reservoir of variola virus, the WHO Smallpox Eradication unit organized informal discussions on monkeypox virus studies among a group of virologists, which met first in Moscow from 26 to 31 March 1969. These experts agreed that monkeypox virus could be readily distinguished from variola and vaccinia viruses by its biological characteristics, and further studies were planned on its morphology and behaviour in experimentally infected primates, and on the use of serological tests to determine its geographical distribution.

The discovery of human monkeypox, and the subsequent reports that a variola-like virus ("whitepox" virus) had been recovered from the organs of animals captured in areas of Africa in which human monkeypox cases had occurred (see Chapter 30), clearly called for expert advice from virologists. Further meetings of the Informal Group on Monkeypox and Related Viruses were therefore arranged. In all, 5 more meetings were held, in 1971, 1973, 1976, 1978 and 1979, and were

attended by a total of 32 scientists from laboratories in 10 countries, including the WHO collaborating centres in Atlanta and Moscow as well as other collaborating centres conducting poxvirus research, in Bilthoven, Birmingham, London, Paris and Tokyo. In addition, field workers from 5 countries in central and western Africa and representatives from the WHO Regional Office for Africa, in Brazzaville, Congo, attended some of the meetings. Laboratory research on monkeypox, variola and "whitepox" viruses was carried out in the laboratories of the scientists who attended the meetings, sometimes with financial assistance from WHO.

Organization of Field Research

To determine the most effective way of conducting the field research, the Smallpox Eradication unit organized a coordination meeting of representatives from central and western African countries in the WHO Regional Office for Africa, in October 1976, to assess the epidemiological situation in relation to human monkeypox, to draw up procedures for field surveys and to assess the sensitivity of epidemiological surveillance. It was clear from the data presented at this meeting that the best surveillance programme was that conducted in Zaire, the only country in the region in which smallpox surveillance had been maintained until eradication was certified in 1977 (see Chapter 25). Following a recommendation of the coordination meeting, an intensive surveillance programme was set up under the leadership of Dr Kalisa Ruti of the Ministry of Health of Zaire and Mr M. Szczeniowski, a WHO technical officer, in a geographically limited area in the northern part of Zaire (Equateur Region, Mongala Subregion), in which a high concentration of human monkeypox cases had been observed.

This activity was extended in 1979–1980; and in May 1980 the Thirty-third World Health Assembly accepted the recommendation of the Global Commission for the Certification of Smallpox Eradication that further research was needed to determine the public health importance of human monkeypox. Field activities in Zaire were strengthened (see Chapter 28), and laboratory support was provided by the WHO collaborating centres in Atlanta and Moscow. The description in the following pages of the clinical features and epidemiology of human monkeypox and the ecology of monkeypox virus is based on these studies, carried out over approximately a decade but most intensively in the years 1982–1986.

Incidence and Distribution

Just over 400 cases of human monkeypox were reported between 1980 and 1986, all of which occurred in tropical rain forest areas of central and western Africa. At the time of writing, detailed analyses were available of the 283 cases reported between 1970 and 1984 (Fig. 29.2; Table 29.3). Of these, 89% were in small villages (under 1000 inhabitants) and 10% in larger villages (1000–5000 inhabitants); only 3 cases were reported in towns of over 5000 inhabitants. Even the last-named population groups had ample opportunities for direct contact with animals killed in the rain forests.

Between 1972 and 1981, the cases reported from Zaire greatly outnumbered those reported from any other country (Table 29.3), probably because the number of people living in villages in tropical rain forests is much larger there. From 1982 onwards many more cases were reported from Zaire than in previous years. This was partly due to the intensive surveillance system that had been developed in enzootic foci in that country,

but there appears to have been a real increase in the incidence in 1983 and 1984. The reason for this increase is still uncertain. It may have been attributable in part to the fact that there were many more unvaccinated children than in earlier years, and in part, perhaps, to fluctuations in the extent of infection in the animals from which human infections were acquired.

Clinical Features

A description of the clinical features of human monkeypox based on 47 cases diagnosed up to the end of 1979 (Breman et al., 1980) needs little revision in the light of experience since then (Arita et al. 1985). Clinically, human monkeypox closely resembles discrete ordinary-type or, occasionally, modified-type smallpox, as described in Chapter 1. No case has yet been seen, among the cases diagnosed in the years 1970–1984, with confluent lesions on the face, nor has any case comparable to flat-type or haemorrhagic-type smallpox been diagnosed. The obvious clinical feature that differentiates human monkeypox from smallpox is the pronounced lymph-node enlargement seen in most cases of monkeypox (Plates 29.4 and 29.5), sometimes only in the neck or inguinal region, but more often generalized. Lymph-node enlargement occurs early, and has often been observed at the time of onset of fever, usually 1–3 days before the rash appears. Lymph-node enlargement was observed in 90% of 98 cases in which its presence or absence was recorded and was a presenting sign, preceding the rash, in 65% of these cases.

The eruption begins after a prodromal illness lasting 1–3 days, with fever, prostration and usually lymph-node enlargement. As with smallpox, the lesions develop more or less simultaneously and evolve together at the same rate, through papules, vesicles and pustules, before umbilicating, drying and desquamating. This process usually takes about 2–3 weeks, depending on the severity of the disease. The distribution of the rash is mainly peripheral. Severe eruptions can cover the entire body (Plate 29.4), including the palms and soles. Most pustules are about 0.5 cm in diameter but some have been seen up to 1 cm in diameter. Lesions have been noted on the mucous membranes, the tongue and genitalia. One patient, who had been vaccinated several years previously, developed only 1 lesion, further emphasizing the fact that some cases can be exceedingly mild and would go unreported in the absence of active surveillance. As is described below, subclinical cases also occur, in unvaccinated as well as vaccinated subjects.

Sequelae

As in smallpox, pitting scars may develop, most frequently on the face, but they tend to diminish in prominence with time. Secondary infection of the lesions is common and this may play a role in scarring. About half of the scars from lesions seen initially on the face and body were detectable 1–4 years after the acute illness. Desquamation of crusts leaves areas of hypopigmentation (Plate 29.5 B). Hyperpigmentation follows after a few months (Plate 29.4 D) and usually diminishes with time. In some cases large shallow residual scars are seen, and in a few cases corneal lesions have caused unilateral blindness.

Laboratory confirmation

Throughout the investigations, great importance was attached to obtaining laboratory confirmation of the clinico-epidemiological diagnoses, initially because of the possible occurrence of smallpox and later because of the suspicion that "whitepox" virus (see Chapter 30) might infect humans. All laboratory diagnoses were made in the WHO collaborating centres, with the results shown in Table 29.4. The methods of laboratory diagnosis were those used for smallpox, supplemented by serology in cases in which viral isolation was not possible. This combination allowed positive diagnoses to be made in the great majority of cases. In spite of unavoidable delays in the collection and transmission of specimens, the percentage of recoveries of virus from samples taken from cases eventually diagnosed as human monkeypox was high. Virtually all the cases found positive by electron microscopy were also found positive by culture, and vice versa, but 60 (22%) of the cases were seen too late to obtain lesion material and could only be confirmed serologically. Retrospective diagnosis by serology was unequivocal in unvaccinated subjects but sometimes less clear in vaccinated persons, although with the experience gained over the past few years diagnoses are now possible in these cases also.

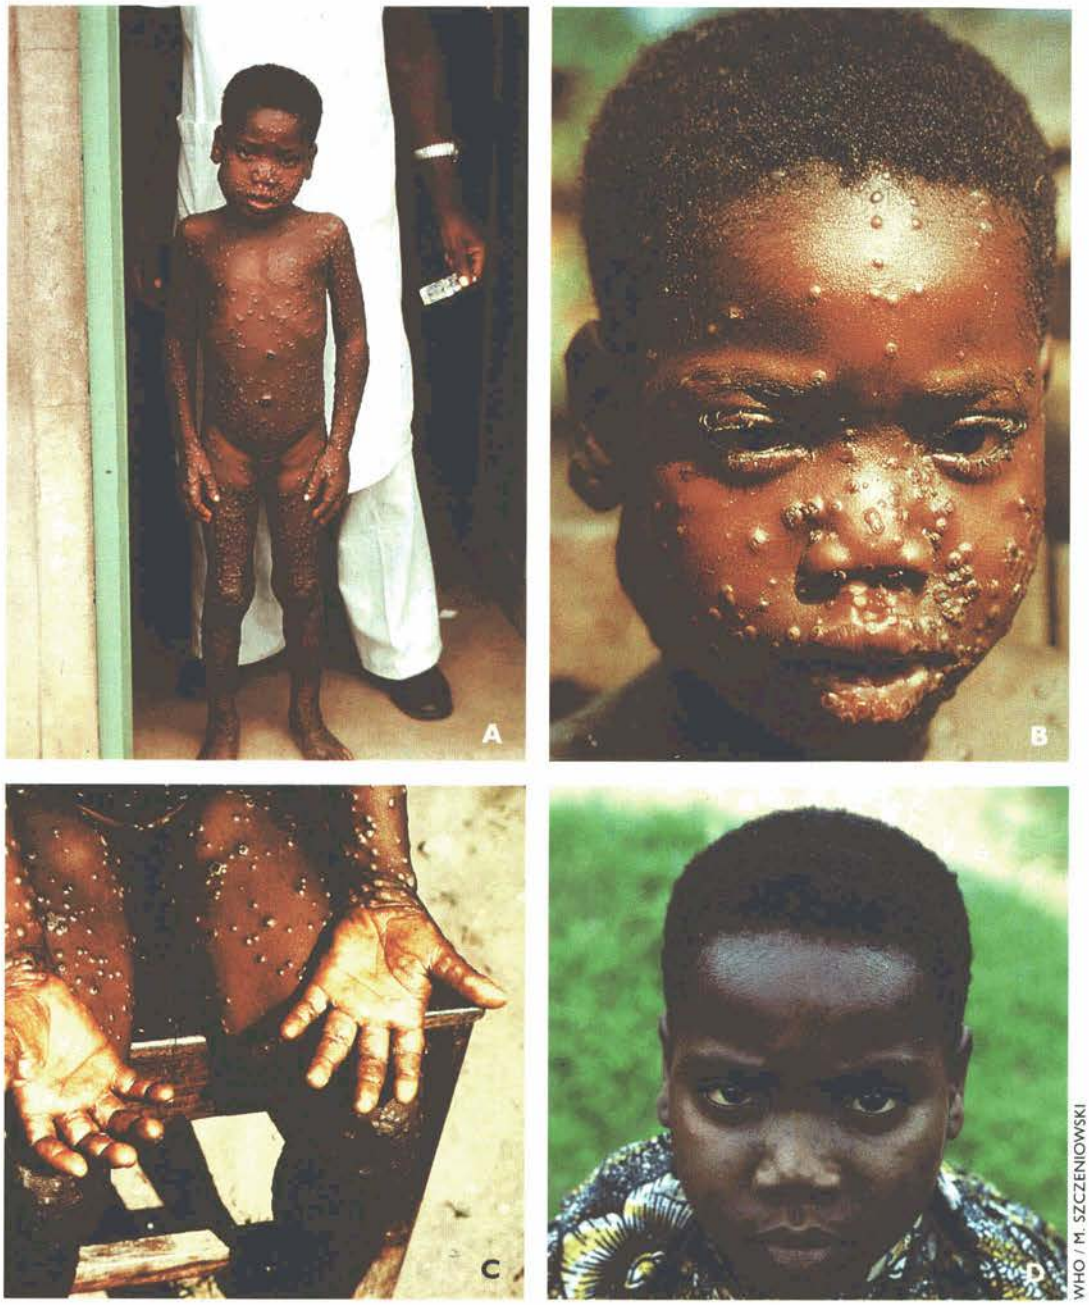

Plate 29.4. Human monkeypox in a 7-year-old Zairian girl. **A, B, C:** Acute stage, day 7 of rash. Note bilateral inguinal lymphadenopathy and enlarged submaxillary lymph nodes on right side. Pustular lesions on lips (**B**) also occur inside the mouth as ulcerated lesions: the enanthem. **D:** Same subject, 4½ years later. There are several hyperpigmented spots and facial pockmarks; in about half the cases of monkeypox these disappear within 5 years of the attack.

1978–1981	23	20	25
1982–1983	70	71	73
1984	57	67	53
Total	172	179	176

Severity and case-fatality rates

On the basis of the number of skin lesions and the severity of systemic symptoms, cases in Zaire were classified as mild, moderate or severe (Table 29.5). The majority of cases (53.1%), and the majority of severe cases among the unvaccinated (58.3%), occurred among unvaccinated children in the age group 0–4 years. The 28 deaths all occurred in children between 7 months and 7 years of age (overall case-fatality rate among unvaccinated subjects, 11.3%), the case-fatality rate for the age group 0–4 years (14.3%) being almost twice that in unvaccinated children aged 5–14 years (7.7%).

Few cases were diagnosed in vaccinated subjects, only 30 of the 277 patients (10.8%) having a visible vaccination scar. The youngest of these was a 5-year-old boy who had been vaccinated shortly after birth and developed monkeypox late in 1983—i.e., about 5 years after vaccination.

Subclinical infections

Some cases of monkeypox in vaccinated subjects were extremely mild, with very few skin lesions. By analogy with smallpox (Heiner et al., 1971a; see Chapter 1), it was to be expected that many infections in vaccinated subjects would be subclinical. A more important question was whether inapparent infections occurred in unvaccinated human subjects. Data pertaining to this problem emerged from the intensive surveillance activities in Zaire in 1982–1984 (Ježek et al., 1986b). During that period 2510 contacts of 131 confirmed cases of human monkeypox were examined and questioned, often on several occasions. Sera were taken from 70% of the unvaccinated contacts and 6% of the vaccinated contacts and tested at the WHO collaborating centres in Atlanta and Moscow (Table 29.6). The laboratory tests showed that 91 (16%) of the contacts examined had been infected with monkeypox virus. Sixty of the 73 cases in unvaccinated contacts had a history or lesions compatible with human monkeypox, and 40 of them appeared to be secondary cases resulting from transmission of infection from another human case. The other 13 unvaccinated subjects (18%) gave no history and had no lesions suggestive of human monkeypox and must therefore be classed as cases of subclinical infection. The majority of such cases occurred in children aged between 2 and 10 years who had been household contacts of a severe case of human monkeypox. Only 1 subclinical case was recognized in a vaccinated subject, a 20-year-

Table 29.5. Human monkeypox in Zaire, 1970–1984: vaccination status, age distribution of unvaccinated patients and severity of illness (including deaths)[a,b]

Vaccination scar	Age group (years)	Clinical severity									
		Mild		Moderate		Severe				Total	
						Recovered		Fatal

old man, but no special effort was made to detect subclinical infections among vaccinated subjects in a way comparable to the studies of Heiner et al. (1971a) with variola major in Pakistan.

Large-scale serological surveys of unvaccinated persons in Zaire (Ježek et al., 1987a; see later in this chapter) also revealed a few cases of subclinical infection.

Epidemiology

Although the clinical features of human monkeypox are very similar to those of discrete ordinary-type smallpox, the epidemiology is quite different. Human monkeypox occurs mainly as single or occasionally multiple sporadic cases, in small villages in dense tropical rain forest in a limited part of Africa, among villagers who are engaged for at least part of their time as hunters and gatherers. Human monkeypox is a zoonosis which is usually contracted from a wild animal. However, human-to-human infection does occur in a minority of cases.

Two observations in the early 1980s deserve comment. Mutombo et al. (1983) reported a bizarre case in which a 6-month-old infant in a small village in the tropical rain forest in Zaire was abducted by a chimpanzee but rescued after sustaining a superficial wound on the lower leg and a fractured femur. The infant developed typical monkeypox, fever beginning 6 days after the incident and a rash 7 days later. Monkeypox virus was isolated from crust material. Lymphadenopathy began in the left inguinal region and eventually became generalized, but the time of its appearance in relation to other symptoms could not be determined. Although not proved, it is a reasonable hypothesis that the infant acquired monkeypox from the chimpanzee.

The other observation concerns monkeypox among Pygmies who live in the tropical rain forests in the southern part of the Central African Republic, adjoining Zaire, in which Khodakevich et al. (1985) discovered a cluster of 5 cases of monkeypox, confirmed by virus isolation. The Pygmies who lived in the rain forests readily recognized the disease when shown a monkeypox recognition card, whereas the Bantus and Pygmies who lived in agricultural settlements had never seen a disease like it. Interrogation through interpreters revealed that the forest Pygmies had a special name for the disease and believed that it was acquired from animals and not from humans.

Age and sex distribution

The ages of patients in Zaire varied between 6 months and 53 years, but the majority were children. The two sexes were equally affected; of 283 cases reported by the end of 1984, 51.3% were in males and 49.7% in females. When analysing the epidemiology of human monkeypox it is useful to distinguish between infections acquired from an animal source (primary cases) and those due to person-to-person infection (secondary cases) (Table 29.7). The vast majority of cases in both groups occurred in children, but cases in adults tended to be more

Table 29.7. Human monkeypox: the age incidence of primary and secondary cases in Zaire, 1982–1984

Total	144	100.0	66	100.0

[a] Presumed to have been infected from an animal source.
[b] Presumed person-to-person infection.

common among persons infected by contact with other human cases, usually mothers infected by sick children.

Seasonal distribution

Breman et al. (1980) reported a preponderance of cases in Zaire in the dry season, but with the institution of more intensive surveillance since 1982 the incidence of cases has been found to be much the same throughout the year. During the period 1982–1984 the monthly incidence of primary cases varied a good deal from year to year (Table 29.8); there was no clearly evident seasonal pattern. Secondary cases showed the same absence of a seasonal effect, although, as with primary cases, the incidence was low in October.

Sources of infection of sporadic cases

Epidemiological investigations in Zaire indicated that wild animals were the probable source of infection for some 70% of patients, and person-to-person infection was suspected in the remaining 30% (see Table 29.8). Since monkeypox virus has a wide host range and evidence of infection in African wild animals has been obtained from chimpanzees, several species of monkey and 2 species of squirrel, the disease is probably transmitted to humans by more than one species of wild animal. It was virtually impossible to determine by case-control studies which animals might have been involved because the whole population in affected localities had multiple daily contacts with the same varieties of wild animals, in the settlements, agricultural areas or nearby forests. Species with which patients had multiple close contacts (within 3 weeks before the onset of rash), through hunting, skinning, playing with the animals or eating the carcasses, included various types of monkeys (65%), squirrels (12%), antelopes and gazelles (12%), terrestrial rodents (9%) and other animals (3%). Seventy-one per cent of suspected monkeys associated with patients belonged to the genus *Cercopithecus*, 12% to *Colobus* and 8% to *Cercocebus*. Two-thirds of suspected rodents were squirrels and the rest were Cricetidae. The majority of animals suspected of being the source of infection were apparently healthy.

The small villages in tropical rain forests, in which cases of human monkeypox occur, are usually not closely surrounded by high forest on all sides. A common situation is that they consist of groups of houses along roads through the forests, with extensive agricultural areas around the settlement itself, consisting of gardens and secondary forest, often with many oil palms, which provide food much favoured by certain squirrels. Beyond this, perhaps 3–5 kilometres away, is the primary rain forest. Each of the 3 zones—settlement, agricultural area, and forest—has a characteristic fauna. Domestic animals and commensal rodents frequent the immediate

[a] Presumably infected from an animal source.

environs of the houses, terrestrial and arboreal rodents and bats are found in the agricultural areas, and larger animals, including monkeys, inhabit the rain forest itself (Khodakevich et al., 1987a).

The various age groups of the population differ in the degree to which they move in and out of these areas. Children below the age of 2 years are rarely let out of their mother's sight; between the ages of 3 and 5 years they accompany their mothers to the agricultural area, and after the age of 5 years they go on their own to this area and hunt for small animals. Only the men and boys over 15 years of age hunt in the forest for large animals, including monkeys, antelopes and porcupines. Persons of all age groups would be exposed to infection from wild animals brought to the household for food. Those who might conceivably be exposed to an additional risk are the hunters and children old enough to capture small animals such as squirrels and rats in the agricultural areas. Very few primary cases have occurred in hunters, whereas children aged between 5 and 9 years have contracted many primary infections but a somewhat lower proportion of secondary infections (see Table 29.7). This may be related to the relatively high incidence of infection among squirrels captured in the agricultural areas (see below).

Person-to-person spread

The largest proportion of cases of monkeypox (48%) have occurred as single sporadic infections. However, sometimes cases have occurred in clusters, suggesting either multiple infections from a common source—co-primary cases—(if the dates of onset lay within the presumed minimum incubation period of 7 days) or person-to-person transmission. The distribution of single sporadic cases, presumed co-primary cases and presumed secondary or subsequent person-to-person infections in Zaire in 1982–1984 is shown in Table 29.9. Intervals of 7 and 23 days between the dates of appearance of the rashes in persons in close family contact have been taken as the limits for presumed person-to-person spread. In the 3 years during which intensive surveillance was operating in Zaire, 66 out of 210 cases (31.4%) appeared to have been due to transmission from person to person. Examples of the type of pattern observed are shown in Fig. 29.3. An extreme example involving 4 probable successive person-to-person infections has been described by Ježek et al. (1986a).

If all these presumed cases of person-to-person infection are accepted as such, the secondary and later generation attack rate was 15.7% among unvaccinated household contacts and 0.6% among vaccinated household contacts. The secondary and later generation attack rate among those having casual face-to-face contact with patients was 3%. These figures are much lower than those for smallpox, in which the overall first generation secondary attack rates in household contacts were 58.4% for unvaccinated persons and 3.8% among vaccinated contacts (see Chapter 4, Table 4.12).

Using these data, which were obtained from a population in which the vaccination rate was about 70%, Ježek et al. (1987b) developed a stochastic model for person-to-person infections with monkeypox virus assuming overall vaccination rates of 50%, 25%, and zero. Although the expected numbers of generations and of cases infected by contact increased with the falling vaccination rate, the model suggested that the person-to-person infectivity of monkeypox was such that the disease always died out, after a maximum number, in the simulation,

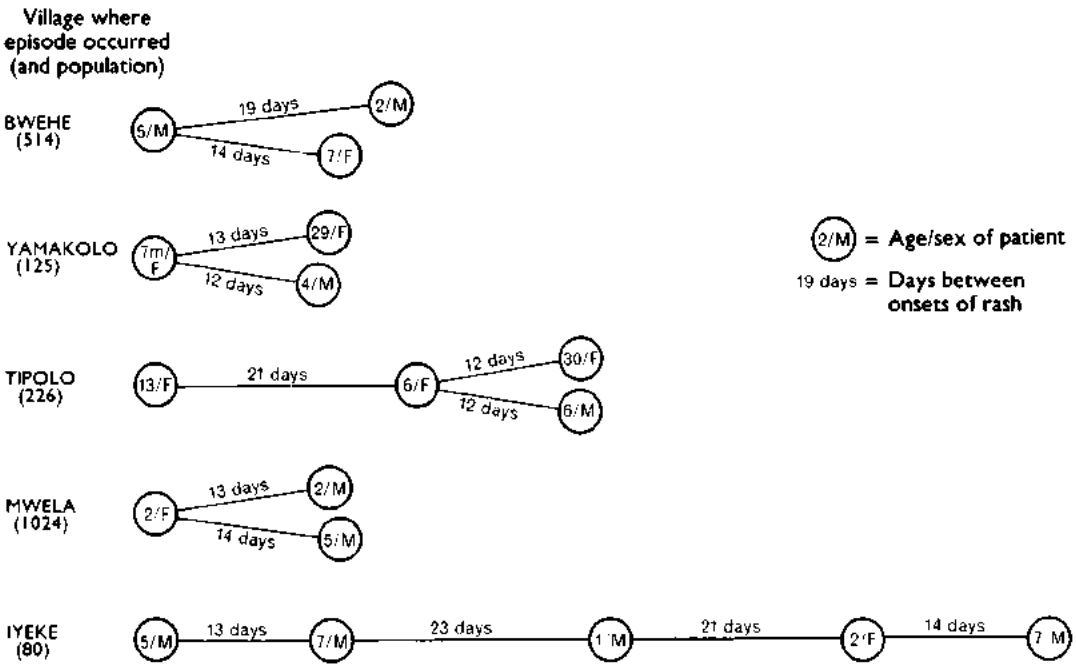

Fig. 29.3. Some examples of presumed person-to-person transmission of monkeypox. All occurred among close family contacts, who lived in small villages in the tropical rain forest. Assuming that patients could remain infectious for about a week after the onset of the rash, the intervals between cases could be longer than the usual incubation period (assumed to be about 12 days, with a range of 7–19 days).

of 11 generations. This result supports an argument based on historical data—namely, that monkeypox virus has been enzootic in animals of the tropical rain forests in Zaire for centuries without ever establishing continuous person-to-person infection in a population that had been almost completely unvaccinated until about 1967.

The prevalence of monkeypox virus infection in humans

In an attempt to discover the prevalence of monkeypox virus infection of humans in tropical rain forest areas in various parts of central and western Africa, serological surveys of persons without vaccination scars were carried out in 1981 in the Congo and Zaire (central Africa) and Côte d'Ivoire and Sierra Leone (western Africa), according to a plan designed by Arita and Dr Joseph McCormick. Cases of monkeypox had been reported from all these countries except the Congo, which borders on Zaire and has a large area (over 21 million hectares) of tropical rain forest. Specimens of serum collected from allegedly unvaccinated persons were tested in the WHO collaborating centres in Atlanta and Moscow, initially for vaccinia haemagglutination-inhibiting (HI) antibody, or by immunofluorescence at the Pasteur Institute in Abidjan, Côte d'Ivoire.

The results are shown in Table 29.10. Of 10 300 sera tested, 15.4% gave positive results by HI or immunofluorescence tests.

Supplementary examination of many of these sera by neutralization and ELISA tests showed good agreement with the results obtained with the HI or immunofluorescence test. The intention was to subject sera containing orthopoxvirus antibodies demonstrable by the screening test to further assay by either a radioimmunoassay adsorption test or an ELISA adsorption test. However, only 420 of the 1583 positive sera could be tested; of these, 73 gave results indicating that the subjects had been infected with monkeypox virus. None of the sera from the Congo gave a positive result by the ELISA adsorption test; the proportions of all sera designated as monkeypox-virus-positive varied from 0.70% for Côte d'Ivoire to 1.01% for Sierra Leone.

Table 29.10. Human monkeypox: results of serological survey among allegedly unvaccinated persons inhabiting villages in tropical rain forest areas of 4 countries of central and western Africa, 1981

Country	Number of sera tested	Positive by haemagglutination-inhibition or immunofluorescence test		Positive for monkeypox virus antibodies by radioimmunoassay adsorption		
		Number	Percentage	Number tested	Number positive	Percentage of total sera
Congo	1 433[a]	231	16.1	78[b]	0	0.0

[a] Tested by enzyme-linked immunosorbent assay with monkeypox antigen.
[b] Tested by enzyme-linked immunosorbent assay adsorption.

Follow-up visits by Dr Alexander Gromyko and Dr Jean-Paul Ryst to Côte d'Ivoire and Sierra Leone in June–July 1982 to examine those who had monkeypox virus antibody in their sera showed that some specimens had inadvertently been taken from vaccinated subjects. However, none of the 13 subjects investigated had unequivocal evidence of past vesiculo-pustular disease (by history or residual pockmarks). If any of them had been infected with monkeypox virus, as the serological results indicated, the infection was subclinical or so mild as to have been forgotten.

Because surveillance was much better in Zaire, it was possible to obtain more informa-

BY COURTESY OF Z. JEŽEK

Plate 29.8. Team leaders of special investigations in Kole, outside Kole hospital, Zaire, in 1981. *Left to right:* K.M. Paluku, M. Mutombo, Okwo-Bele, F.M. Meier, Z. Ježek.

tion about the possible frequency of subclinical infection from the survey in Kole Zone, in which Ježek was able to visit some 400 localities, involving about 10 000 households and about 50 000 persons, who were examined for vaccination scars and facial pockmarks (Ježek et al., 1987a). Only 15% of those investigated had no vaccination scar, and 1.3% of them had facial skin changes suggesting a past attack of a vesiculo-pustular disease. Of a total of 3460 serum samples collected from persons without vaccination scars, 27 showed evidence of the presence of monkeypox-virus-specific antibodies by the radioimmunoassay adsorption test. The subsequent field investigation of 19 of these subjects, who were less than 15 years old, revealed that 12 of them had experienced vesiculo-pustular disease or fever with lymphadenopathy in the past, 1 had a possible vaccination scar, and the remaining 6 had no signs or history of a disease like human monkeypox. The prevalence rate of monkeypox-virus-specific antibodies showed significant differences in different age groups; it was 4 times higher in the children aged 5–9 years (13.1 per 1000) than in those aged 0–4 years (3.3 per 1000).

As with serological surveys among wild animals in Zaire, the lack of a serological test that is sufficiently sensitive and specific to permit the diagnosis of a previous monkeypox virus infection without resorting to serum adsorption has made it impossible to determine the prevalence of human infections with monkeypox virus from the results of these 4 surveys. The significance of the overall orthopoxvirus-positive antibody rate of 15.4% remains obscure; it may have been due to antibodies to vaccinia virus or to a "non-specific reacting material" (J. H. Nakano, personal communication, 1986). However, follow-up studies in 3 countries support the view that emerged from intensive surveillance in Zaire (see Table 29.6)—namely, that some infections of unvaccinated humans with monkeypox virus are subclinical.

Ecological Studies

The epidemiology of primary cases of human monkeypox—i.e., those derived from an animal source—can be elucidated only from a knowledge of the ecology of the virus, involving the determination of which animals act as reservoir and incidental hosts and the way in which the virus is transmitted from one animal to another. Initially, studies of this problem were focused on monkeys. Serological surveys of Asian monkeys were negative, but monkeypox-virus-specific antibodies were found in several species of monkeys that occur in central and western Africa.

Because members of each species of monkey usually move in small self-contained troops, and because monkeypox virus does not cause persistent infections and is not transmitted by flying arthropods, it seems unlikely that non-human primates are the reservoir hosts of the virus. From 1979 onwards, therefore, attention was directed to a wider range of wild animals, especially terrestrial and arboreal rodents, some of which occur in populations that remain sufficiently large to support enzootic monkeypox virus infection.

Serological survey of captive African primates

Altogether 1447 sera of African primates held in various laboratories in Africa, Europe and the USA were tested for orthopoxvirus antibodies by either HI or neutralization tests; all were negative (Arita et al., 1972). With the possible exception of sera from 25 gorillas and 167 chimpanzees, all were obtained from animals captured in countries which have not reported cases of monkeypox, and the monkeys belonged to species occurring in the savanna rather than in tropical rain forests.

Serological surveys of primates from western Africa

Breman et al. (1977c) examined primate sera that had been collected in western Africa for a yellow fever survey. HI and neutralization tests were done on 206 sera obtained from 27 different sampling zones in Côte d'Ivoire, Mali and Upper Volta (now Burkina Faso), which were situated in forest and heavily wooded preforest and in the savanna. Out of 195 sera, 15 (8%) were orthopoxvirus-positive by HI and 44 (23%) by neutralization tests. The testing of 3 HI-positive sera from forest-dwelling monkeys (1 *Colobus badius* and 2 *Cercopithecus petaurista*) by immunofluorescence after adsorption showed that they contained monkeypox-virus-specific antibodies (Gispen et al., 1976).

In another survey, 692 sera obtained from a variety of animals from Chad, Côte d'Ivoire, Liberia, Nigeria, Senegal, Sierra Leone, and Upper Volta between 1970 and 1972 were tested (J. H. Nakano, unpublished observations, 1973). One hundred and fifty-eight (23%) gave positive results by the HI test and 50 out of 186 (27%) were positive by neutralization. Among sera from non-human primates included in the 692 samples, 92 out of 334 (28%) gave positive HI results; 35 out of 147 sera tested by neutralization (24%) gave positive results. Positive HI titres were observed with occasional serum samples obtained from a variety of other animals, including squirrels, rodents, ungulates, and wart-hogs. Subsequently, 273 of the monkey sera were tested by radioimmunoassay adsorption tests. Seven sera contained monkeypox-virus-specific antibodies: 2 from *Cercopithecus petaurista*, 2 from *Cercopithecus aethiops*, 2 from *Cercopithecus nictitans* and 1 from *Colobus badius* (J. H. Nakano, personal communication, 1986). The most interesting result was that obtained with *C. aethiops* from Côte d'Ivoire. Not only is this monkey typically an inhabitant of the savanna rather than the tropical rain forest, but it is the species that was exported from western Africa to North American and European countries on a large scale during the period when monkeypox was occurring in captive monkeys in these countries, and animals of this species may have been the source of infection of Asian monkeys during transit.

Tissues from 648 animals of 73 species obtained in Liberia and Nigeria in 1971 were tested for orthopoxviruses by 2 serial passages in primary monkey kidney cells with negative results (J. H. Nakano, personal communication, 1983).

Studies on material from Zaire, 1971–1979

Since most cases of human monkeypox had occurred in Zaire, attempts to determine the reservoir host or hosts of the virus were subsequently concentrated in that country, mostly in places in which human monkeypox cases had occurred.

Investigations by the WHO collaborating centre, Moscow. Between 1971 and 1975 serological and virological investigations concerning a wild-animal reservoir of monkeypox virus were carried out at the WHO collaborating centre in Moscow. Some 200 sera from areas distant from what is now recognized as the monkeypox enzootic area (see Fig. 29.2) were virtually all negative, whereas monkey sera from Zaire collected in 1971 and 1973 showed 14 out of 81 positive by the HI test and 11 out of 65 by the neutralization test (Marennikova et al., 1975). Subsequently another collection of sera from Zaire yielded

[d] Discrepancies between number tested and number positive due to non-specific reacting material.

24 HI-positive monkey sera out of 117 tested and 26 HI-positive rodent sera out of 245 tested.

Attempts were made to isolate virus on the chorioallantoic membrane from the kidneys of primates, rats, and squirrels collected in Zaire. None yielded monkeypox virus, but "whitepox" virus was said to have been obtained from 4 specimens and vaccinia virus from 1 specimen (see Chapter 30, Table 30.2).

Investigations by the WHO collaborating centre, Atlanta. In July 1979 a large-scale ecological survey in Zaire was organized by Dr Joel Breman, of the WHO Smallpox Eradication unit. Sera and organs were obtained from a wide variety of wild animals. The animal species were identified by expert zoologists and the sera and organs were tested at the WHO collaborating centre in Atlanta. In all, 1331 sera from 45 species of wild animals were tested by the HI test as a screening test for orthopoxvirus antibodies; 227 sera (17%), from a wide range of animals, gave positive results (J. H. Nakano, personal communications, 1983, 1986). All 50 sera from *Rattus* spp. were negative.

The subsequent testing of certain sera by radioimmunoassay adsorption tests cast doubt on the significance of the positive results obtained by the HI test, since none of 25 HI-positive sera of the squirrel *Heliosciurus rufobrachium* gave positive results by radioimmunoassay (Table 29.11). On the other hand, additional radioimmunoassay adsorption tests on monkey and squirrel sera from this collection revealed positive results in 5 species of monkey and in squirrels of the genus *Funisciurus* (J. H. Nakano, personal communication, 1986).

Kidneys and spleens from 930 of the animals from the 1979 Zaire study, including all the monkeys, were passaged in Vero cells, and the monkey material was also tested on the chorioallantoic membrane, with negative results (J. H. Nakano, personal communication, 1983).

Studies in Zaire, 1985–1986. Ecological investigations in Zaire were renewed in 1985, under the direction of Dr L. Khodakevich. Attention was concentrated on animals found around the houses and in the adjacent agricultural area near villages in which cases of human monkeypox had recently occurred. An early and exciting result was the recovery of monkeypox virus from a diseased squirrel (*Funisciurus anerythrus*) (Khodakevich et al., 1986). This species of squirrel is quite common in the agricultural areas adjoining villages, where it feeds on oil palm seeds.

Subsequent studies on sera from terrestrial rodents and goats found near houses and squirrels found in the agricultural area revealed many monkeypox-virus-specific sera in 2 species of squirrel (*Funisciurus anerythrus* and *Heliosciurus rufobrachium*), but none in the other animals (Table 29.12; Khodakevich et al., 1987b). Investigations into the significance of the squirrel, *Funisciurus anerythrus*, as a possible reservoir host of monkeypox virus are proceeding as this book goes to press.

Table 29.12. Results of haemagglutination-inhibition, radioimmunoassay and radioimmunoassay adsorption tests on sera from animals living in the settlements and agricultural areas adjacent to selected villages in Zaire, 1985–1986[a]

MONKEYPOX: THE OVERALL PICTURE

Laboratory studies show that monkeypox virus is a distinct species of *Orthopoxvirus*. First reported as the cause of epizootics among captive monkeys in laboratory colonies in Europe and the USA and in an epizootic in a zoological garden in the Netherlands, it was found in 1970 to be the causative agent of a generalized human infection that clinically resembled smallpox.

Unlike smallpox, however, human monkeypox occurs only in persons living in small villages in tropical rain forests in central and western Africa, where hunting is an important method of obtaining food. The vast majority of reported cases have been found in Zaire, during an intensive surveillance campaign based on health institutions that has been in operation there since late in 1981. The majority of cases can be attributed to infection from an animal source, but person-to-person infection sometimes occurs, mainly between unvaccinated children. The longest chain of transmission observed so far is an incident in which there appeared to be 4 serial person-to-person infections (Ježek et al. 1986a). It seems likely that any of several animal species (chimpanzee, several species of monkey, 2 species of squirrel, and perhaps other animals) may serve as the source of human infections.

Even in the parts of Zaire in which it appears to be the most common and is best reported, monkeypox is a rare disease (331 known cases in a population of about 5 million during the 5 years 1982–1986). However, serological studies suggest that occasionally subclinical infections occur among unvaccinated as well as vaccinated persons. There is no reason to believe that it is a new disease or that its frequency is increasing. Indeed, it appears to be disappearing from countries in western Africa, probably because of ecological changes associated with development.

OTHER ORTHOPOXVIRUS INFECTIONS OF MAN

As well as being the natural host of variola virus and an occasional, incidental host of monkeypox virus, man is susceptible to 2 other species of *Orthopoxvirus*, each of which has a broad host range: vaccinia and cowpox. Deliberate vaccination and accidental person-to-person infection with vaccinia virus have been described in Chapter 7. The present chapter is here concerned with human infections with vaccinia and cowpox viruses acquired from animals and with camelpox.

Vaccinia

General

Since vaccination was formerly practised on such a large scale and since vaccinia virus has a broad host range, it is not surprising that domestic animals were sometimes accidentally infected with the virus (Topciu et al., 1976). Human beings could, in turn, be infected from the lesions on domestic animals. Dekking (1964) found that in 36 virologically confirmed outbreaks of "cowpox" in cattle in the Netherlands, 28 were caused by cowpox virus and 8 by vaccinia virus. In the USSR, Maltseva et al. (1966) showed that each of 5 outbreaks of a pox disease affecting cattle and human beings between 1959 and 1963 was caused by vaccinia virus.

Outbreaks of Vaccinia in Cattle and Man

In 1964 an outbreak of pox infection occurred on a dairy farm in El Salvador in which 22 persons and 450 cows were affected (Lum et al., 1967). It was detected following the admission to hospital of 2 patients with pustular nodules on the hands. All except one of the human cases occurred in milkers; the exception was a woman who washed the towels used by the milkers to clean the cows' udders. Almost all the cows in the herd were infected before the epizootic ceased. The source of the infection was a milker who had been vaccinated on 18 August, had a severe primary reaction, and returned to work on 2 September. The first primary human case occurred 9 days later, presumably via lesions on a cow. Vaccinia virus was recovered from 5 human patients and 1 cow.

Buffalopox

Buffalopox, due to infection of buffaloes with vaccinia virus, was a relatively common disease in India and in other countries in which buffaloes are used for milk production (Lal & Singh, 1977). Usually lesions were confined to the teats of milking buffaloes, but sometimes generalized lesions occurred and calves got lesions on the face and mouth which interfered with their ability to suck. Human infections, usually comprising small lesions on the hands or forearms of milkers, occurred in most outbreaks and acted as the principal mode of transfer of the virus from one buffalo cow to another. The vaccination of milkers was positively incriminated as the source of one outbreak in the USSR (Ganiev & Farzaliev, 1964) and all other outbreaks have occurred in situations in which the infection of the buffaloes could have originated from vaccinated human beings. The causative agent was identified as vaccinia virus in most outbreaks. Baxby & Hill (1971) categorized 1 isolate as a separate species—"buffalopox virus"—on the basis of its biological characteristics, notably a ceiling temperature of 38.5 °C compared with 41 °C for vaccinia virus and the production of smaller pocks on the chorioallantoic membrane and smaller plaques in RK 13 cells. However, analysis of the DNA of this isolate indicates that it is also a strain of vaccinia virus (K. R. Dumbell, personal communication, 1982).

It was assumed that buffalopox would cease to occur after the cessation of routine vaccination in 1979–1980, but outbreaks continue to be reported in Maharashtra State and other parts of India. Analysis of the DNA of viruses recovered from lesions in buffaloes shows that they are strains of vaccinia virus (K. R. Dumbell, personal communication, 1986). These outbreaks do not appear to have been associated with human vaccination; studies on their epidemiology are in progress as this book goes to press.

Cowpox

History and geographical distribution

The history of cowpox in relation to the origins of Jennerian vaccination has been described in Chapters 2 and 6. It was not until 1939 that Downie (1939a,b) clearly differentiated cowpox virus from vaccinia virus. Classical cowpox has not been described outside of Europe, but strains of cowpox virus have been recovered from rodents in Turkmenia (USSR).

Epidemiology

The traditional mode of infection of human beings with cowpox virus was by "inoculation" of the hands of milkers by contact with ulcers on the teats of cattle caused by cowpox virus (see Plate 29.6 A and 29.6 D). This was undoubtedly the usual

Table 29.13. Features of 16 virologically confirmed cases of infection of humans with cowpox virus in England[a]

mode of infection and over the years many such episodes have been reported. Human cowpox was regarded as a rare zoonosis, contracted by the direct contact of milkers with lesions on the teats of cows and resulting in an ulcer or ulcers that remained localized at the inoculation site (Downie, 1951, 1965a; Dekking, 1964).

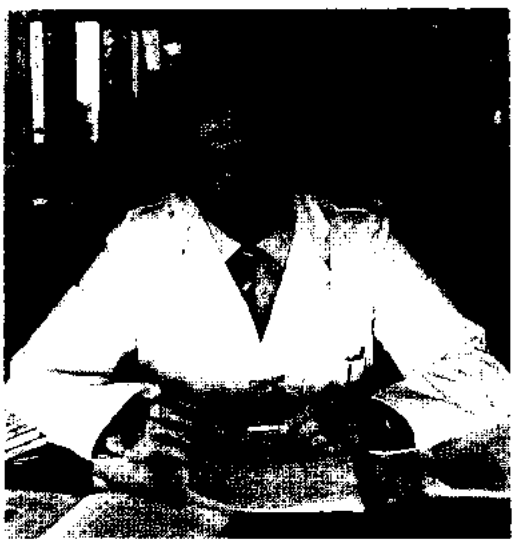

Plate 29.9. Derrick Baxby (b. 1940), British authority on orthopoxviruses, with a particular interest in cowpox and the history of vaccination.

Bovine cowpox is not a common disease (Gibbs et al., 1973) and apparently never was, even in Jenner's time, and the occurrence of lesions of "spurious cowpox" on cows' teats (see below) gave rise to much confusion when such lesions were used as a source of vaccine. Ceely (1842), who provided one of the best and most detailed descriptions of cowpox in bovines, noted that: "The disease is occasionally epizootic . . . more commonly sporadic or nearly solitary. It may be seen sometimes at several contiguous farms, at other times one or two farms entirely escape its visitation. Many years may elapse before it recurs at a given farm or vicinity, although all the animals may have been changed in the meantime."

Baxby (1977a; personal communication, 1983) has pointed out that cows were directly implicated as a source of cowpox virus in only 3 out of 16 virologically confirmed cases in human beings in England between 1969 and 1981 (Table 29.13). No source of infection could be discovered for the other 13 cases. Only 4 of the cases occurred in farm workers. Other studies (review: Baxby et al., 1979) have shown that cowpox virus (defining the species according to the biological characteristics described in Chapter 2, Table 2.3) has caused sporadic infections in domestic cats, large felines, elephants, okapis and a rhinoceros (Table 29.14), none of these infections

having originated from contact with cases of bovine or human cowpox. The validity of the species diagnosis is supported by analyses of the DNA obtained from several of these isolates (Fig. 29.4). All could be clearly differentiated from vaccinia and variola DNA. The dissimilarities between different strains of cowpox DNA relate in a general way to their geographical origins, and strains from unusual hosts (elephants and large felines) clearly have cowpox virus DNA.

Man, cows and the other animals listed in Table 29.14 are probably all incidental hosts of cowpox virus, of no importance as far as its perpetutation in nature is concerned. The recovery of cowpox virus from wild rodents in Turkmenia (Ladnyj et al., 1975; Marennikova et al., 1978b; Plate 29.10) and the demonstration that a substantial number of them were serologically positive (Table 29.15) suggests that susliks and gerbils might be natural reservoir hosts of cowpox virus in Turkmenia. These animals do not occur in the United Kingdom, but Kaplan et al. (1980), in a study of virus infections in small British field rodents, demonstrated orthopoxvirus antibodies in wild voles; these could be due to cowpox virus. It is not unreasonable to suppose that cowpox virus, which has a wide host range, produces enzootic infections in a variety of rodents, from which it is occasionally transferred to other animals: cows, cats, zoo animals (possibly via domestic rats used as feed, as in the Moscow Zoo outbreak; Marennikova & Shelukhina, 1976) and sometimes man (Baxby, 1977a, 1982b). In turn, cows, cats and sometimes zoo animals (Marennikova et al., 1977) could serve as the source of infection for humans.

Differential diagnosis of lesions on cows' teats

Jenner recognized that not all ulcers on the teats of dairy cows were caused by "variolae

vaccinae", so that material taken from such lesions sometimes lacked the capacity to protect humans against smallpox; he termed such lesions "spurious cowpox" (Jenner, 1799). In addition to cowpox and vaccinia virus, 2 other viruses can cause ulcers on the teats of cows (Gibbs et al., 1970; Baxby, 1981). These are bovine herpes mammillitis virus and pseudocowpox virus (Plate 29.6 B). Both are enzootic diseases of bovines, and are much more common than cowpox virus infections in dairy herds. Pseudocowpox virus is transmissible to man, to produce milker's nodules (see below).

Clinical features of cowpox in man

Downie (1965a) has described the lesions found in humans infected with cowpox virus (Plate 29.6 D) as follows. One or more lesions usually appear on the hands—the thumbs, the first interdigital cleft and the forefinger being especially liable to attack. Scratches or abrasions of the skin may determine the localization of the lesions elsewhere on the hands, forearms or face. The lesions resemble those of primary vaccination, passing through the stages of vesicle and pustule before a scab forms. Local oedema is usually more pronounced than in vaccination and there is lymphangitis, lymphadenitis and often fever for a few days. Baxby (1977a) noted that cowpox in children was occasionally rather severe. However, although multiple primary lesions sometimes occur, a generalized rash has not been reported, but one case of post-cowpox encephalitis has been described (Verlinde, 1951).

Camelpox

Camelpox is a common disease of dromedary camels. The original report identifying camelpox virus as an orthopoxvirus (Baxby, 1972) caused some concern to those involved in the global smallpox eradication campaign since it was entitled "Smallpox-like viruses from camels in Iran". However, subsequent investigations (see Chapter 2) showed that it was caused by a distinct species of *Orthopoxvirus* that has a narrow host range. Among camels, skin lesions occur mainly on the head, neck and forelegs, or all over the body. Young animals, in particular, may suffer a severe disease which is sometimes fatal (Plate 29.11). Camelpox is enzootic in Somalia (Ježek et al., 1983) and in most other areas in which camels are common (Egypt, India, the Islamic Republic of Iran, Iraq, Kenya and the USSR) but not among feral camels in Australia.

Although there were occasional reports in the older literature that camel drivers could contract local lesions on the hands and arms from contact with affected animals, the experience during the global smallpox eradication programme, especially in Somalia, suggested that human camelpox rarely if ever occurred. Kříž (1982) described a possible case in a 40-year-old unvaccinated Somali man who was a member of a nomadic group among whose camels there was a severe epizootic of camelpox. There were 3 lesions on the left arm and 1 on the right, which went through vesicular and pustular stages before scabbing. It was not possible to obtain lesion material for laboratory confirmation, but the serum from this patient gave a positive orthopoxvirus HI test. A survey among 286 camel herdsmen in the area, only one-third of whom had been vaccinated, revealed only 2 other cases of skin lesions, both diagnosed as tropical ulcers. A subsequent survey of another 179 herdsmen handling affected camels, 12% of whom had been vaccinated, revealed few skin eruptions, none of which yielded a poxvirus (Ježek et al., 1983). Out of a total of 335 specimens taken from the skin lesions of persons who might have come into contact with diseased camels, none was positive for poxvirus particles, and inquiries among some 20 000 persons at risk yielded only 1 possible case of human camelpox, that reported by Kříž (1982).

PARAPOXVIRUS INFECTIONS

A number of domestic animals—sheep, goats, cattle, and camels—sustain infections with different strains or species of the genus *Parapoxvirus*. The lesions in each species of animal usually take the form either of scattered papules and nodules in the skin or of a papular stomatitis, with lesions on the lips and gums ("scabby mouth" of sheep; bovine papular stomatitis). One strain of parapoxvirus is spread among cows and produces ulcerative lesions on the teats (Plate 29.6 B), which are called pseudocowpox and constitute one of the forms of the "spurious cowpox" of Jenner (Gibbs & Osborne, 1974). Calves sucking from dams with pseudocowpox usually get lesions on the mouth and

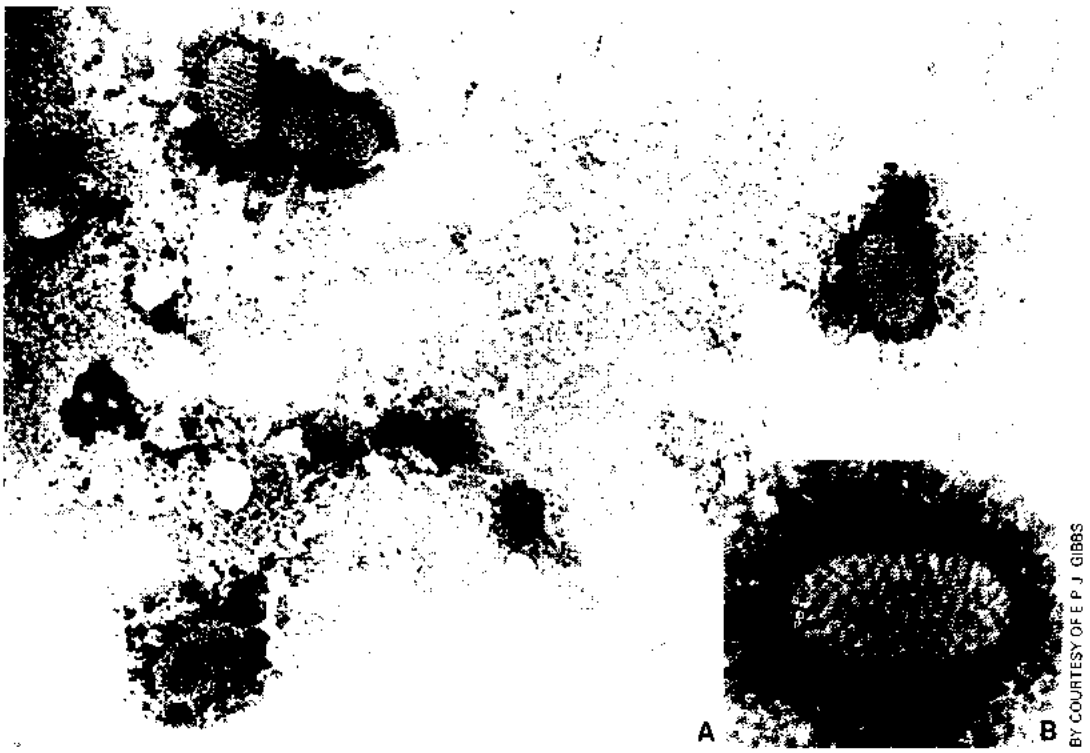

Plate 29.12. **A:** Virions of the parapoxvirus of pseudocowpox, which produces lesions of milker's nodules in humans. **B:** Virion at higher magnification, showing the regular spiral structure of the tubule of the outer coat, which is characteristic of the genus *Parapoxvirus*.

lips. Bovine papular stomatitis is caused by a different species of parapoxvirus and is found more commonly in beef than in dairy cattle (Tripathy et al., 1981). Five out of 57 cases of "camelpox" in Somalia that were investigated virologically in 1978–1979 were caused by a parapoxvirus (J. H. Nakano, personal communication, 1986).

Humans can be infected accidentally with these parapoxviruses through abrasions of the skin. The disease acquired from sheep or goats is termed orf (review: Johannessen et al., 1975); that acquired by milkers from the ulcers on the teats of cattle is called milker's nodules. The lesions in cattle and sheep often ulcerate; milker's nodules in humans are usually small indolent papules (Plate 29.6 E). Human orf is associated with umbilicated proliferative lesions that often ulcerate before healing (Plate 29.6 F).

All parapoxviruses have an identical morphology, which is quite distinctive (Plate 29.12), the virions being smaller than those of the orthopoxviruses and having a regular surface structure.

Parapoxvirus infections are of some importance in the consideration of smallpox for two rather trivial reasons: the lesions on cows' teats constituted an early source of confusion with genuine cowpox, and the particles found in scrapings of human lesions reported by electron microscopists simply as "poxvirus particles" might unnecessarily alarm public health authorities.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a specifically human skin disease caused by a poxvirus which has not yet been cultivated or transmitted to laboratory animals (review: Postlethwaite, 1970). The lesions are pearly, flesh-coloured, raised, firm, umbilicated skin nodules, 2–5 mm in diameter, which may appear anywhere on the body except the palms and soles. The nodules are painless and at the top of each there is often an opening through which a small white core can be seen. There are no constitutional disturbances. The le-

sions may persist for months or even a few years before resolving spontaneously.

Molluscum contagiosum has a world-wide distribution. In some places—e.g., Papua New Guinea (Sturt et al., 1971) and Zaire—it is very common in children. It may occur sporadically or in small epidemics. Direct or indirect contagion appears to be the mode of spread and in western countries public baths and swimming-pools may be implicated. Among young adults it may be a sexually transmitted disease (Brown et al., 1981).

In negatively stained preparations the virions are morphologically very like those of vaccinia virus, although Nakano (1985) noted that the surface tubules were more prominent. However, since the lesions are so distinctive, and since the virus cannot be cultivated, molluscum contagiosum was not regarded as a serious source of confusion in the global smallpox eradication campaign.

TANAPOX VIRUS INFECTIONS

Tanapox was first observed as an acute febrile illness, associated with localized nodular skin lesions and caused by a poxvirus, which occurred in epidemics in 1957 and 1962 among people living in the flood plain of the Tana river in Kenya (Downie et al., 1971). Serological studies (Manson-Bahr & Downie, 1973) showed that it was endemic in this area, and subsequently many cases were seen during surveillance for monkeypox in Zaire in 1977–1984 (Ježek et al., 1985). The same virus (Downie & España, 1972) gave rise to epizootic infection in rhesus monkeys in 3 primate centres in the USA in 1966; in each of these outbreaks some of the animal handlers were infected, apparently through skin abrasions (Nakano, 1978).

Ježek et al. (1985) have published a detailed analysis of the clinical and epidemiological features of tanapox as seen in 264 cases in Zaire in which the diagnosis was confirmed by electron microscopy. The incubation period in natural human cases is unknown, but in a person infected by the intradermal inoculation of about 10^4 infectious particles (as assayed in tissue culture), erythema and central thickening appeared by the 4th day (Downie et al., 1971). Most patients have a mild pre-eruptive fever, sometimes accompanied by severe headache and backache and often with itching at the site of the eventual skin lesion.

The appearance and evolution of the characteristic skin lesions are illustrated in Plate 29.7. Initially there is a small nodule, without the central abrasion that is often seen with an insect bite. The nodule soon becomes papular and gradually enlarges to reach a maximum diameter of about 15 mm by the end of the second week. It is surrounded by an oedematous zone and a large erythematous areola. The draining lymph nodes are enlarged and tender from about the 5th day after the appearance of the skin lesion, which may remain nodular but usually ulcerates during the third week and then gradually heals within 5–6 weeks, leaving a scar. In Kenya, Downie et al. (1971) noted that the lesions were almost always solitary and on the face, neck, upper arm and trunk. In Zaire, however, Ježek et al. (1985) noted that 22% of patients had multiple lesions—usually 2 but sometimes 3 or more, the maximum number seen on one patient being 10. Multiple lesions were often close together and usually evolved simultaneously, although they differed in size. In Zaire the distribution of lesions was different from that seen in Kenya, 72% being on the lower limbs, 17% on the upper limbs, 7% on the trunk and 5% on the head.

Especially if there were multiple lesions, a case of tanapox could initially be mistaken for human monkeypox (or in former times smallpox), perhaps modified because of vaccination, but the slow evolution and lack of pustulation clearly differentiate tanapox from any of the orthopoxvirus infections. The clinical diagnosis can be confirmed by the demonstration with the electron microscope of poxviruses which have a characteristic envelope (Plate 29.13) and fail to grow on the chorioallantoic membrane (Nakano, 1985).

Some strains of tanapox virus grow in cultures of monkey or human cells, producing focal lesions characterized by intense granularity followed by rounding up of the cells. Monkeys, but no other laboratory animals, are susceptible to experimental infection.

Human tanapox has been recognized in Kenya and Zaire, but probably occurs much more widely throughout tropical Africa. In Kenya, Downie et al. (1971) noted that epidemics in 1957 and 1963 were associated with periods of extensive flooding. In Zaire, cases occurred throughout the year but mainly in the period between November and

BY COURTESY OF J-H NAKANO

Plate 29.13. Virions of tanapox virus, as seen in negatively stained scrapings from a lesion. Most virions appear to have an envelope.

March (Ježek et al., 1985). The majority of cases seen in Zaire were found in the township of Lisala, among persons living within 300 metres of the Zaire river. Both sexes and all age groups were affected, and cases occurred much more frequently among persons who worked or played close to the river than among those engaged in hunting or working as plantation farmers. Although clusters of cases occurred both temporally and spatially, there was no indication that person-to-person spread occurred. Tanapox appears to be a zoonosis, but neither the reservoir host nor the mode of transmission from wild animals to man is known. Manson-Bahr & Downie (1973) suggested that tanapox virus may be transferred from monkeys or some other reservoir host to man by biting arthropods, possibly acting as mechanical vectors. Infection by mechanical transmission has been described among animal attendants (McNulty et al., 1968).

GENERAL COMMENT

Man is susceptible to a range of poxvirus infections, but only two of these, smallpox and human monkeypox, regularly produce an acute systemic infection with a generalized rash. Human monkeypox can be distinguished from smallpox only by the cultivation of the virus or the performance of a virus-specific serological test with convalescent serum, but the epidemiology of the two infections is quite different. Monkeypox was the only poxvirus infection other than smallpox seen during the eradication programme that gave rise to serious concern. However, the studies in Zaire described in this chapter provide good evidence that it is a rare zoonosis which cannot be sustained indefinitely by serial transmission in man.

Because vaccination can greatly modify the response of humans to either variola or monkeypox virus, so that if skin lesions do occur, they are very few or perhaps only a solitary one develops, other poxvirus infections sometimes cause problems in the differential diagnosis of smallpox or monkeypox, especially because electron microscopic examination of lesion material might reveal poxvirus particles.

The diagnosis of cowpox and vaccinia infections depends on the cultivation of the virus on the chorioallantoic membrane; that of tanapox on the clinical picture, the appearance of the virion in the electron microscope and its failure to grow on the chorioallantoic membrane. The lack of systemic symptoms and the characteristic chronic nodular skin lesions distinguish molluscum contagiosum from all other poxvirus diseases. The viruses of orf and milker's nodules can readily be distinguished by the characteristic morphology of the virion, as well as by serological tests.

When they were first studied in the laboratory, camelpox virus (Baxby, 1972) and taterapox virus (Lourie et al., 1975) were regarded with considerable suspicion because the pocks they produced on the chorioallantoic membrane very closely resembled those produced by variola virus. It is possible that similar causes of concern may arise, perhaps with orthopoxviruses of wild animals that have yet to be discovered. Comparison of their DNA with that of variola and monkeypox viruses should allow the proper categorization of any such isolates.

INTRODUCTION

The eradication of smallpox was defined by successive WHO expert groups (WHO Scientific Group on Smallpox Eradication, 1968; WHO Expert Committee on Smallpox Eradication, 1972) as "the elimination of clinical illness caused by variola virus". An important corollary of this definition was that it did not involve the extinction of variola virus, as some experts had urged. The procedures for the certification of smallpox eradication described in Chapter 24 were therefore designed to ensure that no human cases had occurred in the countries concerned for at least 2 years—i.e., that the human-to-human chains of transmission of smallpox had been interrupted. Careful follow-up of rumours of suspected smallpox by national authorities and by WHO, described in Chapter 28, has failed to confirm a single case of smallpox in a field situation since the last case was recognized in Somalia in October 1977, although there were 2 laboratory-associated cases in Birmingham, England, in August–September 1978. The correctness of the conclusions that the Global Commission for the Certification of Smallpox Eradication arrived at in its deliberations in December 1979 (World Health Organization, 1980) has been borne out by 10 additional years of freedom from the disease.

As the expert groups which defined eradication recognized, the absence of cases of smallpox is not synonymous with the extinction of variola virus, and if the virus is

not extinct it is possible that further cases of smallpox could occur. This chapter is concerned with the known and hypothetical ways in which variola virus could be preserved and enter again into chains of human-to-human transmission. By far the most important, because it would be the most difficult to eliminate or circumvent, would be the continuing transmission of the virus in some wildlife reservoir or reservoirs. Indeed, such a situation would have made the permanent global eradication of smallpox an impossibility. This was therefore a matter that greatly exercised the staff of the WHO Smallpox Eradication unit from the outset of the global eradication programme (see Chapters 10 and 29). The lack of evidence of infection of humans from an animal host in Europe, North America and Australia, in which the disease no longer occurred, did not exclude this possibility for parts of Africa and Asia in which smallpox was still endemic until the 1970s. Although there was no documented evidence that this had taken place, it was conceivable that infection of man from an animal source might have occurred in the past without having been detected, as indeed proved to be the case with human monkeypox. Because of the reported isolations in laboratories in Bilthoven (Netherlands) and Moscow (USSR) of variola-like viruses ("whitepox" viruses) from animal tissues (see later in this chapter), investigation of this possibility remained a major concern of virologists involved in research associated with the eradication programme throughout the 1970s and into the early 1980s.

Material stored by variolators was another potential source for the recurrence of cases of smallpox which concerned the WHO Secretariat and members of the Global Commission, especially in countries such as Afghanistan in which low temperatures prevailed for much of the year. However, the most obvious source of virus that might cause human infection at some time in the future consists of laboratory stocks of variola virus, from which, indeed, the last known outbreak in the world originated (see Chapter 23). These could be stocks of virus known by WHO to be held in microbiologically secure laboratories, or they could be specimens in the deep-freeze storage facilities of any laboratory that had ever worked with the virus. Finally, stocks of virus may be held secretly, for possible use in microbiological warfare.

Other hypothetical sources of smallpox could be from virus released by reactivation in a human subject who had had the infection, or release of viable virus long preserved in scabs, on old clothes, or even in coffins. For the sake of completeness the possibility that another species of *Orthopoxvirus* might be "transformed" into variola virus (already discussed in Chapter 2) needs to be briefly reconsidered here, as a possible source for the return of smallpox.

IS THERE AN ANIMAL RESERVOIR OF VARIOLA VIRUS?

The presence of an animal reservoir of variola virus is in theory the most important potential source for a return of smallpox. In discussing the origin of variola virus in Chapter 2, we suggested that conditions suitable for its perpetuation as a specifically human pathogen have existed for a few thousand years at the most. Variola virus was therefore probably derived from some closely related orthopoxvirus that survived in nature by circulation in an animal that occurred in large numbers at the time of early man and had a much shorter life-span. In this chapter two possibilities will be discussed: that there is an animal reservoir of variola virus as we know it, or that some other animal orthopoxvirus could be "transformed" into variola virus by a few mutational steps or perhaps by chance recombination with another animal orthopoxvirus. The great importance of this question, from the point of view of smallpox eradication, can be illustrated by reconsidering briefly the history of the first deliberate attempt to eradicate a human disease, yellow fever, which has already been mentioned in another context in Chapter 9.

The Example of Yellow Fever

In 1915 the International Health Commission of the newly established Rockefeller Foundation agreed to help with the global eradication of yellow fever, an undertaking that General W. C. Gorgas, Surgeon-General of the United States Army and the hero of disease control during the construction of the Panama Canal, considered eminently feasible. Yellow fever was regarded as an urban disease, and its global eradication was based on a simple epidemiological concept:

"...that the disease could be acquired only through the bite of an *A. aegypti* mosquito that had become infected by feeding on a human being sick with yellow fever; that there were certain endemic centers of the disease that served as seedbeds; that these foci of infection were few in number, and that if they were destroyed, yellow fever would disappear forever." (Warren, 1951.)

It is a matter of history that this concept was too simple. As early as 1907 Franco et al. (1911) had recognized the existence in Colombia of another epidemiological situation—the contracting of yellow fever in the forest, rather than in urban areas. Another outbreak of yellow fever occurred in the same locality in 1916, but since *Aedes aegypti* could not be found there, it was assumed by the Gorgas Commission that the diagnosis was erroneous (Gorgas, 1917). Eventually Soper (1935, 1936) drew attention again to the paper of Franco et al. and described what he called "jungle yellow fever", which he postulated could be due to maintenance of the virus in another vertebrate host or perhaps long persistence in an invertebrate vector. At about the same time surveys of forest monkeys of many species in both Africa and South America revealed the presence of neutralizing antibodies in their sera. With the discovery of a vertebrate reservoir other than man, it was clear that the global eradication of yellow fever was impossible, although urban yellow fever could be eliminated by ridding towns and cities of *Aedes aegypti*.

The significance of the yellow fever experience was not lost on those who contemplated the global eradication of smallpox and investigations into the possibility that there might be an animal reservoir of variola virus in Africa or Asia were initiated soon after the Intensified Smallpox Eradication Programme was launched (see Chapter 10).

Smallpox in Apes and Monkeys

Experimental observations with variola virus had demonstrated that, unlike vaccinia and cowpox viruses, both of which have a wide host range, few laboratory animals could be infected with variola virus, except under unusual conditions (see Chapter 2). However, it had been demonstrated during the latter part of the 19th century that monkeys (probably *Macaca mulatta*) could be infected with variola virus (Zuelzer, 1874; Copeman, 1894), and later studies (Hahon, 1961) showed that many species of monkeys and apes were susceptible. Noble (1970) found that 3 species of New World monkeys that he tested were insusceptible to variola minor virus, although they reacted serologically but without symptoms to experimental infection with variola major virus.

Reported infections of primates in nature

Arita & Henderson (1968) reviewed the published accounts of supposed smallpox in primates as well as other naturally occurring epidemics of "pox" infections among monkey populations. Only 8 such episodes are known and only 4 of these occurred during the present century (Table 30.1). In only 2 instances was laboratory confirmation available; in each of these there had been close association between the primate concerned and cases of human smallpox.

"Smallpox" infection in a monkey population in the forests of southern Brazil was reported by Bleyer (1922), who noted that carcasses of *Mycetes seniculus* and *Cebus capucinus* were found under the trees, the dead animals having fallen from the tree-tops. Sick as well as dead monkeys were covered with numerous pustules like those seen in human smallpox and the mortality was extremely

high in certain districts. Anderson (1861) reported that a "smallpox" outbreak observed in 1841 in monkeys was followed by a smallpox outbreak in a human population in Panama. Two monkeys that he examined were covered with "perfectly formed" pustules. Schmidt (1870) mentioned 3 other episodes, 2 in France and 1 in Trinidad.

An outbreak of a vesiculo-pustular disease was observed by M. A. Rahman (quoted by Arita & Henderson, 1968) in rhesus monkeys in Bengal, India, in 1936. Many deaths were observed among monkeys which lived in mango groves near the town and visited the town frequently in search of food and water. The sick monkeys were quiet and lethargic and had pustular lesions, particularly on the face, palms and soles. When they died they fell from the trees and roof tops, and the carcasses were disposed of without any particular precautions being taken. Despite the poor vaccinial immunity status of the population, no human pox-like illnesses were observed.

All these episodes must be regarded with caution so far as their significance as evidence of an animal reservoir of variola virus is concerned. They may have been instances of the infection of primates from human cases of smallpox or they may have not been due to variola virus or indeed to any kind of poxvirus. However, 2 episodes have been well documented which demonstrate that primates in close contact with smallpox-infected humans may have become infected with variola virus. Gispen (1949) observed 2 orang-utans in the Jakarta Zoo which contracted a pox infection at the time of a smallpox epidemic in the area. Both animals were in the same cage and demonstrated typical lesions on the face, hands, and soles of the feet; Bras (1952a) performed an autopsy on the one that died (Plate 30.1). Variola virus was isolated on the chorioallantoic membrane of the chick embryo from specimens taken from both affected animals. Other monkeys in the zoo, none of which had been previously vaccinated, remained unaffected. The other episode occurred in India, where Mack & Noble (1970) recorded an unusual situation in which 1 or possibly 2 performing monkeys (*Macaca mulatta*) appear to have been infected with variola virus by intimate household contact with human cases of smallpox.

Throughout the global smallpox eradication campaign attempts were made to identify the source of infection in all outbreaks,

Plate 30.1. Orang-utan (*Pongo pygmaeus*) in the Jakarta Zoo, which was infected during the 1949 epidemic of smallpox and died.

and as the incidence of smallpox fell to low levels in each endemic country, this became a matter of high priority, so that chains of transmission could be traced. Thousands of such outbreaks in Africa and south-eastern Asia were investigated by skilled epidemiologists. In the vast majority, infection could be traced to a case of smallpox. Very rarely fomites (e.g., laundry items or burial shrouds) were implicated. In a few instances it was not possible to determine the source of the outbreaks. Some of them may have been due to infection acquired from mild unrecognized cases, or the source remained undetected through faulty or incomplete investigation. But the possibility of infection from an animal source was always present in the minds of epidemiologists in the rare instances in which no human source could be clearly identified. Never during the global smallpox eradication campaign could smallpox be traced back to an animal source. Finally, although monkeys are common in many of the countries of Africa and Asia in which smallpox was once endemic, sometimes living in close contact with man or

captured by hunters, no case of smallpox has been found in any of these countries since eradication.

Experimental transmission of smallpox between primates

More significant than isolated examples of smallpox in monkeys or the infection of animals by inoculation are 2 sets of observations on the natural transmission of variola virus from one primate to another. Noble & Rich (1969) showed that serial infection could be maintained for as many as 6 successive passages in *Macaca irus* (cynomolgus) monkeys placed in contact with other monkeys during the period of rash, but transmission then failed (Fig. 30.1). Among chimpanzees, Kalter et al. (1979) observed that 2 animals situated in cages near a chimpanzee experimentally inoculated with variola virus contracted smallpox, one suffering a severe illness. One other animal in the group escaped infection. Clearly, primates of several species are susceptible to variola virus, get a rash when infected, and can transmit the disease to other primates in contact with them. However, in *Macaca irus*, the only primate in which adequate studies were conducted, the infection persisted with some difficulty and then died out.

As was discussed in Chapter 2, smallpox could not be maintained in isolated human populations numbering under 200 000. Unless smallpox in non-human primates produced a situation in which recurrent infectivity could occur years after the primary infection, it is likely that populations of any particular species of monkey would be too small to maintain the disease. This is certainly true of chimpanzees and orang-utans, in which infection with variola virus causes a severe disease not unlike smallpox in man.

Monkeypox

It had been known since 1958 that monkeys in laboratory colonies occasionally suffered epizootics due to another orthopoxvirus—monkeypox virus (Magnus et al., 1959; see Chapter 29). Known outbreaks of monkeypox were reviewed by Arita & Henderson (1968), and early in 1969 the WHO Smallpox Eradication unit convened an Informal Group on Monkeypox and Related Viruses (see Chapter 29) to advise it on matters relating to the problem of an animal reservoir of variola virus. The following year one of the members of the Informal Group (Dr Svetlana Marennikova) recognized that the virus recovered from a suspected case of smallpox that had occurred in Zaire 2 years after the last outbreak of smallpox in the area (Ladnyj et al., 1972) was indeed monkeypox virus (Marennikova et al.,

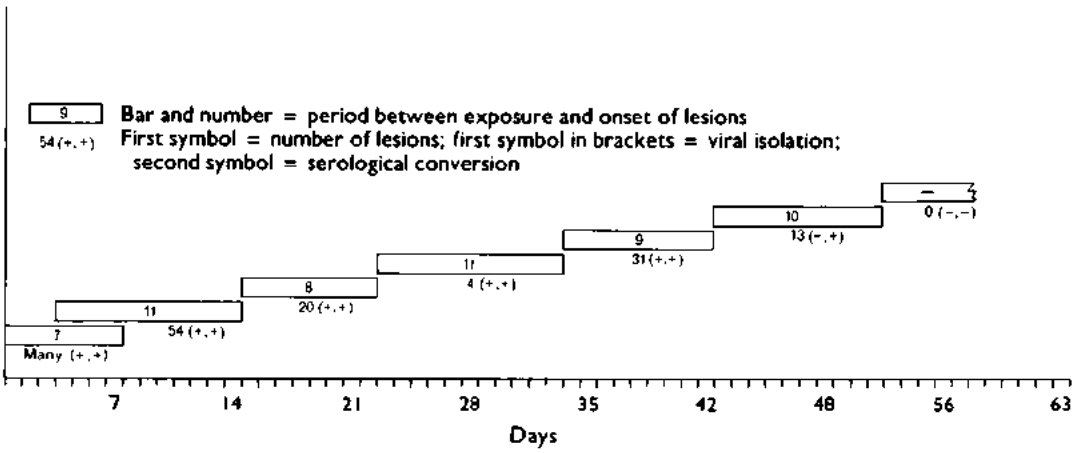

Fig. 30.1. Five successive contact infections of *Macaca irus philippinensis* before failure in transmission. The first monkey was infected by intranasal inoculation and after 7 days (indicated in bar) developed many lesions, from which variola virus was recovered (first "+" symbol) and subsequently showed serological conversion (second "+" symbol). The second monkey was placed in the same cage 3 days after the inoculation and developed 54 lesions 11 days after exposure; it was then placed in contact with the third monkey, and so on. The penultimate monkey in the series developed 13 lesions, but virus was not recovered from the crusts, although antibodies developed. The last monkey failed to develop lesions or convert serologically. (Based on Noble & Rich, 1969.)

1972b). Subsequently, human monkeypox has come to be recognized as a rare zoonosis apparently confined to villages in tropical rain forests in central and western Africa (see Chapter 29). The significance of human monkeypox in the present context lies in observations made in the course of ecological surveys in Zaire designed to elucidate the natural history of monkeypox virus. These resulted in a series of reports on what came to be called "wild whitepox" and ultimately "whitepox" viruses.

"Whitepox" Virus Isolations

Three sets of isolations of "whitepox" viruses have been made which are best dealt with separately and chronologically. The first set ("Netherlands isolates") comprises 2 strains, designated 64-7255 and 64-7275, apparently recovered from normal cynomolgus monkey kidney cell cultures at the National Institute of Public Health at Bilthoven (Gispen & Kapsenberg, 1966; Gispen & Brand-Saathof, 1972). The second

White Pock Mutants, "Whitepox" Viruses and White Clones (Variants) of Monkeypox Virus

The appearance of pocks produced on the chorioallantoic membrane by different species of *Orthopoxvirus* varies from bright red (cowpox virus), through a greyish ulcerated appearance with a haemorrhagic centre (monkeypox virus and some strains of vaccinia virus including rabbitpox virus) to a dense white pock with no sign of ulceration (variola virus, some strains of vaccinia virus and camelpox virus). All viruses that produce haemorrhagic pocks also yield a small proportion of non-haemorrhagic pocks; these are the "white pock mutants" of cowpox, rabbitpox, neurovaccinia or monkeypox virus, which have been used for genetic studies of orthopoxviruses.

In 1966 Gispen & Kapsenberg reported the recovery of orthopoxviruses from apparently normal cynomolgus monkey kidney cells used for viral diagnostic work in the National Institute of Public Health, Bilthoven. One of them was vaccinia virus; the other 3 were regarded as monkeypox virus. However, when studying these "monkeypox" virus isolates, Marennikova et al. (1971) showed that one of them resembled variola virus and was clearly distinguishable from monkeypox virus. Gispen & Brand-Saathof (1972) confirmed this result with 2 of the 3 "monkeypox" virus isolates and in the same paper observed that a white pock mutant that they recovered from monkeypox virus resembled the parental virus in most properties and was clearly distinguishable from variola virus. To discriminate between them, the variola-virus-like strains were called "wild white" poxvirus, or "whitepox" virus.

Between 1971 and 1975 Marennikova and her colleagues at the Moscow Research Institute for Viral Preparations reported that they had recovered white-pock-producing orthopoxviruses from the tissues of 4 species of animals shot in Zaire (chimpanzee, monkey, sun squirrel and multimammate rat). All isolates resembled Gispen's "wild white" poxvirus (and thus variola virus) in all the biological properties that they could test. For purposes of reference, the term "whitepox" virus was used to include all six of these viruses (Arita & Henderson, 1976).

In 1978–1979 Marennikova and her colleagues reported that they had obtained "whitepox" by inoculating monkeypox virus on the chorioallantoic membrane and in hamsters. They called these isolates "stable white clones" or "white variants" of monkeypox virus.

In this way two terms came to be used by virologists associated with the smallpox eradication programme:

(1) White pock mutants—of rabbitpox, cowpox and monkeypox viruses; and
(2) "Whitepox" viruses—from normal cynomolgus monkey kidney cells, from apparently normal wild animals shot in Zaire, or found as "stable white clones" or "white variants" of monkeypox virus.

set ("Zaire isolates") comprises 4 strains of virus reported by workers at the Moscow Research Institute for Viral Preparations to have been recovered from the tissues of 4 different species of wild animal captured in Zaire between 1971 and 1975 (Table 30.2). The third set ("white clones") comprises several isolates made from preparations of monkeypox virus maintained at the Moscow Research Institute for Viral Preparations (Marennikova & Shelukhina, 1978; Marennikova et al., 1979).

Netherlands isolates

During 1964 and 1965 4 orthopoxvirus isolations were made from cynomolgus monkey kidney cells that were being used for the

Laboratory Contamination with Viruses

Bacteriologists are accustomed to the idea that unwanted organisms may occasionally find their way into culture media and multiply there. Indeed, the discovery of penicillin resulted from one such episode (Fleming, 1929). Similar accidents may occur with viruses, especially if manipulations are of the kind that produce aerosols. Only a few cases of the contamination of cultures have been reported (e.g., Andrewes et al., 1944). Another kind of environmental contamination is the accidental infection of laboratory workers (see, for example, Pike, 1979; Wedum et al., 1972), which is an indicator of the possibility of infection of laboratory cultures.

H. Mahnel (personal communication, 1984), concerned about the occasional occurrence of vaccinia virus plaques on "uninfected" cell monolayers, carried out tests with vaccinia and monkeypox viruses under conditions simulating those in the laboratory. The infectivity of tissue culture fluid dried on coverslips and stored in Petri dishes in the shade in the laboratory (temperature 20–23 °C) dropped from $10^{5.8}$ plaque-forming units per ml to $10^{2.8}$ plaque-forming units per ml in 12 days, but the dried material did not completely lose infectivity until the 6th week. He believes that the principal source of laboratory contamination of cultured cells arises from droplets of infected fluid drying on bench tops and in the dust of the laboratory.

Although the risk of cross-infection can be reduced by good microbiological technique, there is an ever-present possibility of the contamination of tissue cultures or eggs. Almost every laboratory manipulation is associated with some risk of producing aerosol particles that could contain virus. Dimmick et al. (1973) have drawn up a table listing the "spray factors" of various laboratory operations and accidents. Assuming that a viral suspension contains 10^7 pock-forming units per ml, it is possible to calculate the number of infectious aerosol particles released as a result of normal laboratory operations or minor accidents.

Operation	*Spray factor*	*Virions per m^3 of working area*
Blender opened 5 minutes after stop	$10^{-5.3}$/min	50
Pipetting, minimal bubbling	$10^{-6.3}$/min	5
Intranasal inoculation of mice	$10^{-7.3}$/min	0.5
Drop spilled from a height of 100 cm	$10^{-6.3}$	5
Removal of plug from test tube	$10^{-8.5}$	0.03

The only certain way of avoiding cross-infection with poxviruses is to use only one isolate at a time, within a glovebox facility or a biocontainment hood, and thoroughly sterilize the working area before handling another strain of virus.

Without special markers and laborious experiments, it was very difficult to "prove" that laboratory contamination had occurred, as Dumbell & Kapsenberg (1982) were able to do, but every experienced laboratory scientist who has worked with poxviruses can recall instances for which he or she believed that contamination was the most likely cause of an unexpected result.

Table 30.2 Details of the circumstances of the recovery in Moscow of "whitepox" viruses from wild animals captured in Zaire

isolation of viruses from human material in the diagnostic laboratory at the National Institute of Public Health, Bilthoven (Gispen & Kapsenberg, 1966). One strain (64-9411) was eventually diagnosed as monkeypox virus (see Chapter 29) and one strain (65-3993) was vaccinia virus, recovered together with herpes simplex virus from vesicle fluid (J. G. Kapsenberg, personal communication, 1981). The other 2 strains (64-7255 and 64-7275) were first regarded as monkeypox virus (Gispen & Kapsenberg, 1966); subsequently Marennikova et al. (1971) reported that strain 64-7275 differed from monkeypox virus in a number of biological characteristics but could not be differentiated from variola virus. This finding was confirmed by Gispen & Brand-Saathof (1972), who later showed that these 2 strains differed from monkeypox virus and resembled variola virus in tests for virus-specific antigens (Gispen & Brand-Saathof, 1974). Subsequently Esposito et al. (1978) and Dumbell & Archard (1980) demonstrated that the DNA electropherograms and restriction endonuclease maps of these 2 isolates, while differing slightly from those of some other strains of variola virus, identified them unequivocally as members of the variola virus species.

Although in a comment at the International Symposium on Smallpox Vaccine, Bilthoven, in 1972 Gispen (1973) stated, correctly, that "there was no known possible contact *of these animals* [from which the kidney cell cultures infected with whitepox virus had been derived; our italics] with pox viruses", it subsequently transpired that on 2 occasions in September 1964, material from smallpox patients from Vellore, India, had been handled in the diagnostic laboratory in which the cynomolgus kidney cells were being used. Skilful detective work by Dr Kapsenberg identified the passage transfer of cell cultures during which viral contamination could have occurred; there was a temporal coincidence with manipulation of the cynomolgus cells in question and cells infected with material from the smallpox cases. That laboratory contamination was the explanation was demonstrated with a high degree of confidence by the fact that the biological properties and restriction endonuclease electropherograms of strains 64-7255 and 64-7275 were identical with those of 1 of the 2 variola viruses isolated from the Vellore cases, which were slightly different from those of most

other strains of variola virus (Dumbell & Kapsenberg, 1982).

Zaire isolates

Five strains of poxvirus were recovered from the kidneys of wild animals captured in Zaire and processed in the Moscow Research Institute for Viral Preparations. Four were identified as "whitepox" viruses (Table 30.2), and the fifth (MK-10-73) as vaccinia virus.

Pocks were always scanty on the membranes on which they were first observed. All subsequent investigations, including detailed DNA mapping carried out independently in 2 laboratories (St Mary's Hospital, London, England, and the Centers for Disease Control, Atlanta, USA), have confirmed that the 4 strains of "whitepox" virus are indistinguishable from variola virus.

A priori it is difficult to believe that a virus which has such a narrow host range as variola virus should be recovered from the tissues of 2 species of healthy rodents that are common in and near tropical forest villages in Central Africa, the rat *Mastomys natalensis* (syn. *coucha*) and the sun squirrel *Heliosciurus rufobrachium*. This view is reinforced by the observation that variola virus and "whitepox" virus strain RZ-38-75, said to have been recovered from *Mastomys natalensis*, multiplied very poorly after intraperitoneal inoculation in that animal (T. Kitamura, personal communication, 1978).

Since the Moscow Research Institute for Viral Preparations functioned as one of the two WHO collaborating centres that carried out laboratory diagnosis of smallpox for the Intensified Smallpox Eradication Programme (see Chapter 10), specimens of variola virus were constantly being handled in the laboratories in which the "whitepox" virus isolates were made. The universal experience of laboratories which have handled orthopoxviruses, including the experience of the National Institute of Public Health in Bilthoven, just described, attests to the difficulty of avoiding occasional cases of laboratory contamination.

Two features caution against too ready an acceptance of this explanation for all the Moscow "whitepox" virus isolates: the positive orthopoxvirus antibody titres found in 3 of the 4 animals whose tissues apparently contained virus, and the reported reisolation of virus from part of the stored kidney of Chimp 9 (from a chimpanzee) and from a ground-up suspension of kidney tissue of RZ-38-75 (from a sun squirrel). However, investigations of the ecology of monkeypox in Zaire, reported in detail in Chapter 29, suggest that there may be several orthopoxviruses circulating among wild animals in the forests of Zaire; the antibody results signify prior infection with an orthopoxvirus, not necessarily variola virus or even monkeypox virus. Reisolation is the standard procedure for confirming the validity of suspicious isolates, but to be acceptable it must be carried out with material that had not been processed in the laboratory at the time the first isolation was made. This situation did not apply to the material from *Heliosciurus*, but it did apply to the kidney of the chimpanzee (S. S. Marennikova, personal communication, 1983), a species which is known to be susceptible to infection with variola virus (Kalter et al., 1979). However, Chimp 9 was one of the two "whitepox" viruses tested by Dumbell & Huq (1986), who showed that it resembled Asian rather than African strains of variola virus in its biological characteristics (see below).

The number of strains of variola virus whose DNAs have been mapped by restriction endonuclease cleavage is too small to allow any conclusions to be drawn about the

Plate 30.2. Farida Huq (b. 1942) undertook graduate studies with Dr K.R. Dumbell in London before assuming responsibility for the smallpox laboratory in Dhaka, Bangladesh. Besides carrying out diagnostic work she studied the viability of variola virus in scabs under tropical conditions.

Table 30.3. The distribution of 4 independent biological properties characteristic of Asian variola major virus according to the geographical origin of the strains tested[a]

Source of variola virus strains	Number of biological properties[b]				
	0	1	2	3	4
Indian subcontinent	0	0	0	5	13
Western Africa	4	2	1	0	0
Zaire	4	1	0	0	0
Whitepox viruses[c]	0	0	0	0	2

[c] Chimp 9 and MK-7-73 (see Table 30.2).

relationship of these "whitepox" isolates to other strains of variola virus from western or central Africa. However, comparison of 4 biological characteristics of 32 variola virus strains originating from the Indian subcontinent, western Africa or Zaire with those of the "whitepox" strains Chimp 9 and MK-7-73 (purportedly recovered from primates captured in Zaire) showed that these "whitepox" isolates had the same group of biological characteristics as the great majority of strains of Asian variola major and were quite unlike 12 strains of variola virus derived from western Africa or Zaire (Table 30.3). Dumbell & Huq (1986) concluded that these two "whitepox" viruses (Chimp 9 and MK-7-73) "did not enter into the chains of transmission which maintained human variola in West Africa".

In summary, and in view of the results set out in the next section, it seems likely that the "whitepox" virus isolates made in Moscow were due to laboratory contamination with Asian strains of variola virus.

"White clones" ("variants") of monkeypox virus

Seeking an explanation for the recovery of whitepox virus strains from the tissues of several species of wild animals from Zaire, Dr Marennikova postulated that they may have arisen as "white clones" of monkeypox virus, which was known to infect non-human primates in that country (see Chapter 29). Several investigators (Bedson, 1964; Gispen & Brand-Saathof, 1972) had previously isolated white pock mutants of monkeypox virus, but found them to resemble the parental virus rather than variola virus in properties such as species-specific antigenicity (Gispen & Brand-Saathof, 1974) and the pattern of their intracellular polypeptides (Harper et al., 1979). In this section attention will be focused on two reports of what Marennikova and her colleagues call "stable white clones" recovered from stocks of monkeypox virus that had been maintained for several years in the Moscow laboratory. All these "white clones", recovered either as pocks on the chorioallantoic membrane (Marennikova et al., 1979) or from organs of hamsters that had been inoculated some weeks earlier with the monkeypox virus material (Marennikova & Shelukhina, 1978), were identical; they were indistinguishable by biological tests from the Zaire and Bilthoven "whitepox" virus isolates, which have now been shown to be variola virus.

In view of the importance of this claim as to the origin of "whitepox" viruses, from the point of view of the feasibility of smallpox eradication, the WHO Smallpox Eradication unit organized a series of studies to determine whether these results could be independently confirmed. The studies in question were conducted in the WHO collaborating centres in London and Atlanta. Dumbell & Archard (1980) reported on 17 white pock mutants recovered on the chorioallantoic membrane from their own stocks of the Copenhagen strain of monkeypox virus and compared their biological characteristics and DNA maps with those of wild-type monkeypox virus, the Harvey strain of variola virus, the 2 Netherlands "whitepox" isolates, 2 Zaire "whitepox" viruses and 2 "white clones" recovered from monkeypox virus by passage through hamsters (Marennikova & Shelukhina, 1978). All the "whitepox" viruses and the 2 "white clones" had DNAs that were virtually identical with that of variola virus (Table 30.4). The monkeypox white pock mutants differed among themselves in both genome maps and biological properties (Table 30.5). Some, which had been recovered after serial passage of the monkeypox virus stock at high concentrations, showed complex genome changes, with deletions and transpositions; some showed minor differences from wild-type monkeypox virus, others were indistinguishable from it. In all cases the DNA maps were readily distinguishable from those of variola and "whitepox" viruses (Fig. 30.2).

[c] Mutants described by Esposito et al. (1985).
[d] Not tested.

Studies at the Centers for Disease Control (CDC), in Atlanta, confirmed the results obtained in London. Four white pock mutants—2 derived in Atlanta from CDC stocks of a monkey strain of monkeypox virus (Copenhagen) and 2 from their stocks of a human strain (Congo)—resembled monkeypox virus in both their DNA maps (Table 30.4) and their biological characteristics (Table 30.5). On the other hand, Esposito et al. (1985) reported that isolations of white pock mutants made by a member of the staff of the Moscow laboratory working in the CDC, but not using the glovebox facility, had

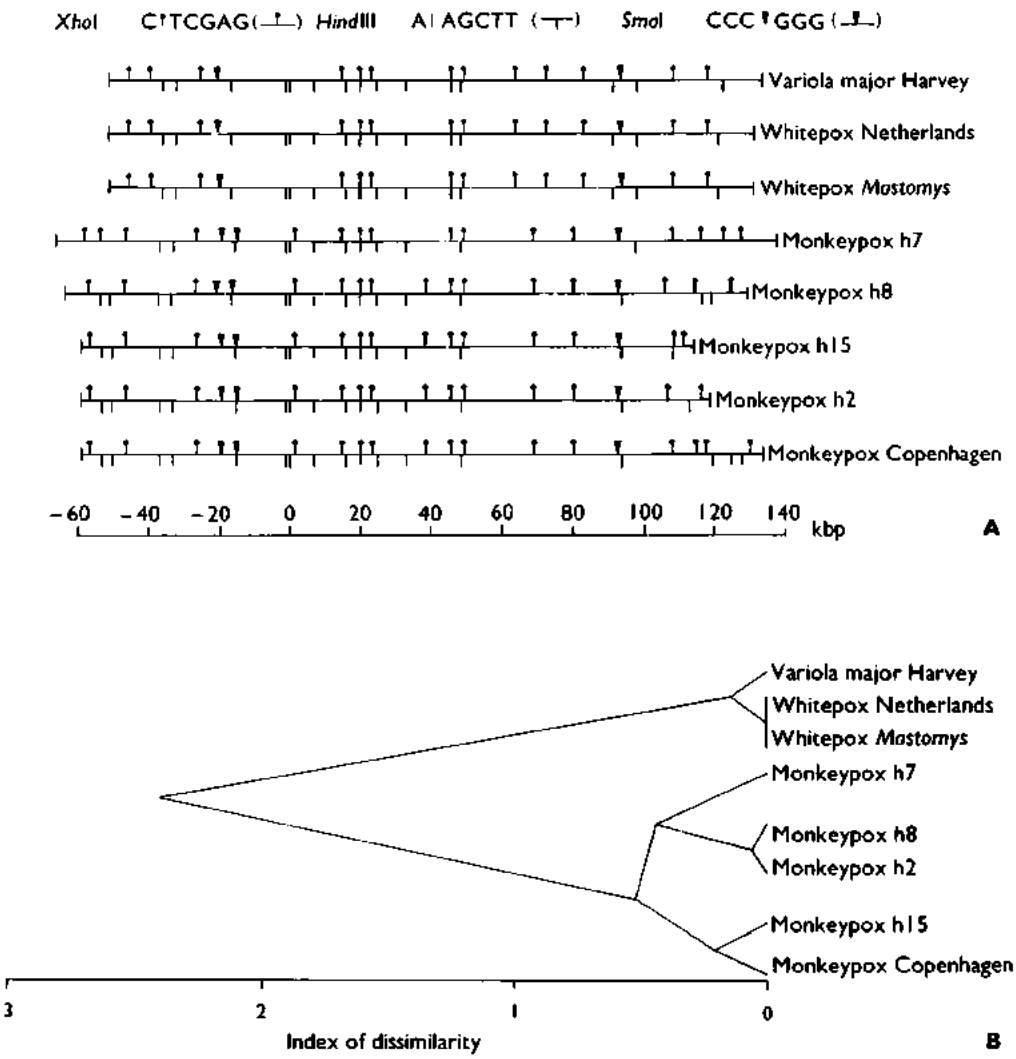

Fig. 30.2. **A**: Physical map locations of *HindIII*, *XhoI* and *SmoI* cleavage sites in DNA from variola, "whitepox" and monkeypox viruses: Harvey strain of variola major, Netherlands "whitepox" 64-7255, "whitepox" *Mastomys* (= Moscow RZ-10-74), Monkeypox Copenhagen, and 4 white pock mutants derived from Monkeypox Copenhagen (Monkeypox h2, h7, h8 and h15. (Based on Dumbell & Archard, 1980.) **B**: Dendrogram illustrating the similarities and differences between these DNAs. Presence, absence or impossibility (because DNA molecules were too small) of coincidence of the cleavage sites illustrated was determined after aligning all maps on a common *HindIII* cleavage site about 60 kilobase pairs from the left-hand end of the molecule; the results were then analysed as described by Gibbs & Fenner (1984), using the squared Euclidean metric (number of attributes = 60). The "index of dissimilarity" has no absolute value, but illustrates the close resemblances between the DNAs of variola virus and the 2 "whitepox" viruses, and between the DNAs of monkeypox virus and the 4 mutants derived from it.

biological properties and DNA maps identical with those of variola virus. On the basis of a detailed analysis of all the data, these authors concluded that "the spontaneous production of whitepox from monkeypox virus would be genetically impossible", and that "the whitepox viruses recovered from monkeypox virus stocks had originated exogenously".

This work was carried out in 1978 and 1979, and in an assessment of the situation in 1980, on the eve of the declaration of smallpox eradication by the Thirty-third World Health Assembly, Fenner et al. (SE/80.154) concluded that "the variety of mutants derivable from monkeypox in the laboratory does not present any greater threat to the success of smallpox eradication than

does the existence in nature of orthopoxvirus species other than variola".

Conclusion: There is No Animal Reservoir of Variola Virus

The evidence reviewed in the foregoing pages suggests that smallpox was indeed a specifically human disease. Variola virus is a distinctive species; DNA analysis of strains of widely differing virulence for man (variola major and variola minor viruses) shows that their DNAs are very similar, but quite different from those of any other species of orthopoxvirus or from those of any viral mutants that have been recovered under conditions that precluded the possibility of laboratory contamination. Variola virus has a narrow host range; besides man the only animals in which serially transmissible infection is known to have occurred are chimpanzees, orang-utans and one species of monkey. The "whitepox" viruses isolated from a variety of animals between 1964 and 1975 are strains of variola virus. The most acceptable explanation is that all of them were laboratory contaminants.

The laboratory evidence must be seen in both epidemiological and evolutionary perspectives. Apart from known contaminants (the Bilthoven viruses), the 4 "whitepox" viruses were recovered from areas of Zaire in which human monkeypox occurred and continues to occur more frequently than anywhere else in the world. The isolation rate in Moscow for the recovery of a virus from wild animals was high (4 out of 61 animals from the areas that were tested, compared with none of 930 animals from the area tested by the Centers for Disease Control, Atlanta, primarily in a search for monkeypox virus). Since human monkeypox is a zoonosis and intensive surveillance in selected areas of Zaire between January 1982 and December 1984 revealed 210 cases of human monkeypox, of which 144 were thought to have an animal source (see Chapter 29), there is clearly the kind of contact between humans and animals in these tropical rain forests that would make infection of humans with variola virus likely, if indeed it occurred in the animals there. However, all cases of "suspected smallpox" in western and central Africa since 1970 that were due to orthopoxvirus infection have been shown by epidemiological and laboratory investigation to have been caused by monkeypox virus.

MATERIAL STORED BY VARIOLATORS

Variolation was a matter of concern as a source of outbreaks of smallpox during the operations of the Intensified Smallpox Eradication Programme in Afghanistan, Pakistan and Ethiopia (see Chapters 14 and 21). In addition, it was known that an outbreak in northern Yunnan Province in China in 1958 was due to variolation, 126 cases having occurred a year after the last known case in that subregion. Late in 1984 it was learned from Dr Jiang Yutu, in a personal communication, that there had been other outbreaks of smallpox in North China (Nei Monggol Autonomous Region (Inner Mongolia) and 2 nearby counties in Shanxi Province) which were ascribed to the activities of variolators and the first of which occurred some 6 years after the last reported cases of smallpox in these regions (see Chapter 8, Table 8.13; and Chapter 27). The explanation for these outbreaks (Jiang Yutu, 1985; and personal communications, 1984, 1987) appears to be that variolators in Shanxi and adjacent parts of Inner Mongolia continued to keep variolation material, stored with honey in sealed jars, and maintained its potency by annual passage in susceptible family members and by the addition of fresh material to the jars. The 1962–1964 and 1965 outbreaks were initiated by such variolated persons but the chains of transmission have not been elucidated. The occurrence of these outbreaks long after smallpox had been eradicated from China led to measures that eliminated this source of the disease and no case of smallpox has been recorded in the country since 1965.

Apart from these episodes in China, which did not come to the attention of WHO until 1984, major concern with the danger of variolators' material causing outbreaks of smallpox after the interruption of transmission centred on Afghanistan. Tests for viable virus in material collected from variolators there gave positive results in one sample 9 months after the material had been collected from a patient; all the others were negative long before this (see Chapter 14, Table 14.15). All the variolators who were questioned about their mode of operation said that, if it was available, they preferred to use fresh material (from a recent case), and as smallpox became less common they usually added fresh

scabs or pustule fluid to their stored material whenever possible. One sample tested contained herpesvirus particles, doubtless derived from a misguided attempt to keep viable stocks for variolation.

Within scabs, out of sunlight and in cool surroundings, viable variola virus can survive for several years. However, variolators' material was never held under such "ideal" conditions, and tests showed that it rarely contained viable virus for as long as one year. The major factor that now further reduces the risk presented by variolation material as a source for the recurrence of smallpox is the passage of time. The last cases of smallpox in countries in which variolation was widely practised during the 20th century occurred in 1965 (China), 1973 (Afghanistan), 1974 (Pakistan) and 1976 (Ethiopia). In Ethiopia, in which smallpox was the most recently endemic, variolation was usually carried out with fresh pustular material when an epidemic threatened, and material was rarely stored (see Chapter 21). The lapse of 10–20 years since the last cases of smallpox in the other countries has reduced the incentive to practice variolation, and even under the best storage conditions (short of refrigeration) the viability of variola virus gradually falls off. The absence of any recurrence of smallpox due to variolation for 10 years or more gives reason to believe that this practice will never again initiate an outbreak of smallpox.

LABORATORY STOCKS OF VARIOLA VIRUS

While the existence of an animal reservoir was without doubt the most serious risk to the achievement of the permanent eradication of smallpox, the existence of stocks of variola virus in laboratories constituted and, while such stocks of variola virus are retained, will continue to constitute a real though remote risk that further cases of human smallpox could occur.

Changes in Attitude towards Work with Variola Virus

The handling of variola virus has been subject to progressively stricter control over the years. In Jenner's day variolation was extensively practised, with no control or supervision of the way in which the virus was handled or administered and usually little or no check on the movements of the inoculated subject. Jenner, and vaccinators after him, did not hesitate to test the efficacy of vaccination by challenge inoculation with variola virus. Variolation, which involved the uncontrolled distribution of variola virus, was not made illegal until 1840 in Great Britain and 1870 in British India, and, as has been noted above, it was widely practised in Afghanistan up to the early 1970s and in Ethiopia until as late as 1976.

Pathologists who were interested in smallpox and vaccinia experimented with variola virus as a matter of course and with few precautions, secure in the protection afforded by a previous attack of smallpox or by repeated vaccination. The attitude of virologists towards handling the virus in the 1950s is revealed in the report on experiments on viability by Wolff & Croon (1968), who stored scabs from a patient in an envelope in a cupboard in their laboratory in 1954, and tested one scab annually for the presence of variola virus. At that time reliance was placed on vaccination and revaccination of all laboratory workers, good laboratory technique, and careful disposal and sterilization of infected material and glassware. Biohazard hoods had not then been invented and work with variola virus was carried out on open benches, although special cubicles were sometimes used when the virus was handled on a large scale. In countries in which smallpox was still endemic—for example, in India, Africa and South America—material for smallpox diagnosis was regarded, with reason, as being less hazardous to handle in the laboratory than, for example, material containing the tubercle bacillus.

Safety Regulations in Laboratories Holding and Handling Variola Virus

Recommendations made in 1969 and 1974

The first comment by WHO on precautions to be taken when handling variola virus in the laboratory appeared in the publication *Guide to the Laboratory Diagnosis of Smallpox for Smallpox Eradication Programmes* (World Health Organization, 1969a), which was prepared by 2 virologists with extensive experience in handling variola virus (Dr A. W. Downie and Dr J. Noble) and 2 epidemiologists (Dr I. Arita and Dr A. S. Benenson). The guide suggested that methods

that ensured high standards of microbiological safety should be employed and that everyone who might have occasion to enter the laboratories should be vaccinated annually. However, recommendations on physical containment were relatively simple (Fig. 30.3A) —a separate room entered via a vestibule, but no provision for sterilization of the ambient air, for biosafety hoods or for 2-way autoclaves.

Following the accidental infection of a laboratory worker in London in 1973 (see Chapter 23), virologists in the United Kingdom interested in smallpox drew up a code of safety practice (Cox, 1974). This code formalized arrangements for vaccination and revaccination and for the first time suggested the use of safety cabinets and emphasized the risk of aerosol production during laboratory manipulations. It recommended that animal inoculation should be performed only in "institutes with specially designed facilities".

During the middle and late 1970s laboratory safety in general became a much more prominent issue. There were several reasons for this, including deaths from Lassa and Marburg fevers contracted in the laboratory, the invention and development of sophisticated methods for the physical containment of infectious agents, and the widespread concern for laboratory safety engendered by the introduction of recombinant DNA technology.

Safety measures recommended by WHO in 1977

Because of this change in attitude towards laboratory safety, and the imminent achievement of the global eradication of smallpox, the WHO Smallpox Eradication unit in August 1977 organized a meeting of experts to discuss safety measures in laboratories retaining variola virus. The expert group included senior staff from the WHO collaborating centres for smallpox research in London, Tokyo, Moscow and Atlanta, and Dr J. H. Richardson of the Office of Biosafety at the Centers for Disease Control, Atlanta. Recommendations for physical containment and the packaging and shipping of specimens were drawn up (SME/77.2). Although smallpox laboratories in the WHO collaborating centres had to a greater or lesser degree already installed the physical facilities outlined in this report, it was the first official statement by WHO prescribing the kinds of physical containment necessary for holding and handling dangerous pathogens, with strict control of entry, facilities for air and biowaste sterilization, gloveboxes (see Plate 30.3), 2-way autoclaves and biological safety cabinets (see Fig. 30.3 B), as well as the usual stipulations about vaccination and regular revaccination.

The laboratory-associated outbreak in Birmingham, England, in August-September 1978 (see Chapter 23) caused serious concern among the general public and the health authorities of many countries. Reacting to this concern, the WHO Smallpox Eradication unit arranged a meeting in Geneva in April 1979 to study the safety measures adopted in laboratories then retaining stocks of variola virus and to discuss the destruction or transfer of the virus if the laboratory concerned was not using it for research. Government officials from the 7 countries and scientists from the 8 laboratories that then retained variola virus attended the meeting and reviewed the situation (WHO/SE/79.137), with special reference to the role of national authorities in maintaining safety standards. They agreed on modifications to the WHO recommendations for physical containment in accordance with further experience with such facilities; these were issued as WHO document SME/77.2 Rev. 1 and later reproduced in Annex 9 to the final report of the Global Commission (World Health Organization, 1980). Eventually, in March 1983, the WHO Committee on Orthopoxvirus Infections, noting that the Organization, through its Special Programme on Safety Measures in Microbiology, had published a book entitled *Laboratory Biosafety Manual* (World Health Organization, 1983) which provided a standard reference for a maximum containment laboratory, recommended that WHO document SME/77.2 Rev. 1 should be withdrawn.

Over the several years after the 1977 meeting steps were taken to ensure that the facilities in the WHO collaborating centres in Atlanta and Moscow were upgraded, and new laboratories were built in each centre. It is not widely appreciated how difficult it is to build a highly secure biocontainment laboratory and maintain it properly, particularly in relation to airflow. For various reasons it took more than 3 years to construct and test the new facilities in both centres, and all research work with variola virus ceased during this period, although studies with variola virus DNA, which is not infectious, continued in

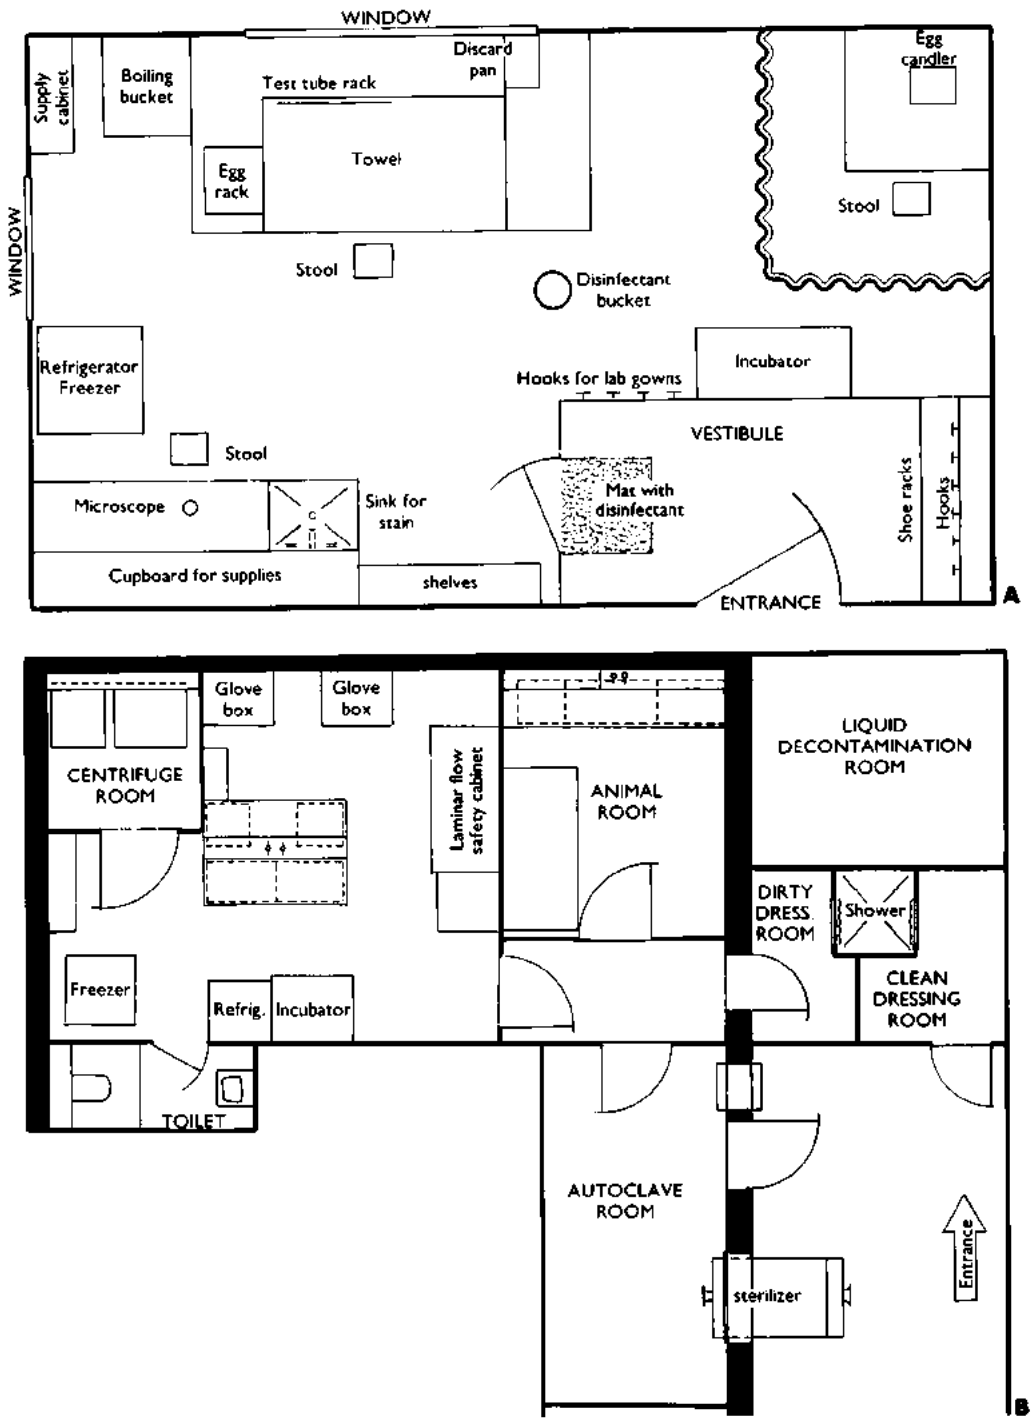

Fig. 30.3. **A**: Suggested layout for a smallpox diagnostic laboratory as conceived in 1969. (From World Health Organization, 1969a.) **B**: Plans of part of the smallpox laboratory at the Centers for Disease Control, Atlanta, GA, USA, drawn in 1979. Note the much more stringent physical containment, with access and exit of personnel through a shower and access of materials through a decontamination box and exit via a two-way autoclave. Effluent air is passed through a HEPA (high-efficiency particulate air) filter and liquid and solid wastes are sterilized by heat treatment. Within the laboratory, virus is handled within a glovebox or under a laminar flow hood and special precautions are taken with centrifugation and other laboratory manipulations.

Plate 30.3. Glovebox facility (Class III biological safety cabinet) in use at the WHO collaborating centre in the Centers for Disease Control, Atlanta, GA, USA. To eliminate the risk of laboratory contamination, only a single specimen was handled at a time and the cabinet was sterilized with peracetic acid before another specimen was introduced.

Atlanta. Between August 1981 and March 1983 urgent diagnostic work on specimens from cases of suspected smallpox or monkeypox was carried out in the Special Viral Pathogens Laboratory at the Centers for Disease Control in Atlanta. Work with variola virus in other laboratories that held the virus in 1979 (see Table 30.6) ceased at various times between 1979 and 1982, when their stocks were transferred to a variola virus storage facility in the Centers for Disease Control.

Two of the 19 recommendations of the Global Commission (World Health Organization, 1980), all of which were accepted by the Thirty-third World Health Assembly in May 1980, dealt with the inspection of WHO collaborating centres approved to hold and handle variola virus. It was recommended that each laboratory that still held variola virus (whether or not a WHO collaborating centre) should report annually to WHO on its safety measures and should be inspected periodically by WHO. The implementation of these recommendations has been described in Chapter 28.

Justification for the Retention and Use of Variola Virus

The potential danger of experimentation with variola virus in a laboratory not equipped with full microbiological security facilities was dramatically demonstrated by the Birmingham outbreak, discussed in Chapter 23, some 10 months after the last known case of naturally transmitted smallpox had been reported in Somalia. In response to the concern expressed by many WHO Member States, a consultation of public health and virological experts who were not themselves involved in laboratory work with variola virus was convened in Geneva in February 1979. Its report (WHO/SE/79.135) was subsequently used by the Global Commission for the Certification of Smallpox Eradication in formulating its final report (World Health Organization, 1980). In essence, the consultation recommended that research with variola virus was justified, at least for the next 3 years, because of the problem then posed by reports of the isolation of "whitepox" viruses and the work on DNA mapping that provided a

The Maximum Containment Laboratory

The 1977 report and the *Laboratory Biosafety Manual* recommended the use of a maximum containment laboratory for the handling of dangerous pathogens. In essence, this is a room or a few rooms (or, for veterinary laboratories handling exotic viruses, a complete laboratory building) in which special measures are taken for the physical containment of dangerous pathogens, to minimize the risk of their escape outside the laboratory. The principal features of a maximum containment laboratory are:

(1) *Controlled access.* The entry and exit of personnel and supplies are through airlock systems. On entering, personnel put on a complete change of clothing, and they shower on exit before changing back into their street clothes.

(2) *Controlled air system.* Negative pressure is maintained by an individual supply and exhaust air mechanical ventilation system with HEPA (high-efficiency particulate air) filters in the exhaust (and in the intake when necessary).

(3) *Decontamination of effluents.* All effluents from the maximum containment laboratory are rendered safe, including the shower water.

(4) *Sterilization of waste and materials.* A double-door pass-through autoclave is provided.

Properly installed, operated and maintained, these arrangements should prevent the escape of dangerous pathogens from such a laboratory. To protect personnel from infection and to minimize the risk of contamination of apparatus and cultures, an additional facility can be operated within the maximum containment laboratory. This is called the *primary containment facility*, of which there are 3 forms:

(1) a fixed "Class III" biosafety cabinet (Plate 30.3), in which material is handled via glove ports and all effluent air is passed through a HEPA filter,

(2) a flexible-film plastic equivalent of a Class III biosafety cabinet, or

(3) a positive-pressure ventilated suit, operated only in a special laboratory which provides a decontamination shower for personnel leaving the risk area.

The WHO collaborating centre in Atlanta handled all specimens of known or suspected variola virus within a Class III biosafety cabinet. One specimen was handled at a time and the cabinet sterilized with peracetic acid before another specimen was introduced. This practice enabled that laboratory to avoid completely any cases of laboratory contamination of cultures by its personnel, throughout its operations in smallpox diagnosis and research.

method of at least partially solving this problem. In January 1979, the WHO Executive Board had asked the Secretariat to recount what measures were being taken in response to the Birmingham outbreak. The Smallpox Eradication unit was able to inform the Board of the proposed consultation and the anticipated meeting on laboratory safety measures, mentioned in the previous section, which were designed to deal with the essence of the problem—namely, whether further research with variola virus was necessary and, if so, whether the laboratories in which such work was undertaken were microbiologically secure.

Reduction in the Number of Laboratories Retaining Variola Virus

The possibility of escape of variola virus from either of the two high-security laboratories that now retain it is extremely remote. But in 1976, as global smallpox eradication appeared imminent, stocks of the virus were held by many more than these two laboratories; in fact, no one knew how many more. It was reasonable to argue that the smaller the number of laboratories holding variola virus, the lower would be the risk of the virus escaping. The Twenty-ninth World Health Assembly, in May 1976, requested "all

Philosophical Considerations regarding the Destruction of Variola Virus

From time to time commentators in scientific journals have questioned the moral rectitude of destroying all known stocks of variola virus, on the grounds that man should not knowingly cause the extinction of any living thing. With the cloning of variola virus DNA this raises some interesting philosophical problems. Are variola virions, in an ampoule, "living things"? In fact they are inert until their genetic potential can be expressed, and the only "natural" form of living variola virus would be that found in a human being, since man was the only known host of the virus. Presumably, the periodic occurrence of cases of smallpox is not what conservationists have in mind when they argue that variola virus stocks should never be totally destroyed.

The other problem is whether the cloned fragments of variola virus can be regarded philosophically as still constituting the essence of life of that virus. Certainly, molecular biologists are, or soon will be, able to produce all the known viral products from such cloned fragments. They could even, with considerable (albeit misguided) effort, reconstitute the intact variola virus DNA molecule and thus by laboratory manipulations, the virus itself.

When viewed against the regrettable but wholesale extinction of species that results from human interventions in natural ecosystems, concern about the preservation of variola virus seems to us to be misplaced. The only criterion by which to judge the necessity for the preservation of the virus, we believe, is whether it is necessary for scientific work.

governments and laboratories to cooperate fully in preparing an international registry of laboratories retaining stocks of variola virus" but, at the same time, urged all laboratories which did not require such stocks of variola virus to destroy them (resolution WHA29.54). This resolution followed inquiries that the WHO Smallpox Eradication unit had addressed in 1975 both to governmental authorities and to the directors of 823 laboratories included in the WHO World List of Virus Laboratories. The unit had also scanned the *Index medicus* in search of references to papers on variola virus published from laboratories during the previous few decades and had written to the directors of these laboratories to find out whether they held stocks of the virus. This information having been obtained, laboratories other than the WHO collaborating centres in Atlanta and Moscow and the WHO laboratories for poxvirus research were asked to destroy their stocks or transfer them to one of the two WHO collaborating centres. Governments were asked to inform WHO of the response to this request. Prior to this, the Director of the National Smallpox Eradication Programme in India had carried out a similar survey in that country and reported that by the end of 1976 all stocks of variola virus in laboratories in India had been destroyed (Basu et al., 1979). The situation in the 6 WHO regions in 1975 and in July 1977 is shown in Table 30.6.

Some noteworthy inferences can be drawn from this table. First, the response from both national authorities and laboratory directors was remarkably comprehensive. Apart from China, the countries that failed to respond were small in size and population and were known not to have a laboratory that had ever handled variola virus. Secondly, there were no fewer than 75 laboratories, several in each WHO region, that were then holding variola virus. Indeed, the real figure was somewhat higher, for it is known that virologists in several laboratories discovered that they did still possess variola virus, after having, in good faith, declared to the contrary; in such instances, the stocks were privately destroyed or taken to the nearest WHO collaborating centre for destruction. This widespread possession of stocks of variola virus is not surprising. Smallpox was endemic in several populous countries and importations into Europe, especially, had occurred in the recent past. In order to have "controls" for the

Table 30.6. Laboratories holding variola virus stocks in 1975 and the reduction in this number by July 1977, in response to requests from WHO

WHO region	Number of countries		Number of laboratories		By July 1977	
	Information sought	Responded	Responded to WHO	Holding variola virus in 1975	Destroyed or transferred variola virus	Retained variola virus
Africa	46	43	15	5	4	1
Americas	34	34	506	18	13	5
South-East Asia	11	11	57	13	13	0
Europe	36	36	185	29	19	10
Eastern Mediterranean	23	23	25	3	3	0
Western Pacific	31	29	35	6(7)[a]	5	1(2)[a]
Total	181	176	823	74(75)	57	17(18)

[a] Although China did not respond to the WHO letter of request, stocks of variola virus were then held at the Institute for the Control of Drugs and Biological Products, Beijing.

laboratory diagnosis of agents that they rarely handle, such as variola virus, virologists usually keep strains of these agents in their deep-freeze cabinets, for comparison with a suspicious isolate. Provided that their staff were regularly vaccinated and used good microbiological techniques, laboratory directors rightly regarded variola virus as less dangerous to handle than other agents sometimes encountered in diagnostic laboratories, such as various rickettsias. Further, even though smallpox might no longer be endemic in their country, it did not occur to them to destroy their laboratory stocks of variola virus. However, in response to the request from WHO, and bearing in mind the imminent world-wide eradication of smallpox, the directors of 57 of the 74 laboratories agreed to destroy or transfer their stocks of the virus.

Further reduction in the number of laboratories retaining variola virus, 1977–1983

With strong support from the Consultation on the Worldwide Certification of Smallpox Eradication, convened in Geneva in October 1977, and subsequently from the Global Commission, WHO continued to exert pressure to try to reduce further the number of laboratories holding variola virus stocks. In its final report in December 1979 (World Health Organization, 1980) the Global Commission recommended that: "No more than four WHO collaborating centres should be approved as suitable to hold and handle stocks of variola virus. A collaborating centre would be approved only if it had adequate containment facilities." Biocontainment standards had been laid down for such laboratories (SME/77.2 Rev. 1) and it was stipulated that each laboratory that held variola virus (whether it was a WHO collaborating centre or not) should be periodically inspected by WHO.

The Birmingham outbreak had a dramatic effect on the attitudes of the directors of several European laboratories, because of Professor Bedson's suicide and the extensive press coverage of the event (see Chapter 23). By the end of 1979, 5 of the remaining 8 European laboratories holding variola virus had disposed of their stocks (Table 30.7). Every year, at the World Health Assembly, Member States continued to express concern about variola virus stocks in laboratories. Gradually, the remaining laboratories holding such stocks responded to the requests from WHO to destroy or transfer their holdings, since with the eradication of smallpox the rationale for retaining stocks of the virus in any laboratory except the WHO collaborating centres in Atlanta and Moscow had disappeared. Scientific developments, notably the cloning of restriction fragments representing the total genome of variola virus (see Chapter 2), removed the last objections,

voiced by the Ministry of Health of South Africa (see Chapter 28, Plate 28.4), and by the end of 1983 only 2 laboratories in the world, both with newly completed biocontainment facilities, still held stocks of variola virus: the WHO collaborating centres at the Centers for Disease Control, Atlanta, and the Moscow Research Institute for Viral Preparations. At a meeting in March 1986, the Committee on Orthopoxvirus Infections recommended that all stocks of variola virus should be destroyed in October 1987, subject to approval by an *ad hoc* committee to be convened by WHO.

There remains the possibility that ampoules containing variola virus may still be stored in deep-freeze cabinets in laboratories, unknown to anyone in the laboratory or indeed in the country concerned. In most laboratories deep-freeze cabinets are rarely thoroughly cleaned out, though sections of them may be. As staff replacements occur and smallpox recedes into the past, all memories of working with variola virus will be lost. Two such incidents have come to the notice of the WHO Smallpox Eradication unit—the discovery of variola virus stocks in a laboratory in California in 1979 (Emmons, 1979), and in a laboratory in the United Republic of Tanzania during the visit of a WHO international commission in 1979 (J. G. Breman, personal communication, 1979). Another possible but unconfirmed example was described in London in December 1985. The dangers posed by such forgotten material are very small provided the laboratory carries out the recommended safety measures—namely, the destruction by autoclaving of any unlabelled ampoules or any ampoules labelled "variola virus" or "smallpox virus". This risk is hypothetical and in any case beyond the control of WHO or any other organization.

DELIBERATE RELEASE

The United Nations (1970) and a WHO group of consultants (World Health Organization, 1970) both included the smallpox virus among some 20 infectious agents that could be used in biological warfare. However, it ranked low in suitability compared with several other viruses, rickettsias and bacteria. As the WHO consultants commented:

"Because of the effectiveness of the vaccine and the relative ease with which it can be produced and administered, it is unlikely that smallpox virus would be used as an agent for a large-scale biological attack against countries systematically practising periodic vaccination.

"The variola virus, however, can easily be employed for acts of sabotage. Such acts, at selected points within a country, could have serious socio-economic effects unless efficiently dealt with by the public service."

That was written in 1969. At present no country is "systematically practising periodic vaccination" and as time passes the immunity of those who have been vaccinated will wane and populations will become completely susceptible.

In 1972 many countries of the world signed a convention outlawing the use of biological weapons in warfare (United Nations, 1984). Unfortunately, as international conventions are subject to infringement, this does not completely exclude the possibility that variola virus might be deliberately released as a means of warfare. However, the risk of any such act leading to the re-establishment of endemic smallpox should not be exaggerated. As has already been mentioned, smallpox spread comparatively slowly, by face-to-face contact. Unless the public health services had completely broken down, the existence of reserve stocks of vaccine (see Chapter 28) and the capacity for the production of vaccine to be rapidly reactivated would ensure the containment of any outbreak that followed a deliberate release of variola virus. With the cessation of vaccination and vaccine production, it will become increasingly difficult for any person or group contemplating the release of variola virus to assure themselves and their colleagues of protection against smallpox. A country's resumption of vaccination against smallpox would now be interpreted as a sign that it might be considering the use of variola virus for aggressive purposes.

Deliberate release, or the threat of it, by an individual or a group, as an act of sabotage or terrorism, is remote because access to the virus is so restricted. A document made public in December 1984 (Young & Lenarcic, 1984) describes tests made in 1964 and 1965 with aerosols containing *Bacillus subtilis* as a marker. The aerosols were experimentally but secretly produced in a crowded airport in Washington, DC, USA, to test the possibility that variola virus might be released in this way and thus cause "inexplicable" outbreaks of smallpox a few weeks later in the diverse

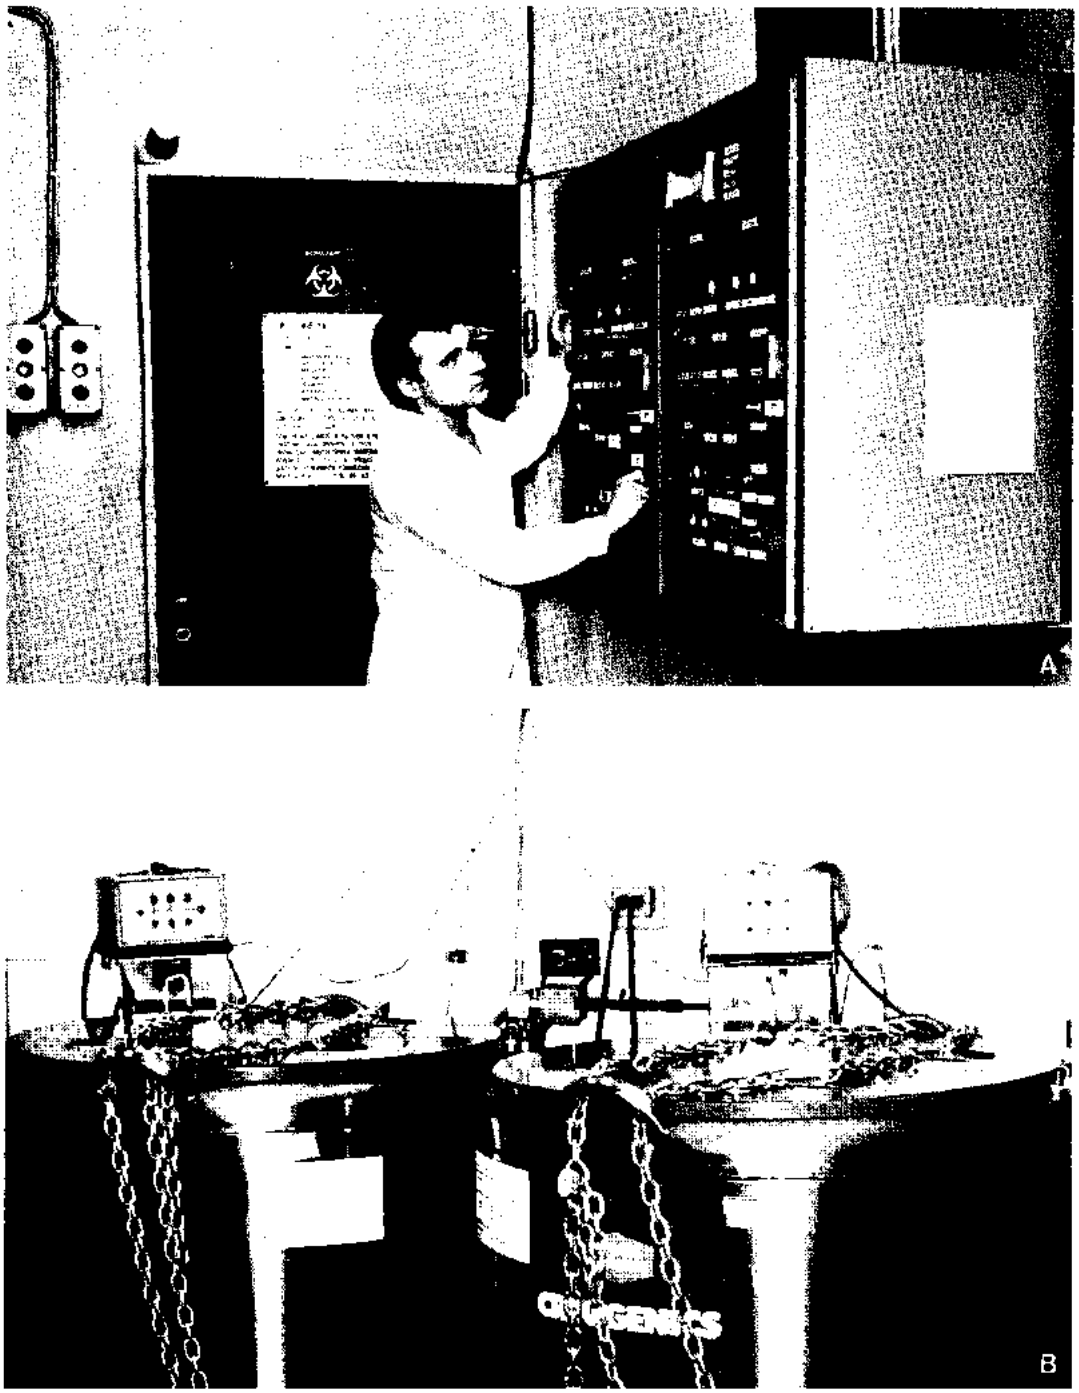

Plate 30.4. Only 2 laboratories in the world retain variola virus. **A**: Entrance to the maximum containment laboratory at the Moscow Research Institute for Viral Preparations, USSR. The door is kept locked and the key retained by the director. **B**: Variola virus is stored in two nitrogen vapour phase freezers in a maximum containment laboratory at the Centers for Disease Control, Atlanta, GA, USA.

places to which infected passengers travelled. The existence of such a possibility emphasizes the need for "military" as well as microbiological security in laboratories holding variola virus stocks. It is melancholy but perhaps realistic to suggest that the possibilities of biological warfare or terrorism now constitute the chief reason for holding reserves of vaccine and for maintaining epidemiological and laboratory expertise for the diagnosis and control of smallpox.

REACTIVATION AND EXCRETION OF VIRUS IN HUMANS

Viruses of many viral families persist for long periods in their hosts and viruses in some families are persistently (Arenaviridae) or intermittently (Herpesviridae) released into the environment. In addition, there is now a vast experience of the reactivation of latent herpesvirus infections (especially cytomegalovirus) in immunosuppressed persons, both those suffering from lymphoreticular diseases and those in whom chemical suppression of cell-mediated immunity is employed to prevent transplant rejection. In addition, steroid therapy has immunosuppressive effects and is associated with the reactivation of latent infections. Such therapies have now been practised for many years, in many countries, but no evidence has ever come to light of the reactivation of variola or vaccinia virus in immunosuppressed persons or those on steroid therapy. This supports the view elaborated in Chapter 3 that the poxviruses in general and variola and vaccinia viruses in particular do not produce persistent infections. This hypothetical possibility can be dismissed.

VIRAL PERSISTENCE IN THE ENVIRONMENT

Although it does not cause persistent infection in man, variola virus in scabs is, for a virus, very resistant to inactivation, especially at moderate temperatures and out of sunlight. Clothing and bedding from smallpox cases, which were often heavily contaminated with virus from salivary excretions and skin lesions, were an occasional source of outbreaks of smallpox among laundry workers (England and Wales, Ministry of Health, 1928b), and virus on imported raw cotton was suspected (without good reason, according to Dixon, 1962) of causing some outbreaks in England. However, the periods for which the virus survived to cause such infections were measured in days or weeks—not years.

Interred corpses have also been suggested as a possible source of infectious virus (e.g., Razzell, 1976), but the only evidence is anecdotal and comes from situations in which the possibility of infection by direct contact with cases of smallpox could not be excluded. The chance of viable variola virus surviving in corpses or coffins for the length of time that has elapsed since there were numerous smallpox deaths in temperate climates seems to us to be extremely remote, and the topic does not lend itself to scientific investigation.

A more bizarre possibility has been raised by Ewart (1983). Noting that bacteria can be preserved in permafrost for years (Boyd & Boyd, 1964), he suggested that active variola virus might still be preserved in interred bodies at York Factory on the shores of Hudson Bay in northern Canada. Six Indians were reported to have died of smallpox there in 1782, and it was the practice to inter the bodies of the dead in wooden coffins, which were placed in graves hacked out of the rock-hard earth of the permafrost. Most of this graveyard has now been eroded by the nearby Hayes river, but Ewart's contention is that variola virus could be preserved for long periods in some such way, somewhere in the Arctic. Whether viable variola virus could be released from a thawed corpse in such a way as to infect a susceptible person is a matter of conjecture. There is no scientific evidence on which to base a firm reply to speculations of this kind; one can merely say that the circumstances that would give rise to infection from such a source are exceedingly remote and impossible to study.

In whatever form the virus may persist in the environment, it is gradually inactivated, probably even at subzero temperatures (see Chapter 2). As the intervals since the last cases of smallpox in various parts of the world have extended from months to years and now to decades, this danger has lessened until it must now (1987) be considered to be very small indeed.

"TRANSFORMATION" AS A SOURCE OF VARIOLA VIRUS

The term "transformation" belongs to an era predating the development of microbial

BY COURTESY OF P. HERRLICH, 1967

Plate 30.5. Albert Herrlich (1902 – 1970), a leading German virologist and public health expert who was Director of the Institute for Comparative Tropical Medicine at the University of Munich. He was principal author of major books on the poxviruses and on vaccination and carried out a definitive study which showed that variola virus could not be "transformed" into vaccinia virus by passage in laboratory animals or cattle.

genetics. It now has a specific meaning: the alteration of the genome of a bacterium or eukaryotic cell by the incorporation of DNA from another source. As it used to be applied to the orthopoxviruses, the term was most frequently used to describe what was regarded as the conversion of variola virus into vaccinia virus, usually by passage through cows. It is impossible to achieve any such change when experiments are carried out under conditions that rigidly exclude the possibility of contamination (Herrlich et al., 1963).

The "white clones" of monkeypox virus, described above, were viewed by Marennikova and her colleagues as examples of the "transformation" of monkeypox into variola virus, but the evidence presented earlier argues strongly that these isolates arose because of the contamination of monkeypox virus stocks with variola virus. Likewise, there is no likelihood that either vaccinia or cowpox virus, of which suitable strains yield a great variety of white pock mutants, could give rise to variola virus by one or a few mutational steps. The clear-cut distinctions in the DNA maps of different species of *Orthopoxvirus* (see Chapter 2) preclude such a possibility.

GENERAL CONCLUSIONS

At this time, 10 years after the last known case of endemic smallpox, there is only one credible source from which another case of smallpox might arise—namely, the infection of a susceptible person with variola virus held in storage, either in a known location (stocks held in the WHO collaborating centres in Atlanta or Moscow) or in an unknown place. The latter could be either a stock maintained for possible use in microbiological warfare or a forgotten and possibly unlabelled specimen lying in a deep-freeze cabinet in a laboratory in which smallpox diagnosis or research was once performed. The likelihood of variola virus still surviving on scabs or associated with corpses or coffins in a form that might give rise to new cases of smallpox is now extremely remote.

Unless there were a complete breakdown of health services, so that countermeasures could not be mounted, the occurrence of an accidental case of smallpox could be readily contained, as was apparent in the Birmingham outbreak. Even microbiological warfare with variola virus should not present a significant hazard, in terms of the re-establishment of smallpox as an endemic disease. Its nature would be quickly recognized and countermeasures could be taken, calling if necessary on the personnel and materials provided by WHO as part of the "insurance policy" (see Chapter 28).

INTRODUCTION

Smallpox is the first disease to have been eradicated by concerted and determined action on a global scale. This was not achieved, however, until more than 175 years after Edward Jenner's demonstration of the use of cowpox as a vaccine and his assertion that it was capable of eliminating smallpox from the earth. The vaccine virus had been promptly and widely distributed in the world, and vaccination was eagerly taken up as a protection against a universally feared disease. However, smallpox continued to spread as sustained control efforts were beyond the capacity of many government and health structures and vaccinations were frequently unsuccessful, especially in warm climates. Through the nineteenth century and the early part of the twentieth, tens of millions of persons were affected, of whom one-fifth or more died; no country was entirely spared. A heat-stable vaccine perfected in the 1920s helped to increase the efficacy of vaccination in the tropics, but it was difficult to produce and was not widely used.

As health systems improved and more extensive vaccination could be undertaken, the industrialized countries became free of endemic smallpox by the 1950s but frequent introductions of the disease from less fortunate countries obliged them to maintain costly national vaccination programmes and to endeavour, not wholly successfully, to protect themselves by compelling all travellers to be vaccinated. In most developing countries, few people were successfully vaccinated and smallpox was essentially uncontrolled.

A change in the approach to smallpox control was proposed in 1958 at the Eleventh World Health Assembly by a delegate of the USSR, who advocated that all countries should collaborate in a global eradication programme. This was unanimously approved by the Health Assembly the following year. At the time, 60% of the world's population lived in areas in which smallpox was endemic.

The next 7 years saw some improvement in the quality of vaccine and some countries did become free of smallpox, but the disease continued to be widely prevalent and epidemics were frequent.

In 1966, the government delegates to the Nineteenth World Health Assembly decided that increased resources were required and allocated special funds for the Intensified Smallpox Eradication Programme that was to begin on 1 January 1967. They proposed a goal of 10 years for the achievement of eradication. This was an optimistic goal, given that some 10–15 million cases were then occurring annually in 31 endemic countries or territories with a total population of more than 1000 million; that a century and a half of vaccination had yielded only modest results; that programmes would have to be conducted in most of the world's least developed countries; and that civil strife, famine and floods could be expected as recurring problems. Nevertheless, the last endemic case of smallpox occurred just 10 years, 9 months and 26 days after this programme began.

The rapidity with which smallpox was finally eradicated after so long a history of persistent transmission suggests that lessons may be derived from the experience of the Intensified Programme to benefit other initiatives in health and development. Most significant is the extraordinary achievement which was possible when countries throughout the world collaborated in the pursuit of a common aim, making use of the structures of an international organization and acting under its auspices. This made it possible for the necessary resources to be mobilized and applied to better effect, for improved methods of management and epidemiology to be introduced and widely applied, for vital modifications in strategy to be communicated quickly, and for new and often very simple techniques suited to a country's capacities and characteristics to be introduced promptly. In consequence, international confidence and accord were strengthened and a foundation was laid for other community-wide health programmes.

The smallpox eradication programme, however, cannot serve as a template for other disease control or eradication campaigns. Every disease has its own epidemiological characteristics and methods for its control which require strategies and tactics specific to it. Also, the approach taken to the eradication of smallpox differed considerably from country to country and was continually modified to capitalize on an evolving understanding of smallpox epidemiology and to deal with different local conditions. It is important also to note that smallpox had a number of features which greatly facilitated eradication. Most important is the fact that its severity and ability to spread in any part of the world commanded both the attention and the concern of health authorities everywhere. It had no known animal reservoir; there were no long-term carriers of the virus; and a single attack of the disease conferred essentially life-long immunity. The detection of cases was comparatively simple because the rash was so characteristic and persons with subclinical infections did not transmit the disease. Finally, a highly effective, easily administered and surprisingly heat-stable vaccine, conferring long-term protection, was available by the time the Intensified Programme started. Taken together, these characteristics are unique in relation to human infections. Indeed, when the goal of eradication from all countries of the world was decided upon, its feasibility in most of the industrialized countries and some of the developing ones had already been demonstrated.

The earliest successes of the Intensified Programme were recorded in western and central Africa, where it was quickly shown that smallpox spread less rapidly and less easily than most people had thought and that the prompt detection and immediate containment of outbreaks were vitally important—facts that were to have a profound influence elsewhere. Although the 21 countries concerned included some of the world's poorest and most heavily infected, 17 of them became free of smallpox within 2 years of the start of the programme in January 1967 and the last cases were discovered in June 1970. In Brazil, too, surprisingly rapid progress was made and endemic smallpox was eradicated from the Western Hemisphere in April 1971.

The provision of adequate supplies of potent freeze-dried vaccine and the introduction of the simple bifurcated needle had a remarkable impact on the incidence of smallpox in most countries, even those in which it was not possible to mount fully satisfactory programmes. This was especially notable in eastern and southern Africa where, by the end of 1971, smallpox had been eliminated from all but 3 countries. Meanwhile, well-executed programmes, in which the detection and

The statue is now in the Executive Board lounge at WHO Headquarters.

containment of outbreaks were an important feature, stopped transmission in East Pakistan (now Bangladesh) in 1970 and in Indonesia and Afghanistan in 1972.

Serious setbacks to the global programme occurred or were first confirmed in 1972. That year Bangladesh became reinfected with the return of vast numbers of refugees immediately after the civil war that had led to its independence; Botswana was swept by an epidemic as a result of introductions of the disease from South Africa; and it became known with certainty that Iran had become endemic in 1970 and Iraq in 1971. By late 1973, however, special campaigns had succeeded in eliminating smallpox from all the reinfected countries except Bangladesh.

In September 1973, greatly intensified campaigns began in the 5 remaining endemic countries: 4 in Asia (Bangladesh, India, Nepal and Pakistan) and 1 in Africa (Ethiopia). In the densely populated areas of Asia, new methods and extra resources were required to cope with smallpox among people who moved much about their country and among the large groups of persons displaced by natural disasters or civil strife. The employment of tens of thousands of health staff in ingeniously devised, well-supervised search and containment programmes made it possible to stop transmission in Pakistan in 1974 and in the other 3 countries in 1975.

Late in 1975, personnel and additional resources were shifted to Ethiopia, then the only country in which smallpox remained endemic. There, the milder form, variola minor, spread tenaciously across a vast and sparsely settled area in which civil strife was widespread and there were few roads or health services. Using many local volunteers and helicopters in yet another type of campaign, the smallpox eradication staff contained the last outbreak, in the Ogaden desert, in August 1976. However, civil war and the exodus of many refugees brought about a reintroduction of the disease into Somalia. Experienced staff and resources from many countries were mobilized to deal with this emergency, and the world's last naturally occurring outbreak took place on 26 October 1977.

Endemic smallpox had been eradicated but the health authorities of the world had to be completely confident of this fact if they were to forego the security—and the expense—of vaccination. Close surveillance and special searches had therefore to be conducted in many countries for at least 2 years after the last known case had occurred before international commissions appointed by WHO could be asked independently to verify the absence of smallpox. Finally, a WHO Global Commission undertook a variety of studies to satisfy itself that eradication had been achieved throughout the world, its conclusions being endorsed by the Thirty-third World Health Assembly in May 1980.

No two national eradication programmes were exactly alike, and all changed as they evolved, different elements and approaches contributing to the ultimate success. In this chapter, we try to identify the most important principles and lessons which appear to have a bearing on other community-wide health activities. Many of the conclusions are shared by other authors (Dutta et al., 1975; Foster, 1977; Sharma, 1980; Yekutiel, 1981; Hopkins, 1985; Jarrett, 1985), but differences are also apparent as each author has approached the question with a different experience and from a different point of view. Finally, we attempt the difficult task of assessing the costs and the benefits of the eradication of smallpox.

PRINCIPLES AND LESSONS

Political Commitment, Coordination and Implementation

For a world-wide programme against a disease to be successfully undertaken, all countries must agree to it and there must be a mechanism for coordinating and monitoring the work. The World Health Assembly provides the necessary and, indeed, the only forum in which global health policies can be agreed upon; and the World Health Organization alone has the requisite channels of communication with the national authorities through which their several programmes can be coordinated, with the support of the international scientific expertise upon which the Organization can draw. Both the Health Assembly and the World Health Organization were essential to the success of smallpox eradication.

The policy decision by the Twelfth World Health Assembly (1959) to undertake the global eradication of smallpox represented an important first step. Through the 1950s, most national governments and colonial adminis-

trations had conducted smallpox control programmes, some of which were very effective. If any disease were to be eradicated by such a widespread although uncoordinated effort, smallpox was the most likely one, given the threat it posed to all countries and the availability of an effective vaccine. However, the interest of national authorities in smallpox control waxed and waned with the varying incidence of the disease and as they became temporarily free of it or, on the contrary, were reinfected from abroad. A concerted and sustained initiative, supported by one or more bilateral assistance agencies, might have succeeded in eliminating smallpox from many countries but it is unlikely that it could have achieved world-wide eradication. Moreover, a scheme to certify that eradication had been accomplished would have carried little conviction without the credit and authority of an international agency which could mobilize respected scientists from throughout the world.

Some countries were encouraged by the decision in 1959 to begin or to intensify their own special programmes and some bilateral support was found, but 3 factors compromised the effort. The first was that the World Health Assembly did not back up its decision by the allocation of special funds, and WHO provided very few staff to coordinate or assist the national efforts and very few funds to help their work. In the majority of countries little action was taken and eradication was assigned a low degree of priority. Second was the fact that in Brazil, South Africa and some countries of eastern Africa, the prevalent form of smallpox was variola minor, which caused only mild illness and few deaths and therefore ranked low among the many other health problems. The third factor was that several large countries were not then Members of WHO. For them, the resolution of the Health Assembly had no direct bearing on their national policies and few of them provided information about the incidence of smallpox or the nature of their activities to control it.

The allocation by the Nineteenth World Health Assembly (1966) of special funds for smallpox eradication signalled a change in priorities. It served to stimulate national commitment to the idea of eradication and encouraged the backing of bilateral assistance agencies; it permitted the recruitment of additional WHO staff; and it provided additional resources for national programmes. The annual allocation of US$2.4 million was not large when compared to the overall need, and minuscule compared to the amounts being expended for the prevention of smallpox in the industrialized countries, but it was an important stimulus without which eradication could not have been achieved.

National support for global smallpox eradication, expressed as unanimous approval of the programme in the World Health Assembly, did not quickly take the form of effective national action, often owing to inertia though sometimes for lack of resources. WHO could not compel a Member State to meet the responsibilities to which it had pledged itself, but by the exercise of moral suasion it was eventually able to overcome reluctance on the part of national authorities. This required WHO staff to play an active role in advocating that eradication programmes should be started and sometimes meant a direct approach to heads of state or other senior national figures when officials at lower levels failed to respond. This encouragement of national programmes and the subsequent support of their work would not have been possible without a technical staff in WHO of sufficient size. From 1959 through 1966, there were at most 1 WHO medical officer in WHO Headquarters and 4 or 5 with field projects who were engaged specifically in smallpox eradication—too few, and with insufficient funds at their disposal, to have any significant impact. In theory, the WHO representatives who were resident in most countries in which smallpox was endemic might have stimulated the development of eradication programmes, but each was responsible for coordinating all the WHO-supported activities in a country and served as a technical resource for other health projects. Few had any particular experience of smallpox eradication or the time to devote to it. As additional funds became available, the number of WHO smallpox eradication programme staff the world over increased to 50 in 1967 and eventually to more than 100. Their professional expertise was to prove essential.

At first, many senior WHO and national staff had believed that management skills only were required. The needs, as they perceived them, were simple and straightforward: to procure sufficient vaccine and to organize vaccination programmes. They believed that generalist managers, rather than epidemiologists or other specialists, were sufficient for this task. It was apparent from

the beginning, however, that the challenge was far greater than the straightforward application of vaccine. It was necessary to adapt vaccination programmes to different administrative, socio-cultural and geographical situations and to devise mechanisms to monitor and assess the work, in terms not only of the numbers of vaccinations performed but but also of their effect on the incidence of smallpox. A better understanding of smallpox epidemiology was required in order to refine the strategies and tactics. Better methods for vaccine production were needed, as were improved instruments for vaccination. It was also important to determine with certainty that there was no natural reservoir of smallpox and to demonstrate that the clinically similar and virologically related disease, human monkeypox, was not a serious threat to the programme. Complementing the staff of physicians was a cadre of non-medical staff, termed "operations officers", who proved to be invaluable in dealing imaginatively with the complex logistics of programme implementation. This network of professional WHO staff, although small in number compared to the tens of thousands of national staff, facilitated the rapid communication of new information throughout the world and assisted in adapting and applying it to national programmes.

In summary, the commitment of the World Health Assembly to a programme of global smallpox eradication provided encouragement to national health authorities to undertake programmes in their countries, an encouragement strengthened by the demonstration in previous years and in a number of developing countries that eradication was practically feasible. However, more was required than good intent and expectation. Meaningful levels of national and international support were essential, as well as mechanisms to harmonize the many different ideas and plans of multilateral, bilateral and national organizations.

The Importance of a Special Programme

Smallpox eradication was conducted through a specifically targeted and time-limited special programme with funds allotted specially for it both in the WHO budget and in most national budgets, and with full-time technical staff assigned responsibility for its supervision. In this respect it may be regarded as the type of categorical programme the conduct of which remains a contentious issue of health policy, especially in developing countries (Vittachi, 1985). Yet, it made important contributions to the development of health services because, far from being separately or autonomously administered, it worked with and through the existing national health service structures and had to coordinate its activities with those of other programmes. The basic health services network, for instance, constituted the foundation of the disease-reporting structure, and in all countries this had to be greatly improved by training and supervision in order to become effective and to provide quickly the accurate information on which the containment of smallpox depended. Immunization programmes were strengthened in many countries as smallpox eradication teams undertook to provide other vaccines, such as BCG, measles, yellow fever and DPT, and assisted with the transport of personnel and supplies for other programmes. Some participation of the existing health staff in vaccination and in search and containment activities was required everywhere because of the small numbers engaged full-time in smallpox eradication. In consequence, many thousands of health staff received training in the execution of vaccination programmes and in field epidemiology; in many cases the only field supervision they received was provided in the course of their smallpox eradication work. A substantial number who now occupy senior positions in national and international organizations are successfully applying methods used for smallpox eradication in programmes against other diseases. These methods include the use of surveillance systems for management and assessment, sample survey techniques to measure performance, and the use of disease-recognition cards to help in case detection.

Experience in the programme demonstrates 3 principles of importance to health policy decisions: (1) the provision of disease control services which reach all persons in the community requires strategies and systems of management for which traditional health care delivery systems are ill-equipped; (2) special programmes to deal with health problems of general concern offer the advantage of attracting both resources and community support; and (3) the significant improvement in efficiency and supervision that can often be realized in special programmes may well

offset the additional costs they sometimes entail.

The delivery of community-wide services

Health officials in most countries have recognized that traditional health care systems—comprising a network of medical practitioners, health centres, and hospitals—have been designed fundamentally to provide therapeutic services for those who seek help and are ill-equipped to deliver preventive and other services which must reach all or most persons in a community. The limitation of traditional health care systems has been that only a proportion of the population, usually the better-educated, has taken the initiative to seek its services and only some of them have benefited from what preventive services have been offered. Few in the health care system have had the training that would enable them to design or implement programmes for the delivery of services to the whole of the population. Just as, in the 1950s and 1960s, most endemic countries assigned special teams to provide smallpox vaccination, so did they have special teams and programmes to deal with tuberculosis, yaws and malaria, for vector control, for family planning and so on.

The experience in national smallpox eradication programmes confirmed that the existing health care structures were inadequate to deal with community-wide programmes of disease control. Health centres, for example, were customarily directed by physicians or others whose training and preoccupation were with curative medicine, whose management skills were limited, who rarely left the health centres and whose work was seldom supervised. Few centres gave vaccinations of any type and, when they did, often used vaccine that was not properly stored or handled. The cases of smallpox that were seen were only occasionally reported and then usually with great delay; outbreaks were rarely contained. The hospitals performed even more poorly, the inadequacy or lack of isolation procedures actually serving in many instances to augment the transmission of smallpox; even the hospital personnel themselves were often unvaccinated. Travelling teams of smallpox eradication staff endeavoured to alter practices and procedures but only when the personnel of health centres and hospitals were trained and regularly supervised by smallpox eradication programme staff did the performance improve significantly.

It became apparent that in all countries there was a need for a specially dedicated and trained professional staff at all levels to decide and coordinate the strategy and tactics of the smallpox eradication programme and to modify these according to local needs, to develop reporting and surveillance systems, to undertake case-detection and containment measures, and to train local health staff in vaccination procedures and the proper preservation of vaccine. There was a need, too, to seek the support of village leaders and, through them, the acceptance and participation of the population. Such activities were alien to most traditional health care units.

The necessity of providing far more than curative care in order to meet the health needs of the community was recognized at the International Conference on Primary Health Care, held at Alma-Ata, USSR, in 1978. It identified primary health care as the key to this goal, being composed of a group of activities encompassing promotive, curative and rehabilitative services for all in the community.

Primary health care is often discussed as though all its activities could be pursued in a like manner, and indeed the skeletal structure of the traditional health care system can sometimes serve as the base for both preventive and curative services. As was apparent in the smallpox eradication programme, however, a different orientation and training of personnel are required for community-based programmes whose objectives are more broadly defined in terms of preventive and other disease control activities intended to reach all in the community. If directed by physicians with traditional training, the standards of the traditional service for the delivery of health care will usually be assessed by the level of training and skill of its practitioners, the quality and sophistication of its facilities and the numbers treated. In contrast, community-wide programmes—whether preventive (such as those for immunization or family planning), curative (such as those for oral rehydration or for the therapy of yaws or malaria), or a combination of the two—require that the standards of performance be assessed in terms of success in dealing with health problems in the community. Such programmes require active outreach through public education and persuasion to ensure their acceptance, the provision of services at a

site and time convenient to their clients as well as methods, such as surveillance, to measure the degree of success. Based on the experience in smallpox eradication, few traditional health care systems have been designed or their personnel equipped to handle both types of activity, and thus curative medicine has remained their dominant concern.

Attraction of resources and community support

Special-purpose programmes to achieve certain clear and specific objectives, usually within a finite period of time, have usually been better supported and financed by politicians and the public alike than have programmes, however laudable, whose health goals have been less explicitly defined. Thus, a programme to eradicate smallpox or to prevent poliomyelitis has had more appeal than one to develop the basic health services; indeed, almost without exception, public service organizations deal with particular diseases (e.g., poliomyelitis, tuberculosis or cystic fibrosis) or groups of diseases (e.g., cancer or lung diseases). Such programmes can serve broader objectives in the development of the health services, as did smallpox eradication, but support for health programmes that have lacked a categorical focus has often proved difficult to obtain.

Such special-purpose programmes are particularly important in public health because it is always more difficult to obtain a political commitment to and financial support for public health programmes than for those involving curative medical services. There are several reasons for this. First, political leaders are more readily persuaded to provide funds for curative services which, with their hospitals and health centres, are more tangible than a community-based programme. Secondly, the physicians who are most likely to be consulted regarding needs and priorities in health care are clinicians, who are more numerous and usually more influential than public health physicians; lacking a public health perspective, they tend to favour the development of clinical facilities which they will use. Thirdly, those who are the most disadvantaged and have the greatest need for community-based health services are usually the least influential politically. Thus, special-purpose public health programmes which can command attention provide an important balance to the traditional biases in allocation of health resources.

Special-purpose programmes are also associated with intensive publicity, which provides an opportunity to educate the population regarding the desirability of selected health interventions. For example, comparatively few people will voluntarily seek to be vaccinated, but more than 80% can usually be reached during the course of a well-publicized and well-executed mass campaign. As Jamison (1985) has pointed out, China's remarkable improvements in health over the past 30 years can be attributed in substantial measure to its special health campaigns, of which there have been 4 or 5 each year.

On a global scale, there is no better recent illustration of the potential for heightened support for community-based health programmes with specific objectives than WHO's Expanded Programme on Immunization, whose goal, established by the Thirtieth World Health Assembly in 1977 (resolution WHA30.53), is to provide 6 vaccine antigens to children throughout the world by 1990. This effort was augmented by UNICEF's Child Survival and Development Revolution and was subsequently endorsed in the United Nations (Mandl, 1985). International support of unprecendented magnitude was mobilized, national governments responded with special programmes and, as a result, levels of immunization coverage significantly increased in many countries.

Efficiency and supervision

Special programmes which involve the large-scale delivery of services permit economies to be realized and can facilitate better management of supplies and equipment than is possible when services are provided only in established health centres or practitioners' offices. Immunization programmes are a case in point. The cost of a dose of vaccine in multiple-dose containers is far less than that of the same dose individually packaged. To take full advantage of this, however, all or most of the contents of the larger container must be used at once, because vaccines deteriorate rapidly after the vial is opened; this is most easily accomplished in a large-scale campaign in which large numbers of people are vaccinated each day. Another but more difficult approach is to assemble large numbers of children at clinics on special vaccination days.

The efficient use of vaccine is also more readily achieved when a few vaccinators

perform many vaccinations than when many health centre staff each perform a few. Throughout the course of the smallpox eradication programme, there were recurring problems in ensuring proper vaccination technique and the proper sterilization of instruments by hospitals and health centres. Despite frequent visits by supervisory smallpox staff, many health centres in all countries regularly stored reconstituted vaccine far longer than the 1 day that was prescribed and ignored or were unable to cope with refrigeration failures. Although similar problems affected vaccination teams, it proved far easier to supervise, say, 10–25 vaccination teams than 100–250 health centres.

Definition of Objectives and Goals

From 1967, the most important difference between the Intensified Smallpox Eradication Programme and the previous efforts was that the strategy and tactics were decided in terms of a clear ultimate objective—a nil incidence of smallpox. Although this objective is implicit in any eradication programme, progress before 1967 had been measured primarily by the numbers of vaccinations performed; the reporting of cases was considered so deficient as to be meaningless (WHO Expert Committee on Smallpox, 1964) but nothing had been done to improve its quality. Focusing on the objective of a nil incidence meant that the reporting of cases had to be improved and surveillance systems and field epidemiology developed. New methods were devised for discovering cases and containing outbreaks; resources were allocated in such a way as to provide for particularly intensive efforts where the incidence was highest, at times when transmission was most susceptible to interruption and in places where the risk of spread was greatest. In effect, this approach served to blend management with epidemiology.

Logic suggests that any disease control programme should provide continuous measurements of its impact on incidence and that these in turn should dictate changes in strategy and tactics. In fact, this is seldom the case even today. Most authorities ignore such information or dismiss efforts to obtain the data as being too difficult. Instead, progress is assessed in terms of activity, such as the numbers of vaccinations performed or of patients treated. Several countries in the early 1960s reported with satisfaction that they had vaccinated half or more of their population against smallpox each year, yet the incidence remained high owing to the use of poor vaccine and to lack of supervision. This clear indication that something was amiss with the management of the programme or the efficacy of the vaccine was ignored, however.

Although progress in the Intensified Programme was gauged primarily by the reduction of smallpox incidence, subordinate programme goals were also established in each country and area. They closely followed the principles for good management enunciated by Austin (1979), being specific, measurable, realistic and dynamic. For example, mass vaccination campaigns were expected to result in more than 80% of the population in each area having a vaccination scar. Assessment teams could easily determine the proportion of the population with a scar and, as experience showed, this goal could readily be achieved with a reasonably effective campaign. As programmes improved, this target was made more rigorous, it being required that 80% of those under 15 years old and sometimes 80% of those under 5 should have a vaccination scar. Although more difficult, these standards were not beyond attainment. For successful primary vaccination, take-rates of 95% or more were established as the standard, one which could be readily measured and was tolerant of error since rates of 99% and more were customary under optimal conditions.

From 1974, standards were also established for surveillance and containment. They established as goals that 75% of outbreaks should be discovered within 2 weeks of the onset of the first case, that containment of the outbreak should begin within 48 hours of its discovery and that no new cases should occur more than 17 days after containment had begun. As the incidence of smallpox decreased or ceased, other standards for the measurement of performance were developed which related to the population's knowledge of a reward for reporting cases and the completeness of reporting of other diseases, such as chickenpox.

The various standards were of the greatest value when the data were promptly collected, analysed and used as management guides for programme action. The knowledge by those collecting the information that their data were being promptly put to use contributed

greatly to the development of the system and to better performance. There was a limit, however, to the number of standards that could be effectively employed. This became evident during the concluding phases of global eradication as more standards were adopted and their stringency was increased: a growing volume of data accumulated, only a portion of which could be satisfactorily analysed and interpreted for use. It was apparent that a few indicators of overall performance, closely followed, were more valuable than a broad spectrum of indicators expressing the measure of many different aspects of programme execution.

Quality Control

Methods to ensure that smallpox vaccine was potent at the time of its use, that vaccination coverage met the expected goals, and that progress was being made in diminishing smallpox incidence all represented forms of quality control. Before 1967, their application was infrequent. In both industrialized and developing countries, vaccines, even at the time of manufacture, often failed to meet the accepted international standards; few independent national testing centres monitored vaccine quality; and few health service staff examined the vaccinated after one week to determine whether their vaccinations had been successful. In many countries, large numbers of vaccinations were regularly reported but seldom was there confirmation of this by sample survey to check vaccination scars. It was known that the cases of smallpox that were reported represented only a fraction of the total but even these data were seldom reviewed to determine epidemiological trends or patterns of incidence.

The evident disinterest in quality control which characterized smallpox control programmes before 1967 is difficult to understand, but in fact it typifies large segments of current public health and medical practice. In many countries, for example, biological and pharmaceutical products are accepted and used with little assurance of their potency or purity and with little confidence that they have been properly refrigerated. Even the most elementary measurement systems, such as the enumeration of deaths by cause and the incidence of important diseases, are manifestly deficient. Where systems exist for the routine collection of information, the data, more often than not, are consigned to statistical reports. The fact that the concept of surveillance, although simple in principle, proved so difficult to apply, reflected the lack of experience with measurement throughout the health field and, indeed, the lack of programme goals which would encourage such measurement.

Programme Management

Multinational, cooperative health programmes are inevitably difficult to manage, given the realities of national sovereignty and the intrinsic problems of international organizations. The smallpox eradication programme could not operate as a monolithic structure, like a military command; rather, it was obliged to function in a collegial structure of many independent national programmes, each with its own administrative traditions and socio-cultural patterns, and utilizing resources from many different sources. It was a programme in which WHO, the coordinating organization, provided only a small proportion of the resources and had no authority with respect to national programmes other than that of moral suasion. Authority and responsibility within WHO itself were highly decentralized, each of its 6 regional offices enjoying a substantial degree of autonomy. With its functions and its structures at the time, the Organization was better suited to the implementation of local or regional programmes than to the execution of a world-wide programme which required international mobilization and the selective allocation and re-allocation of resources on a global basis.

Other global health programmes are confronted with similar challenges today. An effort is therefore made here to identify factors in management which contributed to the eradication of smallpox and which might facilitate more effective and better coordinated programmes of other types.

The network of professional staff

Because a hierarchical structure of international and national staff was not possible, other mechanisms had to be found to coordinate planning and to ensure continuity in the execution of the work, to control the quality of vaccines and of performance alike, and to

assess and redirect the programme as it evolved. Within WHO itself, the successful accomplishment of these tasks depended primarily on the recruitment of capable professional staff who could be given substantial latitude to make decisions, who could be assured of the funds, manpower and administrative support they needed, and who could be provided with leadership by example and exhortation rather than by directive. In the broader reaches of the programme much depended on the extent to which continuing close communication could be maintained between the national and the international staff, on their degree of mutual respect, and on the level of their common understanding of problems and needs.

A unit at WHO Headquarters with overall responsibility and accountability for all activities related to the programme proved to be essential. At first, the responsibility for a number of activities directly pertaining to smallpox eradication was scattered among a variety of units. The testing of smallpox vaccine and the development of its production were the concern of one small unit which had to deal with the entire field of biological products; notifications of smallpox cases were received by the units concerned with the application of the International Health Regulations and with the compilation of international health statistics; and yet another unit, concerned with virus diseases, dealt with smallpox research. The Smallpox Eradication unit gradually assumed the responsibility for all the activities that concerned the programme and they subsequently became more effective and more responsive to the programme's needs.

More rapid progress might have been possible if, from the beginning, there had been special staff to handle two other activities—public information and soliciting contributions from donors. There was a need to publicize widely what was being done, and where and how, in order to encourage national authorities and the participating staff and to recruit support from donors. WHO's public information office did what it could but was unable adequately to meet this need as it was small and had to serve the Organization's many other interests and programmes. Use of the *Weekly epidemiological record* to publish a full and candid account of progress and problems in the programme at intervals of 2 or 3 weeks served well to inform the public health community, but it was not especially helpful in stimulating coverage by the mass media for the information of a broader public. A marked change occurred in 1977, when a full-time public information officer joined the smallpox eradication programme. His efforts proved vital to fostering public confidence that eradication had been achieved and that vaccination could be stopped. There were no professional staff in WHO, however, whose full-time responsibility it was to solicit voluntary contributions even though two-thirds of all international funds for the programme were expected to be provided from this source. The staff of the smallpox eradication programme undertook to raise these funds as best they could but they lacked the expertise, the necessary political contacts and the time, and their success was limited.

The Smallpox Eradication unit at WHO Headquarters provided a central point of contact for those outside the programme, whether scientists in research or vaccine production laboratories, potential donors, possible candidates for service, or the media. Because the unit needed to keep abreast of the latest developments to disseminate current technical information about the programme as widely as possible, frequent and regular communication between the scientific and public health communities and the staff of the unit was encouraged. This facilitated the rapid application in practice of new developments and benefited other operations as well.

A counterpart professional group of at least 2 or 3 persons in each of the 4 WHO regions in which smallpox was endemic would have been invaluable, particularly because of WHO's decentralized structure, but, although this was strongly encouraged, it was implemented in only 1 region. Consequently functions that might more logically have devolved upon the regional offices of WHO often had to be undertaken from Headquarters; national programmes were not always adequately supported or monitored; and the global coordination of activities was less satisfactory than it might have been.

For national programmes, an accountable and responsible professional person, preferably appointed to deal exclusively with smallpox eradication, was considered essential by WHO as a locus of contact and for the planning and implementation of the programmes. Each country was therefore requested to designate a specific person to be responsible for smallpox eradication rather than simply an office or a section of the health

ministry. This proved effective except in countries where officials were frequently transferred. However, 3 functions which were customarily the responsibility of parts of the ministry not directly concerned with disease control often presented special problems: case reporting, quality control of vaccine, and public education.

The national notification of cases was often the responsibility of a statistical unit which mechanically recorded such data as were received, showed little concern with the completeness of notifications and was not responsible for initiating action based on the reports received or compiled. Such systems seldom improved unless the smallpox eradication officer assumed the responsibility for the notifications of smallpox cases and used the data for monitoring the programme and allocating resources. This assumption of responsibility, however, often did not occur until many months or years after programmes began.

The quality control of smallpox vaccine was a problem in most countries which produced their own vaccine. Usually they had no national control laboratories and the production laboratories themselves were the ultimate arbiters of quality. Although it was WHO policy to have a WHO collaborating centre test all vaccines used in the programme, the laboratory directors often opposed this and sometimes refused to submit samples. The national smallpox eradication programme officers had no authority to enforce the policy and so it was frequently necessary for senior WHO staff to intervene with higher-level government officials. Compliance, however, was seldom easily achieved, and in a few countries substandard vaccines continued to be used even though the problem was known and recognized.

Responsibility for health education was usually assigned to a special unit in the ministry of health, but such units were seldom either adequately staffed or especially able or imaginative. Few contributed significantly to smallpox eradication campaigns, most educational efforts being mounted by regional and local smallpox programme personnel who pragmatically developed materials as required.

Overall, the basically collegial management of the programme functioned surprisingly well, its principal handicap being the lack of adequate numbers of senior staff at WHO Headquarters and in the regional offices, in national programme offices and in states or provinces. Paradoxically, national governments were reluctant to provide one or a few additional senior supervisory staff, even when available, although they were almost always prepared to add tens, hundreds or even thousands of vaccinators. In one of the largest countries, for instance, the national programme directorate consisted until 1972 of only 1 professional person, and in one of WHO's regional offices smallpox eradication was the part-time responsibility of a medical officer who had to deal with all communicable diseases.

Personnel recruitment and training

The competence, motivation and experience of the staff ultimately govern the success of all programmes and this was unquestionably the case with smallpox eradication. Within WHO, considerable time was required to assemble the professional staff that was needed. Except for staff at Headquarters, recruitment was the *de facto* responsibility of the regional offices. Other factors of selection sometimes outweighed those of professional competence and motivation, and the smallpox eradication staff at Headquarters were, at first, seldom consulted by the regional offices about personnel decisions. Performance was not always closely monitored and contracts were sometimes renewed irrespective of performance, or personnel who proved unsatisfactory in one post might be transferred to another that could be as crucial to the programme as their previous position. However, increasing numbers of competent staff were recruited to WHO as special efforts were made by Headquarters to identify qualified candidates through personal contacts with an informal network of reputable epidemiologists, and applications were encouraged from staff who had performed well in national programmes.

The quality of national programme leadership was initially no less uneven; as the programme progressed, however, and eradication appeared more attainable, national officials increasingly assigned direction to their more able staff, many of whom had previously demonstrated their competence in field operations. Contrary to a widely held view, most countries had more than enough competent staff who could assume positions of leadership, even if many of them lacked practical experience in management because

their supervisors had been unwilling or unable to delegate authority and accountability.

A common understanding by all the senior national and international staff of the principles underlying the programme, of its essential components, and of the more important measures of progress was as crucial to success as the quality of the staff, for on it depended the ability of the programme directors to introduce effective innovations and to adapt their programmes to the prevailing circumstances. The *Handbook for Smallpox Eradication Programmes in Endemic Areas* (SE/67.5 Rev.1), surveillance reports, national and intercountry meetings, and personal visits all helped to accomplish this. The experience in the programme in western and central Africa suggests that special training programmes of perhaps 2–4 weeks' duration for all newly assigned international and senior national staff would have been equally useful elsewhere. However, a lack of appreciation by the regional offices of the need for such courses and a dearth of senior personnel to conduct them precluded their development until 1974. At that time, the intensification of the programmes in India and Bangladesh brought in sufficient additional WHO staff and consultants and specially recruited national epidemiologists to permit training programmes to be conducted in each of the remaining endemic countries.

National smallpox eradication programmes were usually staffed by persons already engaged in smallpox control and others who were reassigned from other programmes. Most countries had many more health staff than programmes with the resources to support them and their work. Given 1–2 weeks of practical field training for smallpox eradication, a steady flow of the supplies and equipment they needed and good field supervision, most performed competently and with dedication. The quality and the nature of the supervision they received were of vital importance. The best results were obtained where WHO, national, and state or provincial supervisory staff travelled frequently into the field to review activities, to resolve problems and to work with the field staff on the solution of their problems. Monthly or fortnightly meetings at which the field staff and supervisors from different areas met to discuss progress and problems and to compare results also proved valuable.

Not only was smallpox a disease with which the ordinary villager was familiar and that he could easily recognize, though he might confuse it with chickenpox, but it also became evident early in the programme that the villagers and their leaders, if properly approached, were usually willing—indeed, eager—to cooperate in organizing vaccination programmes and in detecting cases. From 1973, when programmes in the remaining endemic countries were intensified, many of them were recruited and trained for part-time work in these activities. Their performance, as that of other field staff, was directly proportional to the clarity of the direction provided and the quality of the supervision they received.

In brief, it was clear that comparatively few, strongly motivated and knowledgeable professionals could organize and effectively mobilize large numbers of persons and that in most countries they could count on the eager support of the health staff and the general population alike. The limiting factor was the inadequate number of motivated and knowledgeable leaders, largely because too few were recruited, trained and assigned to responsible positions.

Financial and other resources

A deficiency of resources was a continual problem, which seriously jeopardized the international effort. Despite the importance of global smallpox eradication for all countries, support for the programme was barely adequate to sustain it, even during the last months before transmission was stopped. In large part, this was due to scepticism during the early years of the programme about the feasibility of eradicating a disease. Global malaria eradication had required and received substantial resources, but it was increasingly recognized to be unattainable. In consequence, disappointed bilateral donors and organizations of the United Nations system gradually withdrew support and many declined to provide more than token help for yet another eradication campaign. Such efforts as were made to inform potential donors of the progress being made in smallpox eradication and of the programme's needs proved inadequate until 1974. An intensified, well-publicized campaign had by then begun to stop transmission in the 5 remaining endemic countries as quickly as possible, before natural or man-made catastrophes could thwart the effort. When it became evident that additional resources were indispensable, special

Plate 31.4. Even Snoopy, the well-known cartoon character, supported smallpox eradication. He was never vaccinated, however. (Drawn by Charles Schulz, 1976.)

funds were made available by WHO and large contributions were received from Sweden and later from several other donors. These made possible the successful, large-scale programmes in Asia, but until 1976 they were insufficient to strengthen adequately the programmes in Ethiopia and Somalia. After the last case occurred in 1977, but long before the necessary work of certifying that eradication had been achieved was completed, support for the programme waned again.

Obtaining sufficient resources in the endemic countries often proved as difficult as obtaining international contributions. Although few countries had to provide significantly more money for smallpox eradication than for their previous smallpox control work, their health budgets were small and competing needs were many. To obtain adequate resources, special appeals to national leaders were frequently required. When a nil incidence was reached and the immediate threat of smallpox was removed, however, there was a strong incentive to allocate the men, money and materials to the control of other diseases; consequently, support diminished rapidly and resources to permit certification activities were seldom more than barely adequate.

Several requirements need to be borne in mind when there is a considerable dependence on voluntary donations of money or materials from different sources: (1) quality control of donated items; (2) standardization of supplies; and (3) availability of discretionary funds.

Donations in kind to the smallpox eradication programme were primarily gifts of vaccine, which was tested by WHO collaborating laboratories to be certain that it met the accepted international standards. Although it had originally been thought that vaccine from well-established laboratories in industrialized countries would not need to be tested, it was soon discovered that some of it did not meet the standards. It was found that many governments licensed producers to distribute vaccine which had been found acceptable only by tests conducted by the producer's own laboratory, and that the least competent producers were the least conscientious in vaccine testing and sometimes certified substandard batches. As a result of these findings, a number of countries were prompted to establish national vaccine control laboratories for the first time. The quality of vaccine subsequently improved significantly, but even then occasional batches of substandard vaccine were submitted for donation.

Standardization of equipment and supplies was especially important for items that required spare parts or knowledgeable mechanics for their maintenance. For vehicles and motor cycles, the most commonly provided articles, it was best to provide models already in general use in a country. The provision of unfamiliar products meant that stockpiles of spare parts had to be created and mechanics had to be specially trained. This could be done reasonably economically on the scale that obtained in the larger countries, but it gave rise to considerable problems in smaller countries. In all countries, however, the provision of only a few vehicles or motor cycles of unfamiliar manufacture usually proved to be more of a problem than a benefit. Standardization with regard to vaccine was also important. At first, vials from different manufacturers contained amounts ranging from 15 to 500 doses (0.15–5.00 ml) of vaccine, but this complicated programme planning and confused the vaccinators; efforts were therefore made to standardize all vials of vaccine so that

they contained 0.25 ml when reconstituted. Package inserts (printed forms detailing uses and contraindications) accompanying the vaccine also proved to be a problem because each country had its own policies regarding the age for and contraindications to vaccination. Eventually, however, all producers were persuaded to use a specially prepared WHO package insert which corresponded to global vaccination policies.

Finally, it is important to note that, for a programme financed principally by voluntary contributions, it was essential to have some unrestricted funds which could be used for any necessary purpose and in any country. Most donations were restricted for use in a single country or were received as contributions in kind; only a small proportion of them were received in cash and without limitations on their use. Fortunately, funds were available under the WHO regular budget to meet programme needs for which provision was not otherwise made. In western and central Africa, for example, the USA provided for all except what were known as "local costs" (costs of petrol, vehicle repair and *per diem* allowances for the teams), which its national policy prevented it from meeting; these costs were covered by WHO. There and elsewhere the sums required were small in comparison with the totals involved, but without discretionary funds most of the programmes would not have been able to operate. Likewise, although almost all the vaccine not produced locally was provided as contributions in kind, discretionary funds were needed for the purchase of vaccination instruments and for the printing of package inserts.

Logistics

Whether a programme functioned or failed depended upon the availability of vaccines, vaccination instruments, vehicles and other supplies. Without them, programmes stopped, the momentum was lost, smallpox spread, and morale fell quickly. It was not always easy to ensure that these items were available as needed, since the demand for them fluctuated as a result of natural and man-made emergencies, unexpected epidemics and a host of other factors. The WHO smallpox eradication programme took an active part in dealing with such problems, acting in an operational capacity rather than restricting itself to the advisory technical role that was more customary in many international programmes. This proved helpful in countless circumstances. Being in frequent contact with national and WHO programme staff, the Smallpox Eradication unit could sometimes anticipate problems and take preparatory action and was able to evaluate requests and to respond quickly. An emergency reserve of vaccine and vaccination instruments was created which permitted these to be distributed within 48 hours of a request being received; supplies and equipment could occasionally be diverted from one country to another; and special funds were sometimes provided for emergency procurement of equipment or to pay for special consultants.

The most intractable problem, and one that was never fully solved, was the supply of vehicles. Most health ministries were short of roadworthy transport and were usually unable to provide for emergency requirements. For vehicles of foreign manufacture there was usually a delay of 12–18 months between the submission of a purchase order and their delivery but it was often impossible to gauge the need for them more than 3–6 months in advance. The difficulty was resolved in some countries by purchasing locally manufactured or assembled vehicles and in others by the local purchase of already-imported vehicles, although this was usually more costly; in some instances, special workshops were established to repair and maintain the often large fleet of unroadworthy vehicles. Better results would have been obtained if it had been possible to procure a reserve fleet of new vehicles which could be dispatched quickly when needed, and if more efforts and resources had been directed to the development or improvement of national vehicle maintenance and repair facilities.

The dispensing of and accounting for funds and the uses to which they could be put were a constant, often formidable administrative problem. In many endemic countries, small *per diem* allowances and long delays in payment all but precluded travel by the national field staff; allowances for petrol often permitted only a few days of vehicle operation each month; budgets for vehicle maintenance and repair were small; and there was often no provision for the disbursement of funds for exceptional needs such as the establishment of facilities for the isolation of patients or the payment of a reward for reporting cases. These and similar fiscal problems were largely resolved by the use of WHO funds to meet the "local costs" mentioned above. Their use was

facilitated by establishing imprest accounts, which were an advance made to WHO advisers and senior national staff, for which they had to account before a further advance was made. The availability of ready cash in this way permitted action to be taken expeditiously and eased the work in the field. Implementation of the system was not without problems, however. For example, in many areas illiteracy made it difficult to obtain the receipts which a proper accounting called for, and in all programmes there were a host of questions as to what constituted proper expenditure. The propriety might be questioned, for instance, of making small payments to smallpox-afflicted beggar families in India to ensure that they remained in isolation. Without the sympathetic and flexible administrative support provided by WHO, satisfactory solutions would seldom have been found.

Operational tactics and strategy

An important principle underlying the operation of the smallpox eradication programme as a whole was that the administrative structure and pattern of operations of each national programme should be integrated as well as possible into the health and sociocultural setting of the country concerned. This differed from the operational strategy in malaria eradication, which called for a separate malaria service and laid down detailed administrative responsibilities and functions for personnel at every level. For smallpox eradication, the operational objective was broadly identified: the ultimate goal was a nil incidence of smallpox, to be confirmed by an adequate surveillance programme. To achieve this, a two-part programme was stipulated. First, a vaccination campaign was recommended to ensure a level of immunity among the population as a whole high enough to reduce the incidence of smallpox substantially; secondly, a surveillance programme was to be established to ensure prompt reporting of cases from all health facilities, to permit the investigation and containment of outbreaks and to analyse patterns of occurrence of smallpox so that corrective measures could be taken in both vaccination and surveillance activities.

Programmes were expected to be designed locally by the national staff and their WHO counterparts working in collaboration and to evolve and change with time in the light of experience. Consequently, programmes differed greatly from country to country and from time to time. The role of the WHO staff assigned to the countries likewise differed somewhat from one country to another. The most effective were those who served as working counterparts and took an active role in field operations. Those who assumed the more traditional role of passive technical advisers and rarely travelled outside the capital city were encouraged to leave the programme. As working counterparts, WHO staff with prior experience in other smallpox eradication programmes transmitted confidence in the feasibility of eradication and were better able to introduce new methods; they frequently served to provide continuity and sustain momentum in programmes when the national leadership changed; and it was sometimes easier for them than for their national counterparts to approach the more senior health officials in the country to seek additional support or changes in policy.

Given this operational strategy, the WHO smallpox eradication staff in Geneva viewed as their first priority a duty to anticipate and to be fully responsive to national programme needs and to provide all possible support to them. An immediate response to requests for resources or advice, continuing communication regarding progress and developments, and frequent contact through visits and meetings were essential elements. In consequence, those who served with the smallpox eradication programme, whether as national officials or as WHO staff or consultants, identified as much with international as with national goals; they related closely to each other; and they sustained a remarkably high level of morale despite incredibly arduous working conditions. Although a pattern of programme management such as this would appear only logical, surprisingly few multinational health programmes currently operate with this philosophy.

Global strategy and priorities were regularly discussed and decided at meetings with regional and national advisers and national programme staff. Forums such as these were valuable as it was in the course of executing national programmes that the most important observations were made, as a result of which significant changes in strategy and tactics were introduced. These international meetings provided opportunities for critical discussion of the experiences communicated,

for a comparison of observations, and for the charting of new directions.

The target of a nil incidence of smallpox—the completion of a finite task—undoubtedly played a role in motivating staff and sustaining interest. There are few health programmes which have such a clearly definable end-point. However, comparable levels of achievement, interest and morale in other programmes should be possible where specific goals are clearly identified, where progress is regularly monitored and where the programme staff are fully supported and encouraged in their efforts.

Research

The importance of the problem-oriented applied and basic research that was conducted throughout the course of the smallpox eradication programme cannot be too emphatically stated. The nature and extent of the research agenda could not at first be fully elaborated or foreseen. The most explicit question when the programme began was whether there was a natural reservoir of variola virus which could thwart the objective of eradication. Beyond this, there was the belief that studies conducted during the execution of programmes could do much to elucidate the epidemiology of the disease and to benefit programme implementation. There was, moreover, the belief that the potential of the tools and methods already available could be further developed to permit the task to be achieved faster and more efficiently.

What was not anticipated at the inception of the programme was the extent to which changes would occur in programme strategy and tactics and in the understanding of the epidemiology and virology of smallpox and other poxviruses. Contributions to these changes were made in a range of disciplines, extending from basic molecular biology to applied technology and the social sciences. The research agenda did not, however, unfold spontaneously. Smallpox eradication programme staff and consultants met regularly to discuss developments and needs. Many staff had to be encouraged and sometimes prodded to explore important questions. Substantial time and effort were expended in editing and preparing for publication many of the papers which were eventually distributed.

The fact that most research was undertaken during and in the context of the field work in order to answer practical questions or to resolve apparent paradoxes provided an unusual impetus to the research effort. Moreover, the interaction of research and programme execution permitted the prompt practical application of many of the findings.

The lesson for other disease control programmes seems evident. However, even today, despite countless discussions about the importance of research for smallpox eradication, other problems of importance to the developing countries receive little research support. Research in applied technology and the social sciences is notably neglected and the potential offered by modern molecular biology has barely begun to be realized. For health programmes in the developing countries, research is neither an academic luxury nor merely an interesting intellectual exercise, as has sometimes been suggested. It is a necessity for the successful prosecution of disease control and was inherent in the achievement of the goal of smallpox eradication.

Certification

A feature peculiar to smallpox eradication was that, once it had been achieved, health officials throughout the world—and the general public—all had to be sufficiently confident of the fact that the disease had been eradicated everywhere for them to abandon the practice of vaccination. To instil the necessary conviction, special certification activities were required; they are not without relevance to other situations in which one country's policy is shaped by the health conditions in other countries.

Fostering the required confidence presented difficulties at many levels. National authorities everywhere recognized that the reporting of infectious diseases was deficient in all countries and that in certain circumstances some governments suppressed information about known cases of smallpox (see Chapters 22 and 23). Within countries, smallpox vaccination, one of the oldest public health measures, was a well-established practice, not lightly to be discarded by those responsible for their country's health. The general population of the endemic countries readily recognized smallpox, and in many cultures it was so familiar as to be considered an inevitable occurrence of normal life. Continual efforts were made by the smallpox

eradication programme to publicize widely and in detail, both in the scientific and the general press, what was being accomplished and how. Accounts of the work appeared in WHO's *Weekly epidemiological record*; comprehensive summaries were prepared each year for the World Health Assembly and the Executive Board of WHO; numerous scientific papers were published; and coverage in the public media was actively solicited. These efforts intensified as the goal of eradication approached and was finally reached. Although they were partly successful in convincing many persons that the programme had been well conducted and that WHO and national officials spoke with justified confidence of the accomplishment, more was required.

In 1971, the decision was made to appoint independent international commissions of recognized scientists to visit each country in the endemic areas 2 years or more after the occurrence of the last known case so that they might satisfy themselves that the measures taken by the programme would have detected smallpox had it been present. If they were not satisfied, they were directed to recommend additional measures which should be taken. Such visits were arranged only when WHO and national staff were themselves confident that smallpox had been eradicated from an area and that the fact could be documented. Confidence in the process was enhanced when most countries followed a precedent set by Indonesia during the visit of the second of the commissions (early in 1974), when the members of the commission were informed that they could go anywhere they wished, that they could have access to any records they wanted and that they could question anyone about any matter pertaining to smallpox and the eradication programme (see Chapter 13). The first of the international commissions was convened in 1973; altogether, 22 commissions visited 63 different countries (see Chapters 24–27).

There were a number of salutary features of this approach which deserve mention. First, it required each country to prepare a special report setting forth the activities and the evidence which documented the absence of smallpox; this requirement stimulated national officials to support smallpox surveillance programmes after the last case had occurred and when the inclination was strong to divert resources prematurely to other needs. Secondly, wider knowledge of the nature of the programme and confidence in its success were gained by involving in the commissions scientists of many different nationalities, including those who were most sceptical. Thirdly, when each commission reached a decision that eradication had been achieved, important opportunities were presented to publicize the fact nationally and internationally.

A global commission, composed of 22 scientists from 20 countries and assisted by 9 advisers from 7 countries, surveyed the status of the programme from a world-wide perspective and recommended other activities which they believed were needed for them to be confident that eradication had been achieved. Although some activities involved special studies in areas and countries to which access by international staff had been limited, all were completed or satisfactory alternative measures devised and conducted.

Certification of smallpox eradication was valuable and necessary in giving the world community confidence in the achievement. Like the eradication programme itself, it was designed specifically to meet this need and cannot serve as a template to be applied to other questions in which mutual confidence among nations is essential for deciding sound policy. However, problems arising from national doubts about the status of conditions in other countries have arisen in the past and can be expected in the future. Such problems have included those pertaining to the acquired immunodeficiency syndrome (AIDS) and cholera, as well as natural and man-made environmental contamination involving chemicals and nuclear materials. In such circumstances, certain of the principles of the certification programme have applicability—specifically, assessment of the problem in question under the auspices of an international organization, the use of respected scientists of different nationalities who are requested to be critical in judgement, and open publication of their observations and conclusions.

COSTS AND BENEFITS

The eradication of smallpox marked the end of the pain and suffering of its victims who, as recently as 1967, are estimated to have numbered 10–15 million each year and among whom probably 1.5–2 million died. It marked the end of the severe disfigurement, blindness and other disabling conditions

among those who survived. It meant that all countries could utilize their smallpox hospitals and wards for other health purposes, that they could stop vaccination programmes and that travellers would no longer need to present vaccination certificates attesting that they had been successfully vaccinated.

The existence of smallpox had important financial implications for all countries. In 1967, all countries were expending substantial funds either to control smallpox and to care for its victims, as was the case in the endemic countries, or to vaccinate and operate quarantine programmes to prevent the disease from being imported, as was the case in countries which were free of endemic smallpox. The expenditure of considerably greater sums for further therapeutic or quarantine services would have accomplished little. However, modest additional expenditures for the prevention of smallpox made a dramatic difference. For the entire global smallpox eradication programme, the annual costs, on average, amounted to only US$23 million over the 13-year period, 1967–1979, a sum which includes both national costs and international contributions.

The benefits to all countries of eradicating smallpox would appear so great and so clear that it is difficult to understand why there were problems in obtaining the requisite resources and political commitment. In part, this reflects the fact that governments tend to be more immediately and generously responsive in providing for the immediate needs of those who are ill. As a practical reality, patients express gratitude for the services received and political support for those providing them. Preventive services are less appealing, the results being reflected in impersonal statistics which indicate that there are fewer or perhaps no patients. An equally important problem is the fact that measures for disease prevention usually require a long period of sustained support and attention before results become apparent. Unfortunately, government officials and donor organizations customarily conceive of plans and budgets in blocks of 3–5 years. Longer-term commitments are uncommon, and with changes in leadership different initiatives are pursued. Even for smallpox eradication, which required comparatively small resources, it proved difficult in most countries to sustain the interest of both national governments and international agencies much beyond 5–6 years.

The Cost to the Developing Countries

For the endemic countries, data regarding the cost of smallpox control programmes are few, and estimates of the expenditure on the care of patients and of the economic losses in productivity due to death or illnss are available only for India. No known data document the cost of rehabilitation for those who were left blind or otherwise handicapped.

In 1967, the cost of smallpox control programmes consisted primarily of expenditure on vaccination, i.e., the cost of vaccine, personnel and transport. For the developing countries, this amounted to about US$0.10 per vaccination performed (World Health Organization, 1966b). From national programme reports, it is estimated that a number equivalent to about 20% of the 2500 million residents of the developing countries was being vaccinated each year. This would suggest that about US$50 million were being expended annually for vaccination (Table 31.1).

The costs of care for those who developed smallpox were computed in a study in India by Ramaiah (1976a), who calculated an average expenditure of US$2.85 per patient. Assuming, as he does (Ramaiah, 1976b), that about 2% of all cases were being reported in India in 1967, the total cost of patient care for that year in India alone would have been US$12 million. Given the fact that India, in 1967, accounted for 64% of all reported cases in the world, it would seem reasonable to estimate the cost of patient care globally at more than US$20 million.

Losses due to diminished economic productivity as a result of death must also be considered. For India, during 1967, they are calculated to have been about US$700 million.

Table 31.1. Estimated cost of smallpox to the developing countries, 1967 (millions of US$)[a]

	India	All developing countries
Smallpox control through vaccination	10	50
Care of smallpox patients	12	>20
Loss from diminished economic productivity	700	>1 000
Total	722	>1 070

[a] Because the most comprehensive data are from India (Ramaiah, 1976a,b; Basu et al., 1979), these are given separately, the figures for all developing countries being extrapolated from those for India. Among a total population of 1079 million persons in the endemic countries in 1967, 513 million (48%) lived in India.

The calculation is based on Ramaiah's analysis (1976a), which employs a life-table approach and defines economic productivity in terms of expected excess of income over consumption during the individual's lifetime. However approximate the calculation, the average loss in economic productivity of about US$825 per death would appear conservative. Extrapolated globally for perhaps 1.5 million deaths which were estimated to have occurred in 1967, it would seem reasonable to assign a value of at least US$1000 million.

Loss of productivity due to the 3–4 weeks of incapacitation associated with illness must also be considered although in India this was found to be small (Ramaiah, 1976a), mainly because a large proportion of cases were in children for whom no loss in productivity was assumed, and, in part, owing to the low productivity of the average worker.

From these data, sketchy as they are, the cost of smallpox to the developing countries in 1967 was substantial indeed, being not less than US$1000 million (Table 31.1).

The Cost to the Industrialized Countries

Almost all industrialized countries spent substantial sums of money for the routine vaccination of their own populations so that, if smallpox was introduced, the disease would not spread widely; international travellers were required to present certificates of vaccination; and at least two countries maintained special hospitals for use should smallpox be introduced.

Only one comprehensive study of the costs of smallpox prevention in an industrialized country has been reported, a study conducted in the USA in 1968 (Sencer & Axnick, 1973). The cost that year to the USA of providing 5.6 million primary vaccinations and 8.6 million revaccinations was calculated to be US$92.8 million—about US$6.50 per vaccination (Table 31.2). Among those vaccinated, 8024 had complications requiring medical attention, 238 were hospitalized, 9 died and 4 were permanently disabled. Other costs were associated with absences from work due to vaccination and vaccination reactions, quarantine services and time lost by the maritime industry in waiting for clearance of vessels. The average annual cost of US$150 million amounted to about US$0.75 per capita for 1968. These data do not permit accurate global estimates of the expenditure by all industrialized countries but, if a cost as low as US$0.25 per capita is assumed for those other than the USA, the annual cost, for 1967, would have been US$350 million.

Table 31.2. Costs associated with smallpox protection in the USA, 1968 (millions of US$)[a]

	Amount
Direct cost for medical services:	
Vaccination	92.8
Treatment of complications	0.7
Indirect costs, loss of productivity:	
Work losses due to vaccination and reactions	41.7
Permanent disability due to complications	0.4
Premature death	0.1
Cost of international traffic surveillance and delays in clearance of vessels	14.5
Total	150.2

[a] From Sencer & Axnick (1973).

Expenditure

Compared to the annual cost of smallpox to the world which, in 1967, was more than US$1350 million, the anticipated expenditures for a 10-year global eradication programme were modest indeed. The Director-General of WHO, in 1966, estimated a need for international assistance of US$4.85 million per year over a 10-year period. He requested that US$2.4 million be appropriated for this purpose in WHO's 1967 budget, although this was accepted by the World Health Assembly by only the narrowest of margins (see Chapter 9).

Ultimately, the costs of the programme were greater than had been anticipated (Table 31.3). International expenditure amounted to US$98 million, about twice what had been foreseen. The endemic countries are believed to have spent no more than twice this amount, about US$200 million.

For all countries, the economic benefits of the programme were substantial as it became possible to stop all preventive measures and to close treatment facilities. The USA, although the largest donor, is estimated to realize in savings the total of all its contributions to the programme every 26 days (Brilliant, 1985).

IMPLICATIONS FOR THE FUTURE

The achievement of smallpox eradication demonstrated the potential of WHO as an organization within which all countries, whatever their beliefs and politics, could cooperate successfully in the pursuit of a

Table 31.3. Expenditure on smallpox eradication, 1967–1979 (US$)[a]

	Estimated expenditure, 1967–1979	% of total
International expenditure		
WHO regular budget	33 565 248	11
WHO Voluntary Fund for Health Promotion	37 643 037	13
Other organs of United Nations system	2 492 328	1
Bilateral assistance	24 269 124	8
Total	97 969 737	33
National expenditure in the endemic countries[a]	200 000 000	67

[a] Based on analysis of financial data from Bangladesh, Ethiopia, India and Indonesia and less complete data from other countries which had endemic smallpox in 1967.

common global objective. It encourages the hope that other challenges might likewise be addressed. By demonstrating how cost-effective a population-wide programme for disease prevention could be, it directed attention to other preventive measures and health programmes which could effectively utilize community-wide strategies. Previously endemic countries, having become aware of the considerable capacity of their own health services when given proper direction and supervision, looked toward new goals. Thus, an important impetus was provided for new initiatives in, for example, immunization, diarrhoeal disease control and the prevention of blindness. This was by far the most significant contribution of smallpox eradication to the shaping of future strategies for the provision of health care.

Global smallpox eradication came at a time when conventional wisdom increasingly held that human pathogens were ecologically so well adapted that the concept of eradication was untenable (Dubos, 1965). However, the demonstration that the eradication of a disease was feasible led a number of scientists to conclude that this very feasibility was the most important lesson to be learned from the programme and to advocate that a similar approach should be taken to other diseases (Stuart-Harris et al., 1982). A number of diseases have been proposed as candidates, and efforts have, in fact, begun to eliminate dracunculiasis (guinea-worm infection) globally and to eradicate poliomyelitis from the Western Hemisphere.

Disease eradication is unquestionably an attractive goal, but the difficulty of its achievement should not be underestimated. It must be borne in mind that when the smallpox eradication programme began, the prospects for its success were more favourable than for any other disease eradication programme that might be envisaged today. The technical feasibility of interrupting the transmission of the smallpox virus had already been demonstrated both in the industrialized countries and in many developing ones; an inexpensive, highly effective vaccine was available; and there was a substantial political commitment to the achievement of the goal that had been set. Nevertheless, however favourable the circumstances, success was by no means a certainty even during the concluding years or even the final months of the programme. Indeed, the gap between success and failure in a number of national programmes was a narrow one, and the issue was often favourably decided by fortuitous and unpredictable political developments and with only marginally adequate resources. It is difficult to conceive of other disease eradication programmes experiencing fewer problems; and if they were technically more difficult or less adequately and universally supported, their success would appear to be doubtful indeed.

The consequences of the failure of an eradication programme must also be weighed. Some have argued that such special efforts as would be required would result, at worst, in better control of the disease. However, the repercussions which followed upon the failure of malaria eradication cannot be ignored. Not only was the judgement and credibility of national and international leadership called into question but a number of assistance agencies decided, as a matter of policy, not to provide resources for another eradication effort. Some agencies, in fact, questioned the desirability of supporting any categorical disease programmes. These views prevailed throughout the smallpox eradication programme, often to its detriment.

Eradication of Other Diseases

The possible eradication of a number of diseases has been considered recently (Stuart-Harris et al., 1982) although, in the enthusiasm and interest, the proper definition of eradication has been deplorably corrupted (see Chapter 9). Some have used the term to refer to the control of a disease to the point at which it is no longer an important public

health problem and some have mistakenly applied the term to programmes intended to prevent hunger or to control accidents and injuries. Here, we refer only to the feasibility of interrupting the transmission of an infectious agent over a geographical area of sufficient size so that control measures may be stopped or greatly reduced, i.e., eradication on a regional or global scale.

The candidate diseases of greatest interest are those in which man is the only host of the pathogen and the pathogens themselves do not survive for long periods in nature or man. The prospects for eradicating diseases which have an animal reservoir—such as yellow fever, rabies or plague—are nil given present technology. Equally problematic are cholera, the vibrio of which can persist for a long time in brackish, polluted waters, and diseases such as tuberculosis and leprosy, of which the mycobacteria can remain latent in man for many decades.

Another important consideration which must be weighed in considering a disease for eradication is obtaining a sufficiently broad and sustained political commitment. Those who decide policy and the allocation of funds must perceive the disease problem to be serious enough to warrant expending additional funds; but, no less, the populations which are most affected must be sufficiently motivated to cooperate. The time required is important as well because, as was noted above, it proved difficult in all countries to sustain an interest in smallpox eradication for longer than about 6 years.

The preventive measures required for eradicating the disease in question must be inexpensive, considering the fact that international support for health programmes has never been substantial and that most developing countries are already hard-pressed to meet the needs of their existing health activities. The smallpox eradication experience must be borne in mind as, despite the relatively small budget it called for and the implications which success had for all countries, the difficulty of having adequate funds available was a major constraint.

Finally, the methods to be used for the eradication of a disease should be comparatively simple to apply and should not require frequent, repeated contacts with individuals in the population. Skilled management in the developing countries is not plentiful, and programmes that require complicated procedures or considerable discretionary judgement are less likely to succeed than simpler ones. Problems can also be anticipated if it is necessary to contact the population on repeated occasions, as would be the case if individual subjects had to be given a drug each day or each week for a period of weeks or months. The cost and discipline required to execute such programmes make them prohibitive in most areas.

The prospects at present for the global eradication of most human diseases are not good. Epidemiological characteristics preclude many from consideration, while the nature and cost of the available technologies rule out others. However, with a growing international interest in prevention programmes and the emergence of new and better vaccines and other technological developments, there is hope that other global eradication programmes may eventually be successfully mounted. During recent years, 4 diseases have been seriously advanced as candidates for global eradication within the foreseeable future: measles (Hopkins et al., 1982; Katz et al., 1983), poliomyelitis (Horstmann et al., 1984), dracunculiasis (Hopkins, 1983b), and yaws (Hopkins, 1976; Burke et al., 1985). In 1985, the Pan American Health Organization approved a regional poliomyelitis eradication programme, the objective of which is the interruption of poliovirus transmission in the Western Hemisphere by 1990. In 1986, a programme for the global elimination of dracunculiasis was approved by the Thirty-ninth World Health Assembly (resolution WHA39.21) although no time limit was established for its accomplishment. The prospects for each of these initiatives are briefly reviewed below.

Measles

The possibility of measles eradication is suggested by the fact that man is the only host of the virus and that a single dose of an inexpensive vaccine provides long-lasting immunity in 90–95% of vaccinated persons. In developing countries, measles is a sufficiently serious disease to warrant an eradication programme. In the industrialized countries, however, complications and deaths associated with measles are so much less frequent that many countries do not now conduct effective control programmes. The wisdom of this policy has to be questioned but, certainly, there is not yet universal interest in the control of the disease, let alone

in its eradication. There are other impediments as well. The measles virus is much more readily transmitted from person to person than was that of smallpox. Not surprisingly, the disease spreads rapidly and widely, and a high proportion of children in developing countries experience measles before they reach 3 years of age. Because the virus spreads so easily and the diagnosis may present difficulties, surveillance–containment measures such as were used in smallpox eradication have not proved to be feasible or effective. To interrupt transmission, it has been calculated (Anderson & May, 1983) that an immunity level greater than 90% will be necessary, a level which is all the more difficult to achieve because vaccination is not possible before the age of 6–12 months, when the child loses its maternal antibody. If there were a vaccine which could be administered at or shortly after birth, the prospects would certainly be better.

Practical evidence that an eradication campaign is premature is provided by the experience in the USA. There, the incidence of measles has been reduced almost to nil but, despite a commitment to interrupt transmission by 1982 and the provision of considerable resources to that end, the measles virus continues to spread.

Poliomyelitis

The feasibility of eradicating poliomyelitis appears greater than that of eradicating measles. Poliomyelitis is more universally accepted as being of sufficient importance to warrant an eradication programme. Man is the only host of the virus and good protection is usually provided by both the inactivated vaccine and the attenuated live vaccine. Many industrialized countries and some developing countries have, in fact, already been successful in interrupting poliovirus transmission, mostly through use of the oral, attenuated vaccine. Some industrialized countries which have used the inactivated vaccine have also been successful.

The decision by the Pan American Health Organization to begin a regional poliomyelitis eradication campaign was preceded by national vaccination campaigns in the Americas in which the inexpensive and easily administered oral vaccine was used. In the early 1970s continuing circulation of poliovirus ceased in North America, and by 1985 the number of reported cases in the Western Hemisphere had diminished to fewer than 1000 a year.

The eradication of poliomyelitis, however, presents a number of special problems. First, the oral vaccine is so thermolabile that refrigeration is required almost to the point of administration, and at least 3 doses are necessary for protection. Vaccination campaigns that must depend upon such a vaccine are inevitably more complex and more difficult than those in which a single dose of thermostable vaccine can be used, as was the case with smallpox. Another matter of concern is the fact that several studies suggest that the oral vaccine is less efficacious in some tropical areas than in temperate climates, although the reasons for this remain unclear. The inactivated vaccine has been suggested as an alternative but it is more costly and requires 2 doses to be given by syringe and needle, a more cumbersome method. A second set of problems concerns the development of surveillance methods by which to detect the presence of circulating poliovirus. Only 1 person among 1000 or more who are infected with the virus manifests paralytic disease, and such cases require confirmation by laboratory examination. The occurrence of paralytic cases signifies that poliovirus is present in an area, but their absence does not necessarily indicate the contrary because it is known that poliovirus can spread over large areas and for an unknown period of time without causing paralytic illness. Confirmation that poliovirus transmission has been interrupted is therefore difficult. A surveillance system for paralytic illness is being developed in the Americas which involves laboratory confirmation of suspected cases and community-wide containment vaccination. The efficacy of this approach in reducing the transmission of the virus and its sensitivity in detecting circulating virus remain to be determined. The experience acquired in the Western Hemisphere will determine the feasibility of eradication in other areas.

Dracunculiasis (guinea-worm infection)

The elimination of dracunculiasis, a parasitic infection, was agreed upon by the Thirty-ninth World Health Assembly, in 1986, as a campaign to be conducted in association with programmes of the International Drinking Water Supply and Sanitation Decade; although the Health Assembly's resolution (WHA39.21) speaks of "elimination", it is

difficult to distinguish the intent of this from that of "eradication". The parasite, *Dracunculus medinensis*, a nematode worm that measures 35–100 cm in length when adult, lives in the skin of man, the female emerging in a painful abscess to discharge tiny larvae when the infected part of the body is immersed in water. The larvae are ingested by a minute freshwater crustacean, *Cyclops*, that serves as an intermediate host, in which they mature and infect man when he swallows water contaminated by the *Cyclops* organisms. Interruption of guinea-worm transmission is reasonably easily and rapidly achieved either by destroying the larval form of the parasite in the water tanks and ponds where people are infected, by filtering or boiling water before drinking it or by preventing patients with infection from entering such bodies of water.

Favouring eradication is the fact that comparatively simple measures have produced a dramatic reduction in incidence and the elimination of infection in many villages and larger areas of Africa and Asia. Moreover, the population at risk is estimated to be no more than 50 million persons, almost all of whom now live in rural areas in a regional belt extending across the middle of Africa and in western India and eastern Pakistan. Finally, the disease itself is a painful, disabling one of concern to the afflicted population, and for surveillance purposes the adult worm is easy to identify.

The principal problems which can be foreseen are those of interesting donor agencies in providing support for the elimination of a tropical disease which is so little known outside the affected countries and of mobilizing national interest and support for the elimination of a disease rarely seen outside rural and often remote areas.

Yaws

Yaws is a treponemal infection, transmitted from person to person, against which widespread control and eradication campaigns were mounted during the 1950s and 1960s (see Chapter 9). A single dose of penicillin effected a rapid cure and these earlier campaigns succeeded in dramatically reducing the incidence of the disease. Initially, it appeared that eradication could be easily and rapidly accomplished, but persistent low-level infections which were difficult to detect resulted in the continuation of transmission. A more concerted effort involving repeated visits to inspect all persons in the afflicted areas was required but, as cases diminished in number, so, too, did both the national and international interest and commitment.

During recent years, there has been a resurgence of yaws in many countries of Africa and some in Asia (*Wkly epidem. rec.*, 1986a) and renewed campaigns have begun in a number of them. Although the eradication of yaws has been proposed as a possible goal, recognition of the extent and magnitude of the problem, of the practical difficulties and of the cost of implementing successful programmes has effectively muted discussion of eradication for the time being.

Conclusion

It is apparent that the successful eradication of smallpox has had important ramifications into other areas of health work, while it also provides illuminating evidence of the need for caution in deciding upon other eradication programmes. Those who were directly engaged in smallpox eradication, and many other health staff as well, gained an understanding of the impact a community-based programme, especially one in prevention, could have, of its remarkable cost-benefit implications and of the considerable human and financial resources which could be mobilized for such an effort. Many of these persons, both in developing and in industrialized countries, are now applying that understanding in public health practice. The establishment of specific, measurable, practical goals and their use in management have begun to be introduced into national health programme objectives and into community-based health initiatives. Surveillance and sample survey techniques elaborated in the course of smallpox eradication have begun to be employed increasingly in health programme management. Throughout the world, more emphasis is being placed on programmes for disease prevention and health promotion, in respect of both communicable and non-communicable diseases, although the need for such programmes is still vastly greater than the effort that is being expended upon them.

WHO, whose role in smallpox eradication was so vital, offers a unique, although as yet not fully realized potential, for promoting these new and growing efforts. It is an organization which demonstrably can catalyse achievements far out of proportion to the

financial resources it commands. The extent to which it is successful will depend upon the confidence which its Member States place upon it, on its effectiveness in enunciating clear and measurable objectives and in mobilizing support for their realization, on the number and competence of its professional staff, and on its ability to set aside extraneous political questions. Its ability to respond appropriately to challenges old and new will be decisive in its task of helping all the people of the world to the attainment of the highest possible level of health.

WHO Documents in the WHO/SE, SE and SME Series*

WHO/SE series

WHO/SE/68.1 Smallpox control in Indonesia during the second quarter of the century and re-establishment of endemic smallpox from 1947 (M.F. Polak)

WHO/SE/68.2 Surveillance—the key to smallpox eradication (D.A. Henderson)

WHO/SE/68.3 Faith Tabernacle smallpox epidemic, Abakaliki, Nigeria (D. Thompson, W. Foege)

WHO/SE/68.4 Cultural resistance to smallpox vaccination

WHO/SE/68.5 Characteristics of an epidemic of smallpox, Gerere Hamlet, Nigeria—1968 (J. Pifer, C.L. Adeoye)

WHO/SE/68.6 An outbreak of smallpox in Chingleput District, Madras (A.R. Rao)

WHO/SE/68.7 A short report on epidemiological findings of smallpox outbreaks in the city of Madras (A.R. Rao)

WHO/SE/69.8 Field investigations of an outbreak of smallpox at Bawku, Ghana: May–October 1967 (V. De Sario)

WHO/SE/69.9 An outbreak of smallpox in a village in Afghanistan (A.G. Rangaraj)

WHO/SE/69.10 Some aspects of the epidemiology of smallpox in Nepal (S. Singh)

WHO/SE/69.11 Endemic smallpox in a rural area (D.B. Thomas, W.M. McCormack, I. Arita, M. Khan, S. Islam, T.M. Mack)

WHO/SE/69.12 "Negative" epidemiological enquiries within the framework of the smallpox eradication programme (G.F. Glokpor)

WHO/SE/69.13 Transmission of smallpox in endemic areas (G.G. Heiner, N. Fatima, A. Ali)

WHO/SE/70.14 An alastrim outbreak in the Gran Sabana (State of Bolivar), Venezuela, 1962 (J.G. Halbrohr)

WHO/SE/70.15 Contribution of the French Territory of the Afars and Issas (TFAI) to smallpox control in East Africa (D. Courtois)

WHO/SE/70.16 The efficacy and acceptability of the bifurcated needle technique: a summary of studies conducted in India

WHO/SE/70.17 A short report on epidemiological investigations of smallpox outbreaks in 1969 in a few villages of Nellore district of Andrapradesh, India (A.R. Rao, T.V. Paramasivam, S. Kamalakshi, A.R. Parasuraman, M. Shantha)

WHO/SE/70.18. Epidemiological and virological studies on the off-season smallpox cases in Calcutta (J.K. Sarkar, S. Ray, P. Manji)

WHO/SE/70.19 A short report on the epidemiological findings of smallpox outbreaks in the State of Tamil Nadu, July 1968–June 1969 (A.R. Rao)

WHO/SE/70.20 Outbreaks of smallpox during 1968 in some villages of Jaipur District, Rajasthan (S. Pattanayak, P.N. Sehgal, N.G.S. Raghavan)

WHO/SE/70.21 Epidemiological investigations—smallpox eradication programme in Togo—1969 (G.F. Glokpor, A.N. Agle)

WHO/SE/70.22 Epidemiological characteristics of smallpox outbreaks in two small Brazilian villages (N. Arnt, L. Morris)

WHO/SE/70.23 Smallpox in the Município of São Paulo, Brazil, 1945–1969: a 25 year review (L. Morris, H. Cappello, R. Soares, J.P. de Leon, W. Leser)

WHO/SE/71.24 Endemic smallpox in rural East Pakistan. Methodology, clinical and epidemiological characteristics of cases, and intervillage transmission (D.B. Thomas, W.M. McCormack, I. Arita, M.M. Khan, S. Islam, T.M. Mack)

WHO/SE/71.25 Endemic smallpox in rural East Pakistan. Intravillage transmission and infectiousness (D.B. Thomas, I. Arita, W.M. McCormack, M.M. Khan, S. Islam, T.M. Mack)

WHO/SE/71.26 A study of inapparent infection in smallpox (G.G. Heiner, N. Fatima, R.W. Daniel, J.L. Cole, R.L. Anthony, F.R. McCrumb Jr)

WHO/SE/71.27 Development of the smallpox surveillance programme in Andhra Pradesh (M.C. Apparao)

WHO/SE/71.28 Smallpox (D.A. Henderson)

WHO/SE/71.29 Field trials of methisazone as a prophylactic agent against smallpox (G.G. Heiner, N. Fatima, P.K. Russell, A.T. Hasse, N. Ahmad, N. Mohammed, D.B. Thomas, T.M. Mack, M.M. Khan, G.L. Knatterud, R.L. Anthony, F.R. McCrumb Jr)

WHO/SE/71.30 Proceedings of the Inter-regional Seminar on Surveillance and Assessment in Smallpox Eradication, New Delhi, 30 November–5 December 1970

WHO/SE/71.31 Results of virological examination of smallpox convalescents and contacts (E.M. Shelukhina, S.S. Marennikova, N.N. Maltzeva, G.R. Matzevich, A.A. Hashmi)

WHO/SE/71.32 Epidemiology of variola minor in Brazil: a study of 33 outbreaks (C.A. de Quadros, L. Morris, E.A. da Costa, N. Arnt, C.H. Tigre)

WHO/SE/71.33 A study of intrafamilial transmission of smallpox (G.G. Heiner, N. Fatima, F.R. McCrumb Jr)

WHO/SE/72.34 Persistence of facial scars of smallpox in West African populations (S.O. Foster)

* Irregularity in numbering is due to errors or omissions in numbering at the time of issue.

WHO/SE/72.35 Case fatality ratios in smallpox (E. Shafa)
WHO/SE/72.36 Simultaneous administration of several antigens (J.D. Millar, S.O. Foster, W.H. Foege)
WHO/SE/72.37 Report on a survey to determine the status of smallpox and levels of smallpox immunity [Argentina]
WHO/SE/72.38 Paraguay: report on a survey to determine the status of smallpox and levels of smallpox immunity
WHO/SE/72.39 Smallpox vaccination in atopic children (J.M. Neff)
WHO/SE/72.40 Infected inanimate objects (fomites) and their role in transmission of smallpox (A.R. Rao)
WHO/SE/72.41 Smallpox transmission on a bus (G.D. Suleimanov, K.K. Mandokhel)
WHO/SE/72.42 Smallpox Eradication unit: selected references available upon request
WHO/SE/72.43 Potency testing of smallpox vaccine (A.C. Hekker, J.M. Bos)
WHO/SE/72.44 Evaluation of virological laboratory methods for smallpox diagnosis (J.H. Nakano)
WHO/SE/72.45 Costs associated with the protection of the United States against smallpox (N.W. Axnick, J.M. Lane)
WHO/SE/72.46 Smallpox vaccination reactions, prophylaxis and therapy of complications (J.A. Goldstein, J.M. Neff, J.M. Lane)
WHO/SE/72.47 Follow-up study of smallpox vaccination in the newborn (U. Lakhanpal)
WHO/SE/72.48 A report from Gemu-Gofa Province, Ethiopia (G. Tilahun, K. Mondaw, M.D. Kraushaar, M.S. Holmberg)
WHO/SE/72.49 Potency and stability characteristics of smallpox vaccine used in the smallpox eradication programme in Western and West-central Africa (A. Bernstein, M.Z. Bierly Jr)
WHO/SE/73.50 Active search operations for smallpox—an Ethiopian experience (C.A. de Quadros, K.L. Weithaler, J. Siemon)
WHO/SE/73.51 Smallpox eradication campaign—Brazil situation in 1972 (C. do Amaral Jr, J.P. de Leon, A.M. Filho, A.L. de Lemos, F.G. Varela)
WHO/SE/73.52 A national reporting system in Brazil (A.L. de Lemos, O.R. de Souza)
WHO/SE/73.53 The eradication of smallpox—the critical year ahead (D.A. Henderson)
WHO/SE/73.54 Camelpox virus (Properties, differentiation from related viruses of the pox group) (S.S. Marennikova, L.S. Shenkman, E.M. Akatova-Shelukhina, N.N. Maltseva)
WHO/SE/73.55 The status of smallpox vaccination: a brief for discontinuing routine vaccination (A.D. Langmuir)
WHO/SE/73.56 Smallpox vaccination before the age of 3 months: evaluation of safety (J.Å. Espmark, E. Rabo, L. Heller)
WHO/SE/73.57 Epidemiologic aspects of smallpox in Yugoslavia in 1972 (S. Litvinjenko, B. Arsić, S. Borjanović)
WHO/SE/73.58 The case for continued smallpox vaccination (A.S. Benenson)
WHO/SE/73.59 Dead men tell no tales (An account of a recent smallpox outbreak in Afghanistan) (A.G. Rangaraj)
WHO/SE/73.60 Active search operations—Equatoria Province, Sudan (J. Lepkowski, O.H.M. Suleiman, A.H.S. Osman)
WHO/SE/73.61 A possible relationship between human pathogenicity of smallpox vaccines and virus growth at elevated temperatures (D. Baxby)
WHO/SE/74.62 Importations of smallpox into Europe 1961–1973 (D.A. Henderson)
WHO/SE/74.63 Indonesia 1972: some smallpox surveillance patterns (G.G.O. Cuboni, W.L.R. Emmet, N.K. Rai, A. Karyadi, I.F. Setiady)
WHO/SE/74.64 Smallpox epidemic in a Brazilian community (E.A. Costa, L. Morris)
WHO/SE/74.65 A field day for smallpox in Sibpur, Bangladesh (A.G. Rangaraj, M.A. Yusuf)
WHO/SE/74.66 Indonesia 1971/72: smallpox vaccinators as surveillance workers (G.G.O. Cuboni, W.L.R. Emmet, P.A. Koswara, N.K. Rai, A. Karyadi, I.F. Setiady)
WHO/SE/74.67 The mystery of the smallpox cases in the Lafit Mountains, Equatoria Province, Sudan (D.O. Bassett, G. Kibaida, A.H.S. Osman)
WHO/SE/74.68 Report of the WHO International Commission on Assessment of Smallpox Eradication in Indonesia, 25 April 1974
WHO/SE/74.69 A persistent focus of smallpox in Botswana, 1973 (G.T. Presthus, J.B. Sibiya)
WHO/SE/74.70 Virus content of smallpox scabs on different days of illness (A.C. Mitra, J.K. Sarkar, M.K. Mukherjee)
WHO/SE/74.71 The smallpox eradication programme in Nepal (P.N. Shrestha, M. Sathianathan, J. Friedman)
WHO/SE/75.72 An account of operations in Gishe Woreda, Ethiopia (W. Barrashand, L. Kaplan)
WHO/SE/75.73 Pattern of intrafamilial transmission of smallpox in the city of Calcutta (M.K. Mukherjee, J.K. Sarkar, A.C. Mitra)
WHO/SE/75.74 Epidemiological implications of the typing of variola isolates (K.R. Dumbell, F. Huq)
WHO/SE/75.75 The experience of Kurara PHC, Hamirpur District, Jhansi Division in the organization and development of the smallpox eradication campaign (S.H.A. Usmani, A.N. Slepouchkine)
WHO/SE/75.76 Surveillance of smallpox (D.A. Henderson)
WHO/SE/75.77 Farewell to Sitala Mayya (S.H. Hassan)
WHO/SE/76.78 Monkeypox and white poxviruses in West and Central Africa (I. Arita, D.A. Henderson)
WHO/SE/76.79 Smallpox surveillance in remote and inaccessible areas of India (Z. Ježek, R.R. Arora, Z.S. Arya, Z. Hussain)
WHO/SE/76.80 Operation Smallpox Zero (Z. Ježek, R.N. Basu)
WHO/SE/76.81 Assessment of Ladakh smallpox eradication programme activities (Z. Ježek, M.H. Kanth)
WHO/SE/76.82 Search at the weekly markets for detection of smallpox outbreaks which occurred during previous years (L.N. Khodakevich, H. Narayana Rao)
WHO/SE/76.83 The eradication of smallpox (F. Fenner)
WHO/SE/76.84 The last known outbreak of smallpox in India (Z. Ježek, M.N. Das, A. Das, L.M. Aggarwal, Z.S. Arya)
WHO/SE/76.85 Freedom from smallpox. Case histories on four countries where cases were missed for extended periods (D.A. Henderson)
WHO/SE/76.86 Chickenpox in Kerala (E. White)
WHO/SE/76.87 Contribution to the problem of challenge vaccination (V. Zikmund, N. Das, R. Krishnayengar, B. Kameswara Rao)
WHO/SE/76.88 Bangladesh smallpox eradication programme, Mohakhali, Dacca

WHO/SE/77.89 International Commission for the Assessment of Smallpox Eradication in Afghanistan

WHO/SE/77.90 Report of the International Commission for the Assessment of Smallpox Eradication in Pakistan

WHO/SE/77.91 Summary of the contributions of the smallpox programme to other health programmes through surveys in Bangladesh (Bangladesh smallpox eradication programme, Dacca)

WHO/SE/77.92 Variolation in the Rajasthan Desert (C. Davis)

WHO/SE/77.93 Viability of variola virus in crusts at different temperatures and humidities (F. Huq)

WHO/SE/77.94 Surveillance at weekly markets in the smallpox eradication programme in India (R.N. Basu, L.N. Khodakevich)

WHO/SE/77.95 The National Commission for Assessment of the Smallpox Eradication Programme in India (R.N. Basu, L.N. Khodakevich)

WHO/SE/77.96 Reinvestigation of smallpox outbreaks (Z. Ježek, R.N. Basu, Z.S. Arya)

WHO/SE/77.97 Problem of persistence of facial pockmarks among smallpox patients (Z. Ježek, R.N. Basu, Z.S. Arya)

WHO/SE/77.98 Report of the Consultation on Worldwide Certification of Smallpox Eradication

WHO/SE/77.99 Emergency logistical operation (for containment of the smallpox epidemic in Somalia) (R. Hauge, J. Wickett)

WHO/SE/78.100 Smallpox eradication programme in the Republic of Djibouti (N. Grasset)

WHO/SE/78.101 Fatality, facial scarring and blindness from smallpox in Bangladesh (K. Hughes)

WHO/SE/78.102 Smallpox pock mark survey in Bangladesh, with an assessment of reporting efficiency (K. Hughes, S.O. Foster, D. Tarantola, A.K. Joarder)

WHO/SE/78.103 A suspected outbreak of buffalopox in Bangladesh (D. Tarantola, F. Huq, K.Z. Hoque, Y. Selivanov, C. Wilson)

WHO/SE/78.104 Outbreak containment in Somalia smallpox eradication programme (A. Deria, Z. Ježek, S. Foster)

WHO/SE/78.105 Smallpox transmission in an isolated nomadic group (S.O. Foster, H.E.S. Abdulgadir, H.A. Kamaluddin)

WHO/SE/78.106 The certification of smallpox eradication in countries without recent reported endemic transmission (L.B. Brilliant, L.N. Khodakevich)

WHO/SE/78.107 Smallpox eradication in Nepal (P.N. Shrestha)

WHO/SE/78.108 Report on a visit to Southern Rhodesia, 10–30 January 1978 (N. Grasset, G. Meiklejohn)

WHO/SE/78.109 Report on a visit to Thailand in preparation for the certification of smallpox eradication, May 1978 (R.N. Basu)

WHO/SE/78.110 Report on facial pockmark and vaccination scar surveys, Southern Rhodesia (Government Health Services)

WHO/SE/78.111 Report to the members of the Global Commission for the Certification of Smallpox Eradication (Ministry of Health, Syrian Arab Republic and World Health Organization)

WHO/SE/78.112 Poxvirus infections in humans following abandonment of smallpox vaccination (J.G. Breman, I. Arita)

WHO/SE/78.113 Smallpox eradication in Thailand (Ministry of Public Health, Government of Thailand and World Health Organization)

WHO/SE/78.114 Report to the members of the Global Commission for the Certification of Smallpox Eradication, Iraq (Ministry of Health, Iraq and World Health Organization)

WHO/SE/78.115 Report to the Global Commission for Certification of Smallpox Eradication, Bahrain (Ministry of Health, Bahrain and World Health Organization)

WHO/SE/78.116 Report to the Global Commission for Certification of Smallpox Eradication, Qatar (Ministry of Health, Qatar and World Health Organization)

WHO/SE/78.117 Report to the Global Commission for Certification of Smallpox Eradication, Oman (Ministry of Health, Oman and World Health Organization)

WHO/SE/78.118 Report to the Global Commission for Certification of Smallpox Eradication, United Arab Emirates (Ministry of Health, United Arab Emirates and World Health Organization)

WHO/SE/78.119 Report to the Global Commission for Certification of Smallpox Eradication, Kuwait (Ministry of Health, Kuwait and World Health Organization)

WHO/SE/78.120 Smallpox eradication in Iran (Ministry of Health and Welfare, Imperial Government of Iran and World Health Organization)

WHO/SE/78.121 Report to the Global Commission for Certification of Smallpox Eradication on the smallpox-free status of the Arab Countries of the Gulf Area (A.G. Rangaraj)

WHO/SE/78.122 Report to the Global Commission for Certification of Smallpox Eradication, Saudi Arabia (Ministry of Health, Saudi Arabia and World Health Organization)

WHO/SE/78.123 A smallpox outbreak in Merka town, Somalia (Smallpox Eradication unit, World Health Organization)

WHO/SE/78.124 Report on smallpox situation in Madagascar (Z. Islam)

WHO/SE/78.125 The Global Commission for Certification of Smallpox Eradication, status report on the People's Democratic Republic of Yemen

WHO/SE/78.126 Visit report of the members of the International Commission for the Certification of Smallpox Eradication, Syrian Arab Republic, 15–22 October 1978

WHO/SE/78.127 Visit report of the members of the International Commission for the Certification of Smallpox Eradication, Iraq, 5–15 October 1978

WHO/SE/78.128 Smallpox eradication in Somalia, status report, 1 October 1978

WHO/SE/78.129 The special programme to confirm smallpox eradication in Iran (L.B. Brilliant)

WHO/SE/78.130 Smallpox vaccination certificate requirements for international travellers and status of smallpox vaccination according to national health legislation, Parts A & B (A.I. Gromyko)

WHO/SE/78.131 Residual skin changes in patients who have recovered from variola minor (Z. Ježek, W. Hardjotanojo)

WHO/SE/78.132 Report of the Global Commission for the Certification of Smallpox Eradication, first meeting, 4–7 December 1978

WHO/SE/78.133 Report to the Global Commission for Certification of Smallpox Eradication, Socialist Republic of Viet Nam (Ministry of Health, Viet Nam and World Health Organization)

WHO/SE/79.134 Report of the International Commission for the Certification of Smallpox Eradication in the Sudan, 15–29 November 1978

WHO/SE/79.135 Report of Consultation on the Justification for Retention and Use of Variola Virus in the Post Eradication Era

WHO/SE/79.136 Report to the International Commission for the Certification of Smallpox Eradication in the People's Democratic Republic of Yemen, April 1979 (Ministry of Health, People's Democratic Republic of Yemen and World Health Organization)

WHO/SE/79.137 Report of Meeting of Officials from Laboratories retaining Variola Virus and National Control Authorities Concerned, 23–24 April 1979

WHO/SE/79.138 Report to the International Commission for the Certification of Smallpox Eradication in the Yemen Arab Republic, June 1979 (Ministry of Health, Yemen Arab Republic and World Health Organization)

WHO/SE/79.139 Report of the International Commission for the Certification of Smallpox Eradication in the Yemen Arab Republic, 2–10 June 1979

WHO/SE/79.140 Report of the International Commission for the Certification of Smallpox Eradication in the People's Democratic Republic of Yemen, 3–11 June 1979

WHO/SE/79.141 Report to the Global Commission for the Certification of Smallpox Eradication in Kenya (Ministry of Health, Kenya and World Health Organization)

WHO/SE/79.142 (Revision 1) Smallpox eradication in China

WHO/SE/79.143 Report to the International Commission for the Certification of Smallpox Eradication, Republic of Djibouti, October 1979 (Ministry of Health, Republic of Djibouti and World Health Organization)

WHO/SE/79.144 Smallpox eradication in Ethiopia, Report to the International Commission for the Certification of Smallpox Eradication (Y. Tekeste, A. Hailu, C. do Amaral Jr, P.R. Arbani, L.N. Khodakevich, N.A. Ward)

WHO/SE/79.145 Smallpox eradication in Somalia, report to the International Commission on the smallpox eradication programme in Somalia (Z. Ježek, M. Al Aghbari, R. Hatfield, A. Deria)

WHO/SE/79.146 Report of the International Commission for the Certification of Smallpox Eradication in Somalia, 1–21 October 1979

WHO/SE/79.147 Report of the International Commission for the Certification of Smallpox Eradication in Djibouti, 9–18 October 1979

WHO/SE/79.148 Report of the International Commission for the Certification of Smallpox Eradication in Ethiopia, 1–17 October 1979

WHO/SE/79.149 Report of the International Commission for the Certification of Smallpox Eradication in Kenya, 1–19 October 1979

WHO/SE/79.150 Joint Report of the International Commissions for the Certification of Smallpox Eradication in the Countries of the Horn of Africa, Nairobi, 26 October 1979

WHO/SE/79.151 Smallpox eradication in the Autonomous Region of Tibet in the People's Republic of China (Government of the People's Republic of China)

WHO/SE/79.152 The Achievement of Global Eradication of Smallpox: Final Report of the Global Commission for the Certification of Smallpox Eradication

WHO/SE/80.153 Human monkeypox, 1970–1979 (J.G. Breman, Kalisa-Ruti, M.V. Steniowski, E. Zanotto, A.I. Gromyko, I. Arita)

WHO/SE/80.154 Monkeypox virus as a potential source of variola virus (F. Fenner, K.R. Dumbell, S.S. Marennikova, J.H. Nakano)

WHO/SE/80.155 Vehicle maintenance in the smallpox eradication programme in Somalia, 1977–1979 (R. Hatfield)

WHO/SE/80.156 The confirmation and maintenance of smallpox eradication (J.G. Breman, I. Arita)

WHO/SE/80.157 (Revision 1) Management of suspected cases of smallpox in the post-eradication period (Smallpox Eradication unit, World Health Organization, Geneva)

WHO/SE/80.158 (Revision 1) Management of reserve stocks of vaccine in the post-smallpox eradication era (Smallpox Eradication unit, World Health Organization, Geneva)

WHO/SE/81.159 Report of meeting on the implementation of post-smallpox eradication policy, Geneva, 3–5 February 1981

WHO/SE/82.160 Report of the first meeting of the Committee on Orthopoxvirus Infections, Geneva, 3–5 March 1982

WHO/SE/83.161 Report of the second meeting of the Committee on Orthopoxvirus Infections, Geneva, 15–17 March 1983

WHO/SE/84.162 Report of the third meeting of the Committee on Orthopoxvirus Infections, Geneva, 28–30 March 1984

WHO/SE/86.163 Report of the fourth meeting of the Committee on Orthopoxvirus Infections, Geneva, 24–26 March 1986

SE series

SE/67.5 Rev. 1 Handbook for Smallpox Eradication Programmes in Endemic Areas (World Health Organization)

SE/68.2 Rev. 1 Instructions for smallpox vaccination with bifurcated needle

SE/68.3 Rev. 2 Methodology of freeze-dried smallpox vaccine production

SE/68.7 Studies of smallpox vaccination by bifurcated needles in Kenya (I.D. Ladnyi)

SE/68.9 Table for handling of animals during scarification and harvest (Specifications)

SE/69.1 Surveillance–containment operations: principles and operational procedures

SE/70.1 Present status of vaccination programmes (by country)

SE/70.3 Present status of vaccination programmes (by country)

SE/71.1 Teaching exercise—field investigation of a smallpox case; problem for students and syllabus for the discussion leaders

SE/71.2 La vaccination des malades hospitalisés et des nouveau-nés: contre-indication de la vaccination (A. Ramachandra Rao)

SE/71.3 Production, stockage et emploi du vaccin (D.A. Henderson)

SE/71.4 Matériel et techniques de vaccination contre la variole (E. Shafa)

SE/72.1 Clinical smallpox: classification and frequency of type of variola major (A.R. Rao)

SE/72.2 Pattern of transmission: relative significance of cases of varying severity (A.R. Rao)

SE/72.3 Incubation period of smallpox (A.W. Downie)

SE/72.4 A comparison of multiple pressure and scratch techniques in vaccination against smallpox (A.S. Benenson)

SE/72.5 Studies of the bifurcated needle and recommendations for its use (D.A. Henderson, I. Arita, E. Shafa)

SE/72.6 Epidemiological investigation of a smallpox outbreak in a city reported to be 100% vaccinated (L. Morris, A.V. Martinez, J.O. da Silva)

SE/72.7 Teaching exercise—smallpox surveillance

SE/72.8 Smallpox surveillance in the strategy of global eradication (D.A. Henderson)

SE/72.9 Training seminar on smallpox eradication, Karachi, November 1972. Inauguration of the seminar (D.A. Henderson)

SE/72.10 The global smallpox eradication programme—the final phase (D.A. Henderson)

SE/73.1 Smallpox—present and future (D.A. Henderson)

SE/73.2 Manual of clinical microbiology: chapter, smallpox, vaccinia and human monkeypox viruses (J.H. Nakano, P.G. Bingham)

SE/74.1 The 1972 smallpox outbreak in Khulna Municipality, Bangladesh II. Effectiveness of surveillance and containment in urban epidemic control (A. Sommer)

SME series

SME/77.1 The Nepal smallpox eradication programme: description and analysis (P.N. Shrestha, D.A. Robinson, J. Friedman)

SME/77.2 Report of a Workshop Meeting on Safety Measures in Laboratories retaining Variola Virus, Geneva, 1–4 August 1977

SME/78.1 Rev. 1 Operational guidelines for smallpox eradication in Somalia

SME/78.2 Smallpox facial pockmarks [photographs]

SME/78.3 Plan of action for the smallpox eradication programme in Somalia 1978/1979

SME/78.6 Methodology for preparation of appropriate data for the 31 countries remaining to be certified free of smallpox (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/78.7 Recommendations of the Third Coordination Meeting for Smallpox Eradication, Nairobi, 17–19 April 1978

SME/78.11 Report on a visit to Ethiopia by members of the Global Commission for Smallpox Eradication, 31 May–15 June 1978 (K. Dumbell, P. Shrestha)

SME/78.13 The eradication of smallpox in Sudan

SME/78.14 Report on visit to the Republic of South Africa and Namibia/South West Africa, 19 January–19 February 1978 (F. Fenner)

SME/78.15 Human monkeypox: update 1978 (J.G. Breman)

SME/78.16 Smallpox eradication in Botswana: status report, 8 November 1978

SME/78.17 Smallpox eradication in Swaziland: status report, 8 November 1978

SME/78.18 Smallpox eradication in Angola: status report, 9 November 1978 (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/78.19 Laboratory aspects of the monkeypox/whitepox virus problem (F. Fenner)

SME/78.20 Report of informal consultation on monkeypox, whitepox and related poxviruses, Geneva, 9–10 November 1978

SME/78.21 Worldwide smallpox eradication: last known foci and global certification (I. Arita)

SME/78.22 Smallpox vaccine stocks (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/78.23 Smallpox eradication in the Yemen Arab Republic: status report, November 1976 (Department of Preventive Health Services, Ministry of Health, Sana'a, and WHO Operations Officer, Smallpox Eradication Programme)

SME/78.24 Assessment of activities in preparation for the certification of smallpox eradication in Angola: visit report, August 1978 (C.H. Tigre)

SME/78.25 Laboratories with variola virus stocks (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/78.26 Report to the Global Commission for Certification of Smallpox Eradication—Socialist Republic of Viet Nam, Annex 6

SME/78.27 Smallpox eradication in the Republic of Djibouti: status report, 23 November 1978

SME/79.1 A study of smallpox transmission rate in Bangladesh (J. Tulloch, D. Tarantola)

SME/79.2 An evaluation of the effectiveness of smallpox surveillance and containment in Somalia (Z. Ježek, A. Deria)

SME/79.3 Résultats préliminaires d'une enquête sur un cas de monkeypox au Nigéria (A.I. Gromyko, M. Daramola)

SME/79.6 Report of the International Commission for Preliminary Assessment of Smallpox Eradication in Ethiopia, 3–18 April 1979

SME/79.7 A possible case of camelpox in man (B. Kriz)

SME/79.8 The epidemiology of measles in a rural community in Somalia (B. Kriz, A. Deria)

SME/79.9 Report of meeting of the study group on orthopoxvirus research, Atlanta, 26–28 June (co-sponsored by WHO and CDC)

SME/79.10 Special report on smallpox and its eradication in Yunnan Province, China (Department of Health, Yunnan Province)

SME/79.11 Report on a visit to the People's Republic of China to consider matters relating to the certification of smallpox eradication, 14–30 July 1979 (F. Fenner, J.G. Breman)

SME/79.12 Nomadic population movement in southwestern Somalia and its influence on the planning of smallpox surveillance (B. Kriz, R. Hatfield)

SME/80.1 Residual facial skin changes in varicella patients (Z. Ježek, W. Hardjotanojo, A.G. Rangaraj)

SME/80.2 Supplément: Recommandations concernant les premières mesures à prendre en présence de cas suspects ou confirmés de fièvre de Lassa

SME/80.3 Conférence-atelier sur la surveillance de monkeypox et fièvres hémorragiques virales, 28 avril–3 mai 1980, Brazzaville

SME/80.4 Places visited and persons examined in preparation for and during visits by International Commissions for the Certification of Smallpox Eradication (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/80.5 Lassa fever update (J.B. McCormick)

SME/80.6 A system of surveillance for monkeypox and haemorrhagic fever (J.B. McCormick)

SME/80.7 An estimation of past smallpox incidence in South-western Somalia (B. Kriz)

SME/80.8 Biosafety procedures (V.R. Oviatt)

SME/80.9 World smallpox situation, 1967–1977 (Smallpox Eradication unit, WHO Headquarters, Geneva)

SME/80.11 Surveillance of Ebola/Marburg fevers (D.I.H. Simpson)

World Council of Churches, 883

World health, special issues on smallpox eradication, 452, *453*, *1106*

World Health Assembly, agenda on Intensified Programme, 446–447
  representation of Member States, 426–427
  1953, Sixth, proposal by Director-General for smallpox eradication, 366, 391–392
  1955, Eighth, endorsement of global malaria eradication programme, 381
  1958, Eleventh, proposal by USSR for global smallpox eradication programme, 366–368
    resolution WHA11.54, 368, 550
  1959, Twelfth, report by Director-General on smallpox eradication, 369–370
    resolution (WHA12.54) on global smallpox eradication programme, 366, 370–371, 811, 1349
  1960, Thirteenth, official register for malaria eradication, 1107
  1961, Fourteenth, criticism of smallpox programme, 396–397
    resolution (WHA14.40), 397, 550
  1964, Seventeenth, criticism of smallpox programme, 403
  1965, Eighteenth, declaration of goal of smallpox eradication, 408–409

World Health Assembly, 1965, Eighteenth (*cont.*)
    report by Director-General, 408
    support for specific WHO budget for smallpox eradication, 409
  1966, Nineteenth, report on plan for Intensified Programme, 410–414
    discussion and voting, 415–416
  1970, Twenty-Third, endorsement of Executive Board resolution on surveillance-containment, 483
  1973, Twenty-Sixth, delegate's comment on smallpox in India, 753
  1977, Thirtieth, resolution (WHA30.52) on smallpox in Somalia, 1053
    resolution (WHA30.53) on Expanded Programme on Immunization, 1353
  1980, Thirty-Third, recommendations on post-smallpox-eradication activities, 1264, 1267, 1270–1271, 1273–1274, 1276, 1280–1281, 1283, 1284
    resolutions (WHA33.3, WHA33.4) on smallpox eradication, *1135–1139*, 1140, 1264
  1986, Thirty-ninth, resolution (WHA39.21) on dracunculiasis elimination, 1367, 1368–1369

World Health Organization, allocation of smallpox eradication funds, by region, 461–462
  budgetary provision for smallpox eradication, 409–410, 460–463
  catalytic role, 1370
  consultants, 431, 483, 549, 555, *556*, 1129, 1361
  Director-General, 392, 399, 425, 427, 429
  expenditure on smallpox eradication, *463*, *464*
  headquarters, *1347*
    programme management, 428, 429–431
    organizational structure, *428*
  membership and governing bodies, 425–427
  post-eradication activities, 1263–1286
  regions, 426
  relations with, China, 1228, 1248, 1250–1253
    countries in southern Africa, 969–970, 982, 984, 985, 1198, 1199, 1205–1209
  representatives in countries, 436–437, 1350
  smallpox control and eradication activities, 1946–1958, 366, 388–393
  smallpox eradication, archives, 1284
    documentation, 1283–1284
    publications, 1283–1284
  staff, 1967, 422–423, 430
